The basis of medical ethics is to be found in the Oath of Hippocrates. It is popularly believed that professional courtesy (no fee for services) had its origin here. However, there is no reference to professional courtesy within the Oath, which reads in part³ "I swear . . . to regard my teacher in this art as equal to my parents; to make him partner in my livelihood, and when he is in need of money to share mine with him; to consider his offspring equal to my brothers; to teach them this art, if they require to learn it, without fee or indenture . . ." In earlier times when medicine was a secret cult the medical practitioner learned by apprenticeship—living in the home of his teacher and sharing his possessions. The practitioner repaid the favor by teaching the apprentices, treating his colleagues without fee and sharing his possessions. While no specific injunctions regarding professional courtesy were existent, the medical profession generally respected the broad principles of Greek medical ethics and tried to resolve moral and ethical problems on the basis of good taste and personal honor. There were no meticulous rules and no specific penalties except through the civil authorities in cases of gross quackery or criminal conduct. During the Middle Ages this medical idealism began to wane and the medical profession sought means to govern itself better.

In 1772 Gregory(1) wrote *The Duties and Qualifications of the Physician*. This treatise dealt with medical etiquette, the personal qualities of the physician, and his duty towards his colleagues. However, it was the appearance in 1803 of a book, *Medical Ethics: Or a Code of Institutes and Precepts Adapted to the Professional Conduct of Physicians and Surgeons*, written by an English physician, Thomas Percival(2), that established the present basis of medical ethics and professional courtesy. When first published it roused physicians all over the world to a new appreciation of their moral obligations. The book stressed

the physician's professional responsibility to the sick, outlined his duties in hospitals and in private practice, at the same time stressing his relationships with colleagues, consultants and other healing professions. Percival's code was an attempt to formulate rules of proper conduct in medical practice by applying concrete rules rather than abstract principles as guides in particular circumstances. Percival called these rules "medical ethics." This phrase has continued in popular usage to the present time. Actually Percival's code is basically a book of medical etiquette concerned with the conduct of physicians towards each other and embodying the tenets of professional courtesy.

Percival was the first to state in writing that members of the medical profession, including their wives and children, should be attended gratuitously by physicians whose assistance might be required. In 1847 when the AMA was founded Percival's code was adopted almost completely in the Code of Ethics of the Association. The concept of gratuitous professional services to physicians and their families was enunciated here. Subsequent revisions of the AMA Code have contained this injunction in much the same language as used by Percival 160 years ago. Section I of the Principles of Medical Ethics states(3) : "As a general rule the physician should not attempt to treat members of his family or himself. Consequently, a physician should cheerfully and without recompense give his professional services to physicians or their dependents if they are in his vicinity."

A review of the medical literature reveals an absence of information regarding professional courtesy, particularly in the field of psychiatry. To ascertain current attitudes regarding professional courtesy in California questionnaires were sent to all the members of the Northern and Southern California Psychiatric Societies. In Southern California 498 questionnaires were sent, 268 returned, a 54% response; in Northern California 330 questionnaires were sent, 153 returned, a 46% response. Of the 828 questionnaires sent, 421 were returned, a 51% response for the whole state. Of these, 9 respondents were not in private practice; consequently the findings regarding the extension of pro-

fessional courtesy were computed on the basis of the 412 psychiatrists in private practice or seeing private patients. All other calculations in the questionnaire were computed on the basis of the 421 respondents. The findings from Northern and Southern California are listed separately to show the remarkable similarity of the statistical findings from the two areas (Figure 1). The historical and sociocultural settings of Northern and Southern California vary and there are some philosophical differences regarding medical practice which makes the similar findings in this survey rather significant. It would suggest that similar studies made elsewhere in the United States might show comparable trends.

No identifying data were requested in the questionnaires so the type of practice of the respondents was not specifically noted. Approximately 14% of the membership of the two psychiatric societies work exclusively in state hospitals and, with a few exceptions, did not participate in the survey. A sampling of the comments made in replying to the questionnaires suggested that the respondents encompassed every kind of private psychiatric practice.

This survey indicated that 98% of the psychiatrists answering did not charge for consultation services to a physician or a member of his family. For the first 5 visits 255 respondents (62%) made no charge; 118 psychiatrists (28.5%) made no charge for 10 visits; 35 (8%) did not charge for prolonged treatment. A few psychiatrists said they did not charge for the first year or for the first 100 visits or did not charge no matter how long treatment lasted. A large number (29%) treated doctors and their dependents at a reduced fee, usually 20%-25% less than the usual charge.

In the questionnaire psychiatrists were asked whether or not they accepted professional courtesy for themselves or their families. The majority (61%) stated they accepted professional courtesy although often with great reluctance. In many cases they requested the usual bill for services rendered but found doctors loath to charge them. However, 82 respondents (20%) said categorically that they refused to accept professional courtesy and insisted on paying full fees for services rendered.

The questionnaire inquired how payment was made for services rendered by other physicians. Most common was the giving of a gift to the physician, it being the method of choice for 64% of the psychiatrists; 40% had insurance coverage; 30% stated that they paid full fees. A small number stated that they made a partial payment of 50%-75% of the usual charge. In a few cases no payment or gift was offered.

It is commonly believed that professional courtesy may act as a barrier to seeking

medical assistance. Half the respondents (53%) stated they had no hesitation in calling a physician but 45% felt that it was a barrier to seeking medical care. However, when the psychiatrist's wife sought help for herself, her husband or her children, 46% of them considered the fact of professional courtesy a deterrent and only 36% found it no problem.

The questionnaire also contained the following items: *Do you believe better care for physicians and their families would result if arrangements for payment for services*

FIGURE 1
Attitudes of Psychiatrists on Professional Courtesy

* Not answered on all questionnaires.

** More than 100% since multiple replies given.

by mutual agreement were possible? Would this help the doctor-patient relationship? In 80% of the responses it was felt that fees should be discussed beforehand and a mutual agreement reached if a healthy doctor-patient relationship was to be achieved.

In psychiatric cases do you believe extending treatment without fee impairs the efficacy of treatment in brief psychotherapy, long term therapy, psychoanalysis? The majority (62%) expressed the view that short term treatment without fee was feasible but did not believe that long term psychotherapy could be done effectively if no payment was made. While 72% indicated long term treatment was not feasible only 66% expressed a similar opinion about psychoanalysis. Many respondents not practicing as psychoanalysts omitted answering this question producing the seeming discrepancy.

Check those situations in which treatment is impaired by your feelings which develop towards the patient in consultation, brief psychotherapy, long term therapy when no fee, part fee, or full fee is charged? Two-thirds of the respondents admitted to having strong personal feelings in one or more of these areas. The majority, 239 respondents (56%), stated that providing long term treatment for patients without charge was disturbing to them. One third stated that long term treatment at reduced fee aroused negative feelings. A small number (5%) felt disturbed if they were to charge a full fee for consultation.

Should the whole problem of professional courtesy be reviewed by the American Medical Association? Four-fifths of the respondents were in favor of this matter being studied to develop a viewpoint more consistent with present day practices. This is particularly essential in view of the differing philosophies of the AMA and APA.

Should physicians avail themselves of insurance to cover physician's medical fees for professional services to their family and themselves? The overwhelming majority (86%) indicated that all physicians should have adequate insurance to provide medical care for themselves and their dependents. Many recommended that the insurance should provide psychiatric coverage also.

DISCUSSION

Reviewing the findings of this survey a number of conclusions can be reached. It is apparent that psychiatrists as a group are keenly aware of professional courtesy. Contrary to popular belief nearly every psychiatrist provides gratuitous services to his professional colleagues and their families. Since, with rare exception, every psychiatric interview takes the same time, usually 45-60 minutes, the findings of this survey are that psychiatrists are willing to donate a considerable amount of time without remuneration. When a psychiatrist is seeing many physicians this can amount to a large percentage of his working hours. One respondent stated that 95% of his practice were physicians or their dependents and that it was manifestly impossible for him to extend more than limited professional courtesy. On the other hand some psychiatrists stated that physicians sought their help only at infrequent intervals and they could undertake prolonged treatment in the individual case without undue financial loss. As a general rule psychiatrists stated that they were aware of the honor implied when a physician or member of his family sought their professional care but at the same time realized that the psychotherapy required in most cases precluded courtesy being extended beyond a certain point. Some psychiatrists stated that they had never charged a physician in their entire professional life. However, the majority indicated that while psychotherapy without charge was possible in some instances usually the payment of a fee was necessary for a satisfactory therapeutic relationship.

The importance, both actual and symbolic, of payment for professional services has not been considered by the medical profession generally, although reference has been made to it in psychiatric articles (4, 5). Many physicians are resentful of the feeling of obligation when they are the recipients of free medical attention. Nearly half of the psychiatrists responding to this questionnaire expressed reluctance in accepting professional courtesy and one-fifth refused medical services unless they paid the regular fee. While nearly all the respondents made some form of payment it is

questionable to what extent cocktail shakers, vases, cases of liquor or similar gifts really meet the needs of the attending physician. It is true that gifts of savings bonds or merchandise orders come closer to cash payment but rarely do these represent more than a token payment for what would be the usual fee. Some physicians are indignant when the treating physician refuses to accept payment and frequently they seek help from another physician who understands their need to be allowed to pay for services rendered. A recent study has shown that 80% of physicians repay their treating physicians by referring other patients to them (6). Psychiatrists are not in a position to make this type of referral in the vast majority of cases.

The survey showed that each psychiatrist determines for himself the most effective relationship in treating his professional patient. In some cases he may choose not to make any charge whereas in other cases he may feel that the payment of a fee is important for a satisfactory therapeutic result. Sometimes the patient who does not pay the psychotherapist may feel inhibited in verbalizing his hostilities as treatment progresses. Sometimes being the recipient of this "favor" increases the patient's hostility. The non-payment for services may accentuate dependency traits or promote "acting out" behavior. It is well known that the manner in which the financial aspect of psychotherapy is handled by the patient is indicative of other attitudes in life, and the ability to discuss this during therapy provides insights that could not otherwise be achieved. The treating physician should be permitted to provide gratuitous services when he believes they will benefit the patient and similarly he should be permitted to charge a fee when he believes that this will facilitate treatment. The present mandate for gratuitous services forces the psychiatrist to treat all his physician patients alike with no consideration being given to the individual aspects of each case.

Many patients become increasingly guilty as treatment goes on without a charge being made. Similarly physicians generally become increasingly hostile when they feel inordinate demands are being made upon

their time. As this survey shows, the majority of psychiatrists believe that negative feelings can arise in both the therapist and patient when prolonged psychotherapy is undertaken at a reduced fee or no fee. It might be worth studying the attitudes of other medical specialists who are "doctor's doctors" to learn if comparable views are held. Some obstetricians, pediatricians, surgeons and internists have a large percentage of their practice made up of medical conferees and their families. Obstetrical care requires a great deal of time extending over the year. Pediatricians treating physicians' children must see them at regular intervals for years. Leading surgeons or internists inevitably find themselves called upon when a medical colleague or his family is in need of their specialized services. Unless the physician is unusual, he cannot help but have negative feelings if there is an inordinate demand for gratuitous services. It would be interesting to poll the faculty of any medical school to ascertain the extent to which they donate services without recompense. Unfortunately, up to this time the medical profession has refused to accept the possibility that these negative feelings can develop as a consequence of professional courtesy, and that poor medical care may result.

The survey showed that many physicians hesitate to seek medical care because of professional courtesy. The findings corroborate the impression long held that their wives are generally reluctant to seek medical care for the same reason. In this survey a large percentage of physicians' wives were reluctant to seek medical attention for themselves, their families or even for their husbands. Unlike other patients they do not always expect to receive the same attention nor can they make the same demands on the physician. Too often they receive inadequate medical care or delay seeking help because of the negative feelings that arise in both the patient and the doctor. In the book *The Physician and His Practice* (7), a chapter entitled "The Doctor's Wife" states that because of professional courtesy there is "embarrassment, fear of imposing and reluctance to consult" by doctors' wives.

Many physicians may not be aware of the

time required for psychotherapy. In other branches of medicine the initial contracts with the patient for a complete medical workup or for a surgical procedure may take hours but subsequent follow-up treatment usually does not require lengthy visits with the patient. In many cases the physician's nurse or technical assistant can be of great time-saving assistance. Every psychiatric visit takes almost one hour of the therapist's time; no one can substitute for him. Some physicians do not realize that psychotherapy may entail hundreds of hours; the average psychiatric case requires more time than all but the most complicated cases in medical practice.

While some psychiatrists have been the objects of resentment because they charge colleagues for psychotherapy, it is well known that other physicians also charge their colleagues for services rendered. Physicians commonly charge for x-ray or laboratory studies and many also bill for other medical services. Generally the personality of the attending physician and the extent of the demands on his time determine whether or not he requests a fee from a colleague. Because of the resentment held toward psychiatrists by some of our colleagues, a few physicians may openly or covertly express their hostile feelings, occasionally rendering a charge for services only because the patient is a psychiatrist.

Leake(2) has cogently discussed "the doctor's dilemma" in medicine's struggle between idealism and hedonism. Idealism is concerned with the needs of humanity while hedonism is concerned with self-interest. The medical profession has historically striven to be idealistic, with the interests of mankind, particularly the sick patient, pre-eminent. Yet at the same time the physician must live, he owes a debt to himself and to his family as well as to society. The code of medical ethics has been formulated basically to handle the schism between the needs of mankind and the financial needs of the individual physician. In Leake's opinion, the introduction of the phrase "medical ethics" by Percival was a misnomer since Percival's code was chiefly rules of etiquette developed to regulate the professional contacts of doctors with each other. It is his

belief that medicine has always had medical etiquette and medical ethics confused.

Medical etiquette is concerned with the conduct of physicians towards each other and embodies the tenets of professional courtesy. Medical ethics is concerned with the ultimate consequences of the conduct of physicians towards their individual patients and towards society as a whole and includes a consideration of the will and motives behind this conduct. "The difficulty is that professional courtesy is put upon the same plane and given the same respect as professional morality, when the common sense which characterizes the [medical] profession demands that it be relegated to a much less significant position"(2).

CONCLUSION

In treating a physician or a member of his family the psychiatrist should decide the basis for extending professional courtesy (no fee or reduced charge) upon the specific circumstances of the individual case. Generally psychiatrists do not charge for the diagnostic workup or for short term therapy. If long term therapy is indicated the matter should be discussed and a mutual agreement reached before undertaking treatment. In many cases prolonged treatment without charge may be conducive to poor therapeutic results owing to negative feelings in both the patient and therapist.

Professional courtesy may be a barrier to good medical treatment, in many cases causing delay in seeking medical help and producing negative feelings on the part of the patient and the treating physician. Insurance coverage for medical care would permit an adequate recompense being given without embarrassment to either party.

The present philosophy of the AMA that physicians are unethical if they charge other physicians or their families is not in keeping with present day practices. The doctor-patient relationship is impaired and frequently good medical care does not result. While the extension of professional courtesy reflects the best traditions of medical practice, physicians should be permitted to extend it by choice rather than by fiat.

THE INHIBITORY INDEX IN RELATION TO EXTRAVERSION-INTROVERSION

N. McCONAGHY, M.B., D.P.M.¹

Jung's concept of extraversion-introversion as a basic dimension of human personality has been most intensively investigated by Eysenck and his colleagues (1, 2, *etc.*). In the course of their studies these workers have attempted to discover the type of nervous system that is associated with this dimension. Eysenck (2) put forward a "Typological Postulate" in which he related extraverted behaviour patterns to the type of nervous system in which "excitatory potential is generated slowly and weakly and reactive inhibition is developed quickly and strongly and dissipates slowly." Introverted behaviour is related to the opposite type. Though his postulate is worded in such a way that it is compatible with the existence of types of nervous system in which both excitatory and inhibitory processes are weak or both are strong, in his subsequent treatment he concerns himself only with weak excitation in combination with strong inhibition or vice versa. On the other hand, in the writings of Pavlov (3, 4) a "weak" type of nervous system in which both processes are weak and a "strong" type in which both are strong are repeatedly described.

To derive a theory of nervous type in respect to extraversion-introversion from the findings of Pavlov, it would seem most relevant to consider the two types of dog he constantly contrasts in his writings—the quiet and the lively. In human typology

these would correspond to the introvert and the extravert respectively. Pavlov (4) concluded that the inhibitory process is stronger in the former and the excitatory process stronger in the latter, and his experimental data strongly support this conclusion. Hence, in relating extraversion-introversion to a measure of inhibition it would be predicted from these findings that extraverts would show weak and introverts strong inhibition. This is in opposition to Eysenck's postulate. A complication in utilising Pavlov's theories in relation to inhibitory processes is that he advances evidence for the existence of two types—external and internal. In an attempt to relate these findings to recent developments in neurophysiology it has been suggested that external inhibition is the inhibitory process which accompanies attention and is associated with the arousal response of the EEG (5, 6). This is in conformity with Kogan's demonstration (7) that this response has both excitatory and inhibitory aspects. As Sokolov (8) and Anokhin (9) have demonstrated, this response is produced in an animal whenever an unexpected event occurs or an expected event fails to occur. These are precisely the situations in which learning takes place. It has been hypothesised (6) that when an unexpected event occurs, cerebral excitatory connections are set up to represent it and link it to those connections active immediately prior to the event occurring, so that in similar circumstances in the future there will be a tendency to expect the event. (These connections make up the "neuronal model" in Sokolov's, or the "acceptor of the action" in Anokhin's terminology.) Similarly when an expected event fails to occur, internal inhibitory connections are set up within the linkages active prior to the failure of the event to occur, *i.e.*, within the linkages responsible for the faulty expectation, so that in similar circumstances in the future the tendency to expect this event will be weakened. Hence, the event in the focus of attention—the ex-

¹ E. H. Flack Medical Research Scholar, Depts. of Psychiatry and Electroencephalography, Alfred Hospital, Melbourne, Australia.

Gratitude is expressed to the Board of Management of the Alfred Hospital for providing facilities for this research and in particular for making a grant from the E. H. Flack Medical Research Scholarship for 1961.

Dr. W. Ronald Kingston, Head of the Dept. of Psychiatry, and Dr. John A. Game, Head of the Depts. of Neurology and Electroencephalography, Alfred Hospital, Melbourne, are thanked for their advice and assistance as are the Alfred Hospital Medical Students and Professor A. S. Buchanan and students of the Dept. of Chemistry, University of Melbourne for their co-operation.

citatory area of the arousal response—is linked with excitatory connections; and the linkages active prior to the arousal response, but now under the external inhibition produced by it, are weakened with internal inhibitory connections. It would therefore seem probable that a function of the arousal response is to produce excitatory connections in its area of excitation and inhibitory ones in its area of inhibition. Pavlov(4) has shown that stimuli which produce linkages in areas of the cerebrum under inhibition produce internal inhibitory linkages. In fact he put forward a theory similar to that stated above:

the mechanism of development of a conditioned reflex and the mechanism of external inhibition are somehow similar, and the process of external inhibition bears some relation to the development of new connections.

Aleksanian(10) has stressed this point in relation to internal inhibition: "internal inhibition develops on a basis of inhibition produced by the mechanism of induction" (i.e., in this context, on the basis of external inhibition).

To develop a theory of personality based on the above mechanisms one could postulate variations in strength of both the arousal response and of internal inhibition. If both were weak, excitatory and inhibitory connections would be established slowly; if the arousal response were weak but internal inhibition strong, excitatory connections would be established slowly but inhibitory ones more rapidly; if the arousal response were strong but internal inhibition weak, excitatory connections would be established rapidly, but inhibitory ones more slowly; and if both were strong, both types of connection would be established rapidly. Such a classification would be in reasonable conformity with the findings of Pavlov, as to the variations of these processes in dogs(3), and in complete conformity with the findings of followers of Pavlov as to the variations of these processes in humans, e.g., Briks(11).

It has been advanced(6) that a type of abstract thinking, called allusive thinking, exists in a percentage of normal persons. It was suggested that this thinking is due

to a weakness of external inhibition in the nervous activity of these individuals. The well-known difficulty in learning the central items of word lists was investigated in a group of allusive and non-allusive thinkers. Using the above learning theory it was suggested that in learning a list attention is focussed on each item in turn, so that the linkages in the cerebrum representing the items not in the focus of attention would be under external inhibition. Internal inhibitory connections would therefore be set up in these linkages, thus producing the difficulty in learning the central items. If allusive thinking is due to weak external inhibition it would be expected that persons with this condition would show less difficulty in learning these central items. Using the "inhibitory index" as a measure of the difficulty this was shown to be the case. However, if persons also differ in the strength of internal inhibition this would contribute to the difficulty of learning the central items of a word list. The inhibitory index would then measure the combined strength of external and internal inhibition.

As previously stated, Pavlov's findings indicate that extraversion is related to weak and introversion to strong inhibition. Whether this inhibition is internal or external or a combination of both does not seem apparent. However, whichever is the case, if the inhibitory index measures a resultant of both these inhibitory processes, this index should also be related to the dimension of extraversion-introversion in such a way that the scores of extraverts on this index would be lower than those of introverts. Eysenck has indicated(2) that from his theory the reverse would be predicted. In the following experiment this relationship between extraversion-introversion and the inhibitory index is investigated:

The Experimental Group. This consisted of 28 fourth year medical students, 15 third year chemistry students and 20 acquaintances of the author, the last group being selected to contain 10 individuals with and 10 without allusive thinking. The former two groups were interviewed individually for approximately 10 minutes by the author and classified into those with and those without allusive thinking on the

basis of the description advanced previously (6). All subjects were given Eysenck's 6-item extraversion-introversion scale to complete. The subjects were then divided into 4 groups on the basis of these two dimensions—allusive extraverts, allusive introverts, non-allusive extraverts and non-allusive introverts. The characteristics of these subgroups were as follows.

There were 13 allusive extraverts, 11 males and 2 females, with a mean age of 22.1 yrs. (range 20-30); 30 allusive introverts, 25 males and 5 females, with a mean age of 23.3 yrs. (range 19-37); 13 non-allusive extraverts, 7 males and 6 females with a mean age of 27.2 yrs. (range 19-39); and 7 non-allusive introverts, 6 males and 1 female with a mean age of 24.4 yrs. (range 20-39). The age and sex of each subject are given in Table 1.

METHOD

The measurement of the inhibitory index of each subject was made by a technique modified from that described previously (6). Each subject first learned 2 lists of 9 nonsense syllables, to the criterion of 2 consecutive correct performances or for 16 trials, whichever came first. This was followed by the learning of 3 word lists of 16 words, to the criterion of 2 consecutive performances or for 10 trials, whichever came first. The technique was otherwise identical.

RESULTS

The difficulty each subject had in learning the central portion of the word lists was quantified by the use of the following formula, modified from that given previously.

$$\text{Inhibitory Index} = \frac{\text{Total number of items learned correctly up to but exclusive of the first correct performance or in 10 trials, whichever criterion was reached first.}}{\text{Total number of items in the middle 1/4 of the list learned correctly in the same number of trials.}}$$

(I.I.)

As in the previous experiment, the lowest value of I.I. for each subject was selected, in order to test the relationship with allusive thinking. The rationale for this procedure

is that external inhibition, the inhibitory process accompanying attention would be, like attention itself, a very labile and fluctuating process and therefore differences in its strength in different individuals would manifest themselves only with measurements made when it was near one of the extremities of its range, *i.e.*, at its strongest or its weakest. However this would not necessarily apply to internal inhibition. So to test the relationship between I.I. and extraversion-introversion, both the lowest value and the mean of the values for the 3 word lists were employed. These scores are given in Table 1. Both of these values were related to extraversion-introversion in such a way that extraverts (subjects with scores of 7 or more on the extraversion-introversion scale) showed lower I.I. scores than introverts (subjects with scores of 6 or less on the scale). The relationship with the lowest value of I.I. is significant only at the 10% level. However, that with the mean value is significant beyond the 1% level. (The "t" test was used to estimate these levels of significance.) The tetrachoric correlation coefficient for these relationships of I.I. with extraversion are for the lowest value of I.I., $r_{tet} = -.15$; and for the mean value of I.I., $r_{tet} = -.60$.

In regard to allusive thinking the mean value of I.I. shows no relationship. However, as in the previous experiment (6), the lowest value of I.I. is higher in non-allusive than in allusive thinkers ($r_{tet} = .2$), but on this occasion not significantly so. This could mean that the relationship previously observed is not valid. However with the present group of subjects there is a marked correlation between the presence of extraversion and non-allusive thinking ($r_{tet} = .5$). This means that the tendency for extraverts to obtain low I.I. scores would oppose any tendency for non-allusive thinkers to obtain higher scores than allusive thinkers. In order to eliminate this influence of extraversion on the relationship between allusive thinking and the inhibitory index, a partial correlation coefficient was computed. The value of this partial correlation was .32.

The possibility that differences in age and sex of the subjects might contribute to the above relationships was investigated. This was found not to be the case.

TABLE 1

DISCUSSION

It has been shown that extraversion-introversion is related to the assumed inhibitory process which produces difficulty in learning the central portion of a serial learning task. Furthermore this relationship becomes more apparent when the mean of three learning tasks by each person is utilised. Under these conditions the relation of allusive thinking to this difficulty disappears. This suggests that extraversion-introversion and allusive thinking produce this difficulty through two separate inhibitory processes, that with which extraversion-introversion is related being more stable and the other more labile.

The learning theory advanced in the introduction led to the conclusion that this difficulty was due to the combined action of external and internal inhibition. It has been advanced that allusive thinking is due to weak external inhibition and its clinical nature is consistent with this(6). It is therefore hypothesised on the basis of the present finding that extraversion-introversion is related to internal inhibition and in such a way that extraversion is associated with weak and introversion with strong internal inhibition. This is in conformity with the prediction made from Pavlov's finding, as stated in the introduction, but in opposition to the theory of Eysenck. As Eysenck's theory has been related to a considerable amount of experimental data, this will now be examined for possible incompatibilities with the finding of the present study.

Franks(12) has reported that introverted normal subjects condition better than extraverts. Eysenck explained this by his postulate that extraverts build up inhibition more rapidly than introverts and therefore condition more slowly. Relating the rate of conditioning to the strength of inhibition in this way is incompatible with Pavlov's finding that there is no fixed relation between the two processes of excitation and inhibition. In terms of this theory rate of conditioning is a measure of the excitatory process only. So there would appear to be no necessary incompatibility between Franks' finding that extraverts condition poorly and that of the present study that they show weak inhibition. Together they support Pavlov's con-

clusion that the excitatory and inhibitory process show no fixed relationship.

The finding that sodium amytal reduced conditionability and at the same time increased the degree of extraversion of human subjects(13) has been similarly used to support Eysenck's theory. However it has been shown by Livshits(14) that narcotics in fact temporarily weaken internal inhibition. It would therefore appear that narcotics weaken both excitatory and inhibitory processes, as would seem probable, since these are both active processes. Hence the increased extraversion produced by depressive drugs is associated with a weakening, not a strengthening of inhibition, as required by Eysenck's theory.

Other correlations reported between extraversion-introversion and behavioural characteristics are that extraverts tend to develop hysterical and psychopathic psychiatric illnesses, and show low persistence and greater reminiscence and figural after-effects. Introverts tend to develop anxiety states, reactive depression and obsessional states, and show high persistence and less reminiscence and figural after-effects(2). In regard to reminiscence and figural after-effects, Becker(15) has shown in reviewing the literature and in a study of his own, that measures of these phenomena show no significant relation to extraversion-introversion.

Eysenck explains the relation to psychiatric illness and persistence by Frank's finding that hysterics and psychopaths condition poorly(12). He concludes that hysteria and psychopathy result from a strong inhibitory process. However weakness of inhibition has been reported in hysteria(16-18) and psychopathy(19). Eysenck has explained the psychopathic-like behaviour of post-frontal lobectomy patients as due to poor condition-ability resulting from strong inhibition. Again weakness of both excitation and internal inhibition has been reported following this operation(20, 21).

Hence it would seem there is a body of evidence supporting the conclusion that hysteria and psychopathy—the psychiatric illnesses associated by Eysenck with extraversion—are accompanied by a weakness of inhibition. In accounting for this the author believes the theory of Anokhin(9) to be

relevant. He has concluded that when an animal commences to carry out an act, a neuronal model is set up in the nervous system of the completed act—the “acceptor of the action.” Unless the results of the act as it is completed in reality coincide with this model, the orientation reaction is called forth and the animal shows evidence of excitement, restlessness, *etc.* The author believes this to be significant for the understanding of human anxiety. It is considered that a degree of anxiety or tension is experienced whenever an action is suspended (*e.g.*, in a conflict situation when one of the conflicting actions cannot be carried out) or inadequately completed (*e.g.*, in response to a threatening situation which cannot be adequately dealt with). Under these conditions the excitatory process in the CNS which is producing the action is held under inhibition, to produce the mental sensation of tension, and through the orientation or arousal reaction, the physiological concomitants of anxiety.

The process of internal inhibition is that which is responsible for producing fine differentiations. Hence the accuracy with which the result of the completed action is compared with the “acceptor of the action” will be a function of internal inhibition. If this process is weak a poor resultant action will be adequate to coincide with the neuronal model. If it is strong a much more accurate end result will be required. That is to say, if instructed to carry out a task, extraverts (who show weak internal inhibition) will be more content with a poor performance than introverts who, if sufficiently motivated, will be more likely to show anxiety unless a reasonably high level of performance is reached. Similarly in a conflict situation extraverts would be more likely to react with a poorly effective response, *e.g.*, an emotional outburst or an hysterical symptom, while introverts would continue to experience anxiety.

An experiment relevant to this theory is that reported by Russell Davis(22). He utilised a situation in which “subjects were obliged to carry out for a relatively long time a task in which they were unable to obtain a satisfying level of performance.” He found his subjects tended to fall into two groups: one—the overactivity class—

continued to try to overcome the test difficulties but showed agitation, restlessness, flushing or pallor and visible sweating, and felt excited, tense or sometimes frankly anxious. Subjects in this class sometimes returned and asked to do it again or talked about it with surprising persistence—indicative of the excitatory process persisting under inhibition. The second group—the withdrawal class—early showed a tendency to overactivity, but were less hurried, showed less restlessness and later became bored and lost interest. They gave the impression of lowering their standards to well within their powers. Russell Davis does not relate his classes to the extraversion-introversion dimension. However in another experiment (23) he gave neurotic subjects a similar task and concluded that overactivity tended to be shown by those assessed as obsessional, and withdrawal by those of hysterical disposition. Also Venables(24) has shown that extraverts tend to change their performance in the direction of inertness with an increase in task difficulty whereas introverts do not. The theory advanced above is therefore considered to explain the tendency for extraverts to show low persistence and hysterical and psychopathic reactions, and introverts to show high persistence and anxiety reactions, on the basis that the former show weak and the latter strong internal inhibition.

In summary, there appears to be no incompatibility between the findings with which Eysenck has supported his theory and the present study which indicates that extraversion is associated with weak and introversion with strong internal inhibition.

THE TREATMENT OF PARKINSONISM WITH UK 738 : A CLINICAL TRIAL

DAVID SUMNER, M.B.¹

Despite the efficacy and relative safety of modern surgical methods for relief of Parkinson's disease, there will always be a place for the medical treatment of this condition. It is important, therefore, that any new drug be critically evaluated.

Such a new substance is UK 738 (n-ethyl-nortropine-benzhydryl-ether-hydrobromide), one of a series of compounds synthesised by Jucker and Lindenmann in 1959(1). The structural formula is :

Although of the atropine group this compound contains neither tropic acid nor any free hydroxyl groups, and could be expected, therefore, to possess properties differing from those of the parent atropine. Pharmacological studies of UK 738 indicate that in vitro it has a peripheral anticholinergic activity comparable to atropine, but in vivo this peripheral action is about 10 times weaker although its central effects are as great if not greater than atropine on a weight for weight basis. UK 738 may be regarded therefore, as an anticholinergic agent with a high ratio of central activity. UK 738 exhibits in addition considerable histamine activity, and this property, together with its central anticholinergic ac-

tion, suggests that it should be useful in the treatment of parkinsonism(2).

Recently May and his colleagues have described their experiences with UK 738 in the treatment of the parkinsonian syndromes induced by phenothiazine(3, 4). In 23 of 24 patients in an uncontrolled trial the extrapyramidal signs and symptoms could be removed or reduced by the new drug despite continuation of the phenothiazine therapy. It was in view of these encouraging findings that it was decided to assess the usefulness of this drug in the treatment of naturally occurring parkinsonism.

MATERIAL AND METHODS

It should be widely recognised today that if a therapeutic trial is to give any worthwhile results, it must be carefully controlled and preferably blind or double blind, as has been made very clear by Reid (5) and Truelove(6). Before embarking on such a trial in this case, however, a preliminary open trial was carried out. This was done for the following reasons.

1. To determine a suitable dose to be used in the controlled trial.
2. To give some indication of the frequency, nature and severity of any side effects which might occur.
3. To see if the drug was effective at all. Open trials will frequently give a false positive result but never a false negative. If the drug appeared valueless in the first trial, there would be no point in continuing with the second.

Patients taking part in the trial were selected from the neurological outpatient department of the General Infirmary at Leeds. The only criteria for inclusion were that they were suffering from noniatrogenic parkinsonism, were able to attend frequently and regularly for assessment and were willing to take part in the trial; none were excluded on the grounds of the mildness or severity of their disease. It was explained to all those taking part that they

¹ Senior Neurological Registrar, General Infirmary, Leeds, England.

The author would like to thank Messrs. Sandoz for their generous supplies of UK 738 and benzhexol, and for preparing the identical tablets required for the double blind trial. His thanks are also due to Mr. Blacow, pharmacist to the Leeds General Infirmary, for his help in managing the double blind trial and for preparing the random treatment schedules. Finally he would like to thank Dr. Hugh Garland, whose patients took part in the trial, for permission to publish this report and for his help in its preparation.

were being given an experimental drug, but no further details were disclosed to minimise any effects of suggestion. No distinction was made between those suffering from arteriosclerotic, post-encephalitic or idiopathic parkinsonism, and indeed it was impossible to allocate some patients with any certainty into any particular group.

Each patient was seen monthly and at each visit asked for his opinion of the previous month's therapy. He or she was specifically questioned about well being, tremor, rigidity, and any specific symptoms such as oculogyric crises or retropulsion. Unless mentioned by the patient, side effects were not mentioned. Obvious changes, if any, in tremor and rigidity were noted.

Attempts to develop simple, reliable and useful methods of objective assessment were unrewarding and this has been the experience of other workers. Webster(7) who devised a complex mechanical method of measuring rigidity and tremor confesses that "Most objective methods have not correlated well with surgical and medical therapies," while Burns and DeJong(8) who used a battery of more simple tests found that day to day fluctuations were so great that they were only able to obtain significant results when using the untreated side as a control in patients who had had a pallidectomy. Agate, *et al.*(9), claimed to be able to detect significant changes in signs after therapy but their apparatus, involving the use of a torque converter, is far too complex for clinical use. Kaplan, *et al.*(10), found that an overall assessment was of more value than the measurement of individual signs, while Merrit(11) states that "The beneficial effects of medical therapy seem largely to be of a subjective nature." No attempt, therefore, was made to record physical signs quantitatively, although in every patient the speed and quality of handwriting was noted.

Quite apart from these considerations it was felt that a considerable degree of objectivity would be introduced into the investigation by the fact that the second trial would be a double blind trial. When all is said and done the usefulness of a palliative drug is not to be measured by the reduction of physical signs but rather by any improvement the patient himself feels.

PRELIMINARY TRIAL

Twenty patients took part in this trial, of whom 14 had been treated with other drugs in the past and were able, therefore, to express their view as to the efficacy of UK 738 in comparison with their previous therapy. The dose used ranged from 4.0 mg. to 10.0 mg. per day in divided doses. The maximum corresponded to a daily dose of 0.2 mg. per kilo of body weight. It was found that most patients obtained the maximum improvement with the minimum of side effects on a dose of 6.0 mg. per day, and this was taken to be the optimum dose to be used in any subsequent trial. No side effects were seen in the patients who had the maximum dose per body weight. Side effects were found to be drowsiness, "light-headedness" and ataxia which, while never very severe, were enough in 3 cases to counteract any possible beneficial effect.

The results are summarised in Table 1 and suggest that UK 738 might be of use in the routine treatment of parkinsonism. Indeed several of the patients were enthusiastic that this was a great advance on their previous treatment. It was decided therefore that a carefully controlled trial should be carried out.

TABLE 1

	IMPROVED UNCHANGED INTOLERANT			
Untreated	6	5	1	0
Previously treated	14	11	0	3
Total	20	16	1	3

DOUBLE BLIND TRIAL

Since the purpose of this investigation was to determine not only whether UK 738 was effective in the treatment of parkinsonism but to see if it marked any advance over existing therapies, it was compared not only with a dummy, but with benzhexol. This substance was chosen as a representative of existing remedies because it is generally accepted as the most effective(12), and because the author had more experience with this than other products. Identical tablets were prepared therefore containing either 2.0 mg. of UK 738, an inert substance or 2.5 mg. of benzhexol.

A randomised treatment schedule was drawn up by the hospital pharmacist and was not available to the clinician until the end of the trial which lasted 3 months. He merely wrote a prescription for "parkinsonism trial" and was quite unaware of the order in which the patient was receiving the drugs which changed each month. Each patient therefore acted as his own control and, in fact, was not aware that he had more than one drug.

Twenty patients took part in this trial as in the first, 9 being men and 11 women. Their ages ranged from 37 to 67 with an average of 54 years. The duration of their illness ranged from 2 to 20 years with an average of 8 years.

RESULTS

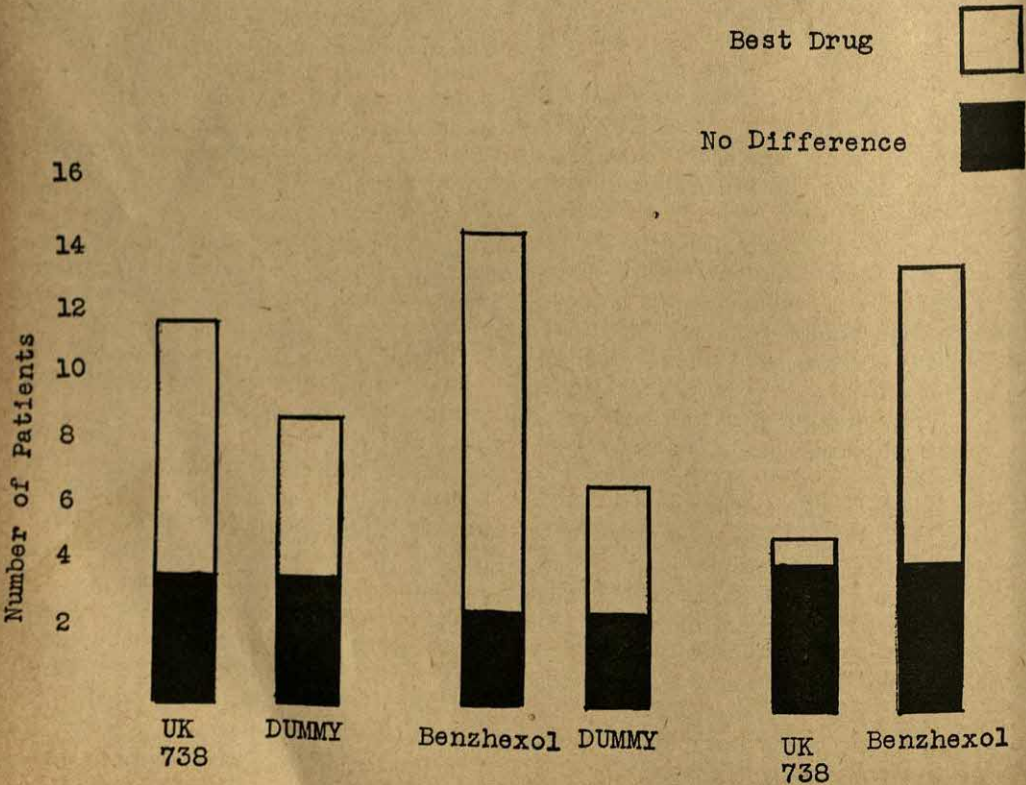

Any improvement which patients felt on either UK 738 or benzhexol was usually described as a "loosening up" and a general feeling of well being. Few patients noted any reduction in tremor and when

this was mentioned, it took place equally on the new drug or the dummy. In no case was it possible to detect any change in rigidity or tremor by conventional clinical examination. No change in speed or quality of handwriting was observed, nor was any reduction in salivation, retropulsion or the frequency of oculogyric crises to be seen.

With the dose used, no side effects were seen with benzhexol, but 2 patients complained of "lightheadedness" with UK 738, while 1 patient complained bitterly of nausea while taking the inert tablets. Many patients however said they were "worse"—i.e., their rigidity or tremor was worse on one or other of the three treatments. This "negative placebo reaction" in which a dummy tablet, expected to do good in the patient's mind, can produce an exacerbation of the original symptoms is very difficult to explain.

The results of this trial are summarised in Table 2. The striking feature is not only the minimal difference between the dummy

TABLE 2
Results of "Double Blind" Trial Expressed as Differences in Pairs of Treatments

and UK 738, but the only moderate effectiveness of benzhexol when taken "blind." The contrast between the results obtained in this trial and in the preliminary open trial is what experience would lead one to expect.

CONCLUSION

These results show that UK 738 has only a very slight effect on the symptoms of naturally occurring parkinsonism, and it is not as effective as benzhexol. When compared with a dummy in a double blind trial, benzhexol itself is not outstandingly effective.

These results are very different from those obtained by May and his colleagues (3, 4) and although their cases were of phenothiazine induced parkinsonism, it is more likely that the discrepancy is due to their lack of control in the trial than to any difference in aetiology.

THE PHYSICIAN, PSYCHIATRY AND THE PUBLIC HEALTH¹

MATHEW ROSS, M.D.²

There exist in both the industrialized and the developing communities and nations of the world remarkable opportunities and broad horizons for an integration of public health and psychiatric concepts and practices into the everyday services rendered by physicians everywhere. The intent of this presentation is to foster further realization than has heretofore occurred.

It is common knowledge that the patient is, has been, and always will be the *raison d'être* of a community's medical service and that the character of this service is largely determined by the cultural structure of the community. Of unquestioned importance is the stage of development in scientific and technical knowledge of the community, but the psychiatric aspect of this community service must be considered also. Up to now in many of the so-called civilized communities of the world this has not been the case.

We are reminded that psychiatry among the various branches of medicine by the very nature of the diseases which are its concern requires a very high degree of specialization in addition to the broadest medical and cultural education. Medical historians have reminded us that the history of medical psychology has been punctuated by the physician's struggle to rise above the prejudices of the ages so that he might identify himself with the psychological realities of his patients. One viewpoint is that the history of psychiatry is essentially the history of humanism. Every time humanism has diminished or degenerated into mere philanthropic sentimentality, psychiatry has entered a new ebb. Every time the spirit of humanism has arisen, a new contribution to psychiatry has been made and therefore a new contribution to the public health and welfare. Throughout the

world physicians are striving to assume their rightful responsibilities to attain and maintain the highest possible levels of health among the peoples for whom they are the health guardians(1).

If one were to initiate a mental health program as an integral part of a health service we would benefit from the world-wide experience that competently trained personnel are the starting point, for unless a nucleus of well-trained professionals is available, the creation of new services, or the expansion of any existing ones had better be postponed, since inadequately staffed programs are costly not only in terms of health, morbidity and money but also in the potential loss of public confidence which may impair the future support and developments.

The shortage of high quality medical practitioners is a problem of world-wide concern for there are but one million physicians in the world today being produced at the rate of 65,000 per annum from 80 countries and 670 medical schools. If this be the case and the possibilities for expansion while likely are certain to be a long time in coming because of the nature of the required preparation and training, one perhaps needs to raise the question of the philosophy and content of medical education as well as the optimum utilization of scarce professionals. Throughout the world opportunities to make decisions in these areas exist widely. It is the hope of this presentation that some of its philosophy will become incorporated in the decisions.

Medical historians point out that where medicine has emerged beyond the stages of magic and empiricism, medical education has been based on and characterized by the principles of, first, a scientific approach to professional activities, second, a charitable and ethical approach to the patient, and third, a constructive, critical, and understanding attitude toward the environment. Current trends in medical education throughout the world would indicate an increasing predilection to prepare the stu-

¹ This is adapted from a presentation entitled: "The Physician and the Community Mental Health" delivered at the First Pan-African Psychiatric Conference, November 12-18, 1961, Aro Hospital, Abeokuta, Nigeria, West Africa.

² Formerly, Medical Director, American Psychiatric Association, 1700 Eighteenth Street, N.W., Washington 9, D. C.

dent for medical work in what has been referred to as the "open community" and not merely in the hospital alone although this latter form is by far the most prevalent. The rationale lying behind this is familiar. Current medical practices would indicate that the patient should as far as possible remain in his usual environment and in an independent and self-supporting fashion. He should utilize wherever possible the support and guidance of his immediate family members and, failing this, an extension beyond the home into outpatient facilities and, finally failing these extramural services, in-hospital services which should be kept minimal in duration to avoid dangers of hospitalization familiar to modern practitioners. If indeed mental health plays an integral part in any health program, and medical schools are obliged to prepare their students to assume the responsibility for the professional services, community leadership and their own continuing education, then a variety of teaching resources and teaching methods, often referred to as community medicine, are indicated. Here the student is introduced to the process of applying the scientific component of medicine together with the resources available in the community by cooperating with other health workers on the one hand and approaching the home and occupational environment of the patient on the other.

Very often the development of a department or a chair of preventive and social medicine is a desirable prerequisite in meeting this primary responsibility for that part of the student's education which is dependent upon the study of the patient in the aforementioned situation. This indicates the utilization of the community as a laboratory for the study of health and illness phenomena under the same rigid standards that apply to the study of those aspects of disease which must be observed in the science laboratory and the hospital ward. One immediately thinks of extra-mural teaching facilities of the health center, field demonstration, and family care agencies which are already available in some medical centers.

If the physician of tomorrow is to practice in the light of available medical knowl-

edge and render his patients the services they need, undergraduate medical education must afford opportunities for the student to develop understanding of the origins, recognition, and management of psychologic processes and psychiatric disorders, just as it provides these opportunities in so-called physical or organic medicine(2).

Not all of these concepts have to be presented by psychiatrists. Instructors in pediatrics, internal medicine, and obstetrics, gynecology have much to offer, as have social scientists. Longitudinal courses in family medicine, and participation in urban and rural community health center activities afford many occasions for students to acquire knowledge of the social and environmental aspects of various disorders. Such knowledge is crucial to the practice of top-flight medicine anywhere in the world.

It is not a vain hope that one day curricula committees in medical schools will recognize four basic clerkships—medicine, surgery, pediatrics, and psychiatry. If the physician of tomorrow is to develop as an effective personal and community advisor, and to make a lasting contribution to the mental health of his community, he must, during his student days, acquire a genuine understanding of social, cultural, anthropological, and community problems. At the same time, emphasis on the student's need for compassion and humanism must not be confused with the scientific knowledge of human behavior which he also needs.

It is reasonable to hope that, in the future, admission to a medical school will include as true prerequisites some education in the social sciences and the humanities in addition to the usual present day emphasis upon the biological and natural sciences. These requirements for admission not only would ensure the physician's professional interest in the total personality of his patients but would also prepare him for recognition of a possible participation in the mental health aspects of illness in general.

Medical faculties today are being encouraged to pay greater attention to the individual medical student, his motivation, goals, interests, and special abilities. Certainly, if physicians are going to care for the mental health of their communities, they

must be so trained and cannot be allowed merely to depend upon some sort of intuitive humanism. Some professors in America maintain that clinical teaching is an attempt to bring our knowledge of human biology to the bedside, and certainly the practitioner's use of available biologic knowledge is seriously deficient if it does not include mental health and mental illness.

With increasing family mobility throughout the world in both the industrialized and developing nations a definite amount of knowledge of preventive psychological medicine is a desirable attribute for the physician who is uniquely placed to help the family make its moves under the least emotionally traumatic circumstances, since current indications suggest the crucial importance of the family unit to the stability of the individual. Sometimes the physician can enlist the support of the nursing and social welfare professions when he himself cannot follow the family to its new location. In any event, the physician will be most effective when he clearly recognizes his role in maintaining the home as a healthy, stable unit which will contribute to the physical and mental health of the children and their parents(3).

If his training has been adequate, the good family physician of the future will apply psychological principles to the life crises of his patients—the child facing an operation, the grief-stricken parent, the expectant mother who needs information, attention and advice from the physician himself, from the midwife, and from the public health nurse. All maternity care personnel—medical students, general physician, obstetricians, nurses, and public health workers—should, during their training period, acquire “an adequate knowledge of personality structure and development” to “aid them in understanding and modifying human behavior.” The World Health Organization believes that such education can be more effectively carried out when well integrated into the curriculum of established courses rather than given on a separate course(4). Practical physicians will encourage all such training programs so that the value of the paramedical personnel who work with them will be increased.

During the normal growth and development of the child, the good physician will be aware of the psychological components and will be able to reduce the anxiety of the overzealous mother. The well-child clinic offers physicians opportunities to carry out good health procedures not only for the physical well-being of the child, but for his proper emotional development through parental guidance and reassurance.

The child who becomes ill—especially if stricken by a chronic illness—presents more psychological problems. Proper or improper use of hospitalization will determine the value of rehabilitative care; the doctor will recognize that hospitalization in itself causes anxiety not only to the parents but to the child himself. Such anxiety may result, not only in upset behavior on the child's part, but in prevention of successful diagnostic study.

Other normal “crises” in child development are the concern of the physician: the child's normal grief at bereavement, for instance, should a parent die, or be lost to him through divorce or separation, and the child's concern when an important family member becomes physically or mentally ill. On the somatic side is the delirium of a child suffering fever or as the result of drugs. Nor must the prophylaxis of communicable diseases be overlooked, especially against those that may effect the central nervous system. Physicians too often neglect the continuation of such preventive medicine when the child is over five.

More specifically, the general physician will readily recognize those signs and symptoms in children which may indicate the onset of severe mental illness. Naturally, the first line of defense is service to the child and his family in his own home, but the second line comes within the school system; schools can be useful in performing early detection and case finding, and in rendering early service(5).

There is a widely held concept that attitudes at the top administrative levels of any organization tend to set the tone for other levels. The importance of the school administrator's own mental health in relation to that of his teachers and students is readily apparent.

The physician will find three obstacles

which must be overcome if he is to involve the school system in detection of psychological problems in children: 1. The lack of interest of some school health workers in the psychological aspects of childhood health problems. 2. The lack of training among those who do have an interest. 3. The fact that the school health worker cannot deal with psychological problems unless she has expert assistance.

Among supporting services which school and physician should be able to utilize are the public assistance programs. These agencies can offer much assistance to disturbed children who are able to remain at home, but who may need supplementary help from day-care, home-care, or day-hospital services, and for children who have no families, or at best, inadequate families, and who may need foster-family care, a group home, care in a therapeutically oriented institution, or care in a residential treatment center. It is hoped that the physician will realize the value to himself as well as to the agency and the community of his serving actively on the boards of child-focussed agencies. Through such service, he will become aware of the changing patterns of social needs and social care of children in his community. By thus assuming responsibility for health promotion in the social fields, he works indirectly for the improvement of the physical and mental health of the community's children.

The role of the physician in his capacity as a citizen requires him to exercise his citizenship responsibilities by becoming informed about the essential needs of his community, by serving on social and health agency boards, by taking part in community planning and action committees, and by acting as a volunteer advisor on health problems to public and voluntary services. As a member of his medical society he can urge his fellow-members to: 1. Set standards for medical aspects of health programs, including the mental health aspects, and then to work for their adoption; 2. Work actively with other responsible community groups towards the same end; and 3. Urge that research move forward into areas where knowledge is most urgently needed.

"Every medical act," says the World Health Expert Committee on Training of

Health Personnel, "provides an opportunity for useful education work . . . treatment of illness is recognized as only a part of the total professional responsibility of the physician. His responsibilities are considered to include also those educational interventions which will contribute to the application of preventive measures by the individuals and families whom he serves" (6).

It has been said: "Knowledge and understanding about mental health and mental illness are essential to the public. The general public needs accurate and current information if there is to be community responsibility for the mentally ill and community provisions for mental health."

Often the physician has an opportunity, not only to provide information to the community leaders, but to carry out some more general form of public education. To achieve the latter goal, he may effectively work through teachers, lawyers, judges, police officers, probation and parole officers, and the clergy. Other receptive groups will be newspaper and magazine editors and writers, and radio and television producers and writers. These groups exercise a very strong influence on the community, as do leaders of labor and management organizations. The third group is the general public, whose attitudes are shaped in many ways by the "leading groups" but who still need much individual attention, if we are to reach them at a level and in a way which is appropriate to their own needs—one might say on the level of their personal and family interests and concerns, as opposed to broader civic or community needs.

Throughout the world, the physician is a community leader. This gives him a unique opportunity to participate in local, regional and national affairs. If his contribution to improve the lives of all citizens is not narrowly defined, he has an opportunity to serve on school boards, city councils, various regional and national legislative bodies. When he attempts to educate, mold, and influence public opinion, his participation need not be confined to the speaker's podium. He may serve in any number of ways in church, luncheon groups, labor, commerce, fraternal, community, and other organizations.

As a legislator he can exert his influence to support colleges and universities with their various academic and professional schools; the public hospital system; the various welfare agencies interested in child and maternal health and welfare, the handicapped, the aging, the juvenile; and lend his support to an adequate salary structure which will ensure the continuing attraction of people of ability and outstanding caliber. Where a costly new medical school and related facilities are contemplated, he can provide expert medical opinion. In the area of improved care in the penal system, he can make certain that rehabilitative measures include the psycho-social aspects. He can ensure that laws dealing with mental disorder are medically humane and socially and psychologically sound.

As a physician and a citizen he can formulate well-thought-out research programs. The opportunities are limited only by man's ingenuity. They include genetics, physiology, chemistry, child development, anthropology, sociology, epidemiology, ecology, aging, social studies, and even the techniques of mental health promotion and administration, to say nothing of the obvious necessity for clinical research. These are but a very few of the horizons which are apparent to all of us; those who are more perceptive will see a good many others.

As for the public health physician, the World Health Organization declares:

The most important long term principle for future work of the World Health Organization in the fostering of mental health is the encouragement of the incorporation into public health work of the responsibility for promoting the mental as well as the physical health of the community (7).

Perhaps we might begin at the level of what has been described as "the appreciation of human problems in a human way." In general one would look for the means whereby the public health team can assume responsibility for promoting mental as well as physical health in the community, and to integrate these mental health activities with other health problems whenever possible. If medical officers in public health received as comprehensive a training in the principles of mental health and hygiene as

they do in physical health and hygiene, their contribution could be of top importance in improving the mental health of a community. But this is not yet the case. Nonetheless, the public health physician in a rural health unit, while he might well exclude treatment for the more serious psychiatric disorders, can make a significant contribution in terms of secondary prevention, including recognition and case-finding for referral or for psychiatric consultation. A psychiatrist should be available as both consultant and teacher in the local health unit, and perhaps the public health doctor's primary responsibility is to make this fact known to the planning authorities and to insist upon its implementation.

Few physicians take serious issue with the notion that each generalist must assume responsibility to achieve a degree of familiarity with basic psychiatric principles comparable to his familiarity in other branches of medicine. It is assumed that a specialist physician will have made every effort to acquire the same skills and knowledge of psychiatry as he has in all specialties other than his own. Hopefully, too, he would make a particular effort to understand as much as possible about the emotional and psychiatric components of those disorders peculiar to his own specialty.

Public health physicians have extraordinary opportunities in their work with infants, mothers, preschool children, and the aged. They should be sharply aware of the emotional problems involved in public health practice and appropriate knowledge of the special problems of mental health care. Because these persons are trained in the techniques and skills of public health and social medicine they have knowledge and techniques particularly applicable to the mental health field. There is urgent need for the education of public health workers in the field of mental disorder; in the principles of aftercare, rehabilitation and resettlement of patients in the community; and in the promotion of acceptable mental health practices, as well as the eradication of those factors which are considered inimicable to sound psychological development both for individuals and groups. If the public health administrator who is responsible for all aspects of the health of

the community is going to discharge this responsibility, he must be educated and trained to deal, not only with the prevention of disease, but also with the impact of social, economic, and emotional factors as they effect the individual and the community.

Some of the challenges which lie ahead for the physicians of the world have been eloquently outlined as follows(8) :

We have not been able to do our best for the mentally ill to date, nor have we been able to make it wholly clear what kept us from doing so. Attempts to provide more humane care for the mentally ill and transform insane asylums into hospitals and clinics true to the healing purpose of medicine have occurred periodically during the last two centuries. While each reform appears to have gained sufficient ground to give its supporters some sense of progress, each has been rather quickly followed by backsliding, loss of professional momentum, and public indifference.

Even if we can find the road to a substantial reduction in the human and economic problems of mental illness, we are obliged to remain in full view of certain intervening observations that provide little cause for hope except as we can dispose of them. We must note, for instance, the curious blindness of the public as a whole and of psychiatry itself to what in reality would be required to fulfill the well publicized demand that millions of mentally ill shall have sufficient help in overcoming the disturbances which disturb their self-respect and usefulness.

Further, we must rise above our self-preservative functions as members of different

professions, social classes, and economic philosophies, and illuminate the means of working together out of mutual respect for our fellow man. We each have a responsibility that is common to all—our responsibility as citizens of a democratic nation founded out of faith in the uniqueness, integrity, and dignity of human life.

MOTIVATION AND ABILITY TO MOVE¹

ARNOLD J. MANDELL, M.D., CHARLES H. MARKHAM, M.D.,
FRANK F. TALLMAN, M.D., AND MARY P. MANDELL, M.S.²

The relationship between the function of the "extrapyramidal" motor system (particularly the corpus striatum and the thalamus) and the behavioral manifestations of "alertness" and "attention" as well as "movement readiness" have been of considerable interest to neurophysiologists over the past several years. Stimulation and ablation studies in this system have produced hypo- and hyperkinetic states as well as changes in sensorium from hyper-alertness to sleep (1-4). Buchwald(5) has demonstrated the relationship between the inhibition of learning and/or performance produced by activation of what he calls the "caudate loop" associated with EEG spindling and general drowsiness and inactivity. He has shown this system to be antagonistic to the arousal and motor facilitatory system of Moruzzi and Magoun(6).

In addition to the interesting neurological-behavioral issues that these studies stimulate, a possible relationship is suggested between what might subjectively be described as "attentiveness" or "alertness," and an organism's motor activity level. Probably all of us, at one time or another, have subjectively confirmed such a relationship in ourselves. It was with this general orientation that we approached the study and treatment of a group of patients manifesting parkinson's syndrome. This patient group appears to be a good one with which to study the relationship between subjective mood state and motoric activity because, as in most pathological conditions, the relationship appears to be quite exaggerated.

It has long been known that, in addition to the problems of localized tremor and rigidity, parkinson patients may manifest a

more global dysfunction which has been called "akinesia"(7) either relatively alone or in combination with the other symptoms. It is a rather difficult dysfunction to characterize, but generally it indicates the decreased capacity to initiate and carry out volitional motor acts as well as a reduction in automatic and associative movements. Mettler(8) feels this impairment generalizes into all fields of psychic and psychomotor functioning describing this patient group as "rigid, inaccessible and depressed." Along the same lines, Jacobson(9) reports 2 cases of manic-depressive psychosis with parkinsonism whose neurological symptoms, especially akinesia and rigidity, disappeared during the manic phase and returned during their depressed episodes. Boardman and Fullerton(10) found that phenothiazine-induced parkinsonism in their patients was associated with dejection, hopelessness, and apathetic inertia. They felt that the picture was undifferentiable from "endogenous depression." What is interesting is that with double-blind treatment with antiparkinson agents, the patients showed, in addition to the clearing of the parkinson picture, a renewal of interest with increases in activity and initiative.

It is the purpose of this paper to demonstrate further the relationship between the akinetic and rigid neurological features of parkinson's syndrome and mood state and the concomitant alleviation of these problems with an antidepressant, imipramine chloride. This particular antidepressant was chosen for several reasons: 1. It has been an effective drug clinically in our experience, particularly with endogenous depression; 2. In lower dosages in animals, it has been demonstrated to cause an increase in frequency in the EEG (the "arousal" pattern)(11), a condition which is consistent with the activation of the system which has been shown by Buchwald(5) to be antagonistic to the inhibitory system; 3. As an adrenergic potentiator (at least peripherally)(12), it may also be considered a

potential activator of the arousal system (13) and again antagonistic to this inhibitory system.

Methods. A group of 42 parkinson patients from the Neurological Clinic of the Neuropsychiatric Institute were studied. The pilot group of 7 was selected for refractoriness to other medication, the next 35 were unselected, consecutively appearing patients. The patients received an MMPI and Leary Interpersonal check list for psychological evaluation, a physical therapy check list consisting of 106 items relevant to self-care and motor functioning in their environment, a complete neurological examination, a brief psychiatric evaluation focused on subjective mood state, and a base line rapidly alternating movement task for 30 seconds in both hands. The patients were then followed with psychiatric and neurological exams on a once to four times per month basis during and after the trial of drug or placebo. After a suitable trial (usually 6 to 8 weeks) the entire battery was repeated; those that responded were continued on the medication and followed for up to 16 months. The drug was added without departing from the regimen the patients were following at the time. Twenty patients were studied with-

out, 22 with double-blind control. The drug or placebo was used with the following dosage schedule: 100 mg. a day for the first week, 150 mg. for the second week, 200 mg. during the third week; some patients were placed on 250 mg. The data reported here will be exclusively from the double-blind studied group, though the findings are consistent with our pilot findings reported previously (14). The data were analyzed graphically and statistically using conventional techniques of correlation and rank order correlation of pertinent scales on the psychological tests, the activities check list, and the timed alternating movement.

Results. The patients with parkinsonism appeared to be significantly more depressed clinically than a normal group. The MMPI depression scales were considerably higher than those reported for patients with slow-growing cancer by Blumberg (15). This would tend to indicate that reaction to an illness, per se, may be contributory to the depression picture, but not necessarily the entire explanation. In addition, there appeared to be a relationship between the amount of apparent subjective depression and apathy and the patient's ability to function as reflected both on the neurological examination and the clinical history.

FIGURE 1
DEPRESSION AND MOTOR MOVEMENT

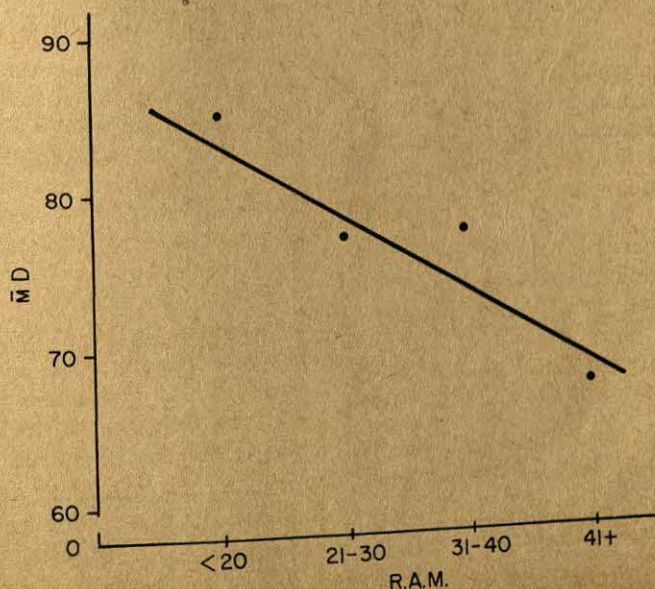

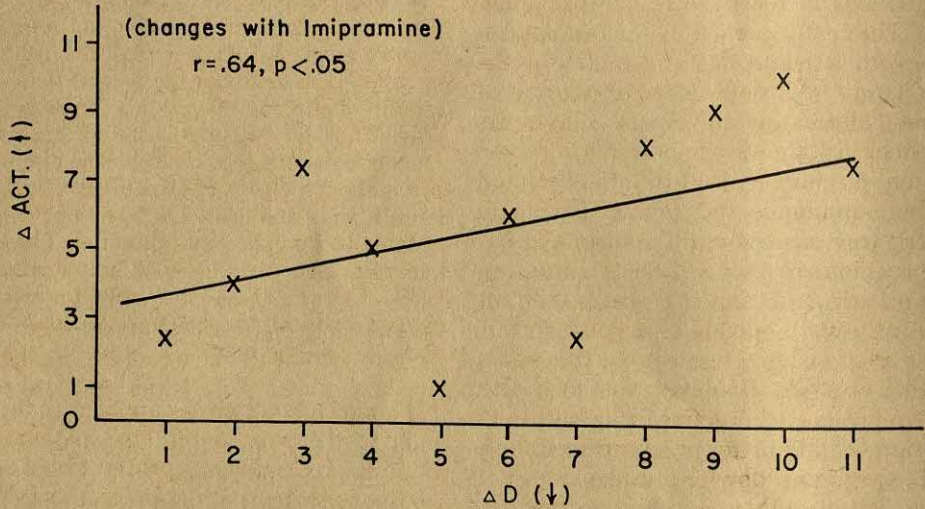

Figure 1 shows the relationship between score on the depression scale and number of rapidly alternating movements done in a 30-second timed interval on all the parkinson's patients at the time of the initial evaluation. It is apparent that the higher the

reflected in the relationship between the changes with imipramine treatment in the D scale in the MMPI and the number of items checked as "capable of" on the Physical Therapy Check List.

Figure 2 demonstrates that as the depres-

FIGURE 2

RANK ORDER CORRELATION-DEPRESSION AND ACTIVITY

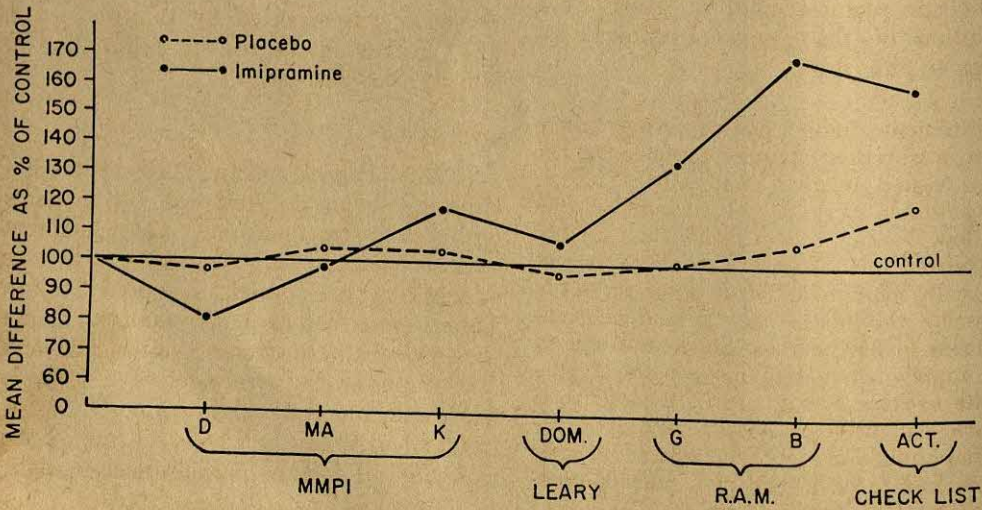

depression the lower the number of movements (and vice versa). The same relationship between mood and motor activity was

sion goes down the number of activities goes up.

Figure 3 is a summary picture of the

FIGURE 3

DOUBLE BLIND DRUG TREATMENT - PARKINSON'S SYNDROME

effect of imipramine compared with placebo under double-blind conditions. The placebo has a mild ameliorating effect on the depression which is represented by the MMPI D score; it increases the MA scale, felt by some to represent reflection of general energy level; and an increase in the K scale which has been used by some investigators as a reflection of adaptive functioning or ego strength. Accompanying these small psychological changes is a mild decrease in the dominance variable on the Leary scale which is said to reflect interpersonal dominance. The better hand ("G") does not improve with placebo, but interestingly the worse hand ("B") does improve in terms of the timed alternating movements. The activities check list shows a moderate improvement on placebo. Aring(16) has pointed out the importance of placebo effects in the drug treatment of parkinsonism and has made a comment that 70% of patients improve on any drug and that drugs will not consistently work outside of a good doctor-patient relationship. Here we see the placebo effect at work. However, the solid line which represents the active drug seems to work significantly better in most dimensions. The D score goes down; the MA does not change significantly; the K ego-strength scale goes up more, the person becomes more dominant; the good hand improves on timed alternating movements; the bad hand improves even more on timed alternating movements; and the amount of self-care and work activities significantly increases.

A holistic picture might be given by a description of the range of clinical responses to this drug.

The extremely stable, non-depressed school teacher was retired, but kept active in her garden, visited relatives, and busied herself with charitable works in the community. She had a low D score, tremor rather than rigidity characterized her illness, and she was not functionally too debilitated. In response to the imipramine she made only a moderate improvement in her neurological picture and in timed rapidly alternating movements. At the opposite extreme is a group of 9 patients, 8 of whom had been considered candidates for custodial hospital care by their relatives. Seven of them had to have care of a nursing type.

They could not dress, cook or keep themselves clean. Severe rigidity and akinesia rather than tremor characterized this group. These patients were quite severely depressed and, in general, out of contact with their environment in an adaptive sense. They all manifested high D scores on the MMPI. They were irritable, could not make decisions, and were a burden on their relatives. They had great difficulty in starting, stopping, turning and in performing repeated or fine movement, arising from a chair, and occasionally had trouble in swallowing and talking. Eight of these 9 patients, following about 3 weeks of imipramine chloride, manifested considerable all-over functioning improvement. Relatives called the change "a miracle." The ability of the patient to do timed rapidly alternating movements improved markedly. They all began to care for themselves. Only one patient required someone else to help her, although she was able to feed and dress herself, walk and cook. Only one of this group eventually wound up in a hospital. Three men had not been able to work for a couple of years. One of these was able to return to paying work and two began to do considerable work around the house.

Tremor tended most consistently to characterize the least debilitated patients and akinesia and rigidity appeared to characterize the most depressed, the least mobile and poorly functioning group. It is this latter group who were most aided by imipramine.

An interesting incidental observation was that as rigidity lessened and functioning improved, frequently tremor became more marked. Conventional antiparkinson agents were added to the regime in order to control this when it occurred. A similar phenomenon was reported by Whittier, *et al.* (17), following the use of imipramine in Huntington's disease.

DISCUSSION

In 1922, Patrick and Levy(18) reported a clinical psychiatric study of 146 patients with parkinson syndrome. They felt that over 1/3 manifested depressive reactions which they considered of serious import. They report that as many occurred before the onset of the syndrome as after. Schwartz (19) reported the treatment of a severely depressed, suicidal parkinsonian with a prefrontal leukotomy in which the depression was relieved and the parkinsonism marked-

ly improved. The feeling of some workers is that life experiences and personality characteristics producing depression (such as a loss) lead to a decompensation of defenses and the emergence of signs of the underlying organic disorder. Riklan, *et al.* (20), have characterized the depressive-like decompensation of the parkinsonians as being a reaction to the impact of an activity-constricting disease.

The recent neurophysiological demonstration of a learning and movement inhibitory system in the corpus striatum and thalamus that produces drowsiness and sleep as well as the demonstration that the phenothiazines that produce parkinson's syndrome also produce depression and that both are reversible using antiparkinson drugs leads us to interpret our data in a different way.

It is our feeling that many features of depression including apathy, inertia, failure in functioning, and slowness of movement are a reflection of the malfunction of the extrapyramidal motor system and are concomitants of the akinetic and rigid features of the parkinson syndrome. The relationship between depression and neurological and adaptive functioning as demonstrated in this study we feel (though not proof) is at least consistent with this hypothesis. The concomitant reversal of the multiple clinical features noted above with the use of an antidepressant drug which is thought to be a stimulant to the arousal-motor facilitory system (and antagonistic to the striatal-thalamic inhibitory system) appears additional evidence in favor of such a hypothesis.

The general relationship between motoric "doing" and mood, which has been discussed using a neurophysiological model, has been described and documented using a dynamic model in a recent paper by D. A. Schwartz (21). He has shown that many depressions begin concurrently with the loss of the capacity to function: a decompensation of the "doing defense." As the depression remits, the "doing" function and the mood appear to improve concomitantly. We may both be describing the same phenomenon with different theory and data language.

This system appears manipulatable both

psychologically (as indicated by the placebo response in our study as well as in others) and pharmacologically. The therapeutic implications of this study in no way supercede the use of other, more classical drugs or the operative procedures for tremor and rigidity, but appear to suggest a valuable adjunct in treating the global functioning defect in patients with parkinson's syndrome. This study may have implications for a neurophysiologic theory of depression.

DISCUSSION

Lothar B. Kalinowsky, M.D. (New York, N. Y.).—The authors originally titled their paper "Relationship between Psychiatric and Neurological Features in Parkinson Rigidity." It was this challenging attempt to correlate psychiatric and neurological manifestations which encouraged me to discuss this paper, and which probably gave the Program Committee the idea to ask me to discuss it. However, it is difficult to say to what extent this very interesting study actually contributes to the question inherent in the present title "Motivation and Ability to Move."

There is a large literature on the neurological side effects, or better concomitants, of neuroleptic drugs and their therapeutic effect on psychiatric symptoms. Applying such methods as the testing of handwriting it could be shown by Haase that probably all patients under neuroleptic drugs show increasing micrographia; and this includes patients who do not show or do not yet show parkinsonian symptoms of a more definite nature. Another symptom showing the relationship between psychiatric and neurological manifestations is the neuropsychiatric syndrome described as "akinetic aboulie state." Its main symptoms are a diminished drive and a more complacent attitude. This syndrome is often a precursor of a parkinsonian state, but it should be pointed out that it does not contain the depressive mood which the authors of the present study consider as an essential symptom of parkinson's disease.

Do the observations of psychomotor changes have a parallel in the effect of antidepressant drugs? The authors make a valiant effort to establish such effect. They have succeeded in collecting good and thought-provoking observations, even though the interpretation of their findings can be manifold. We cannot agree with Boardman and Fullerton whom the authors quote as stating that the parkinsonian syndrome due to neuroleptic drugs has depressive features indistinguishable from an endogenous depression. Furthermore, the depressive mood of some, but by no means of all, patients with parkinson's disease is certainly not identical with an endogenous depression. The authors' observation that imipramine, which has been called a psychic energizer, has a favorable effect on the total psychiatric-neurological symptomatology of parkinson's

disease is very valuable. Their case material is quite convincing, and in accordance with my own belief that antidepressant drugs are particularly valuable in atypical depressions, more so than in endogenous depressions; and I am inclined to list depressions in parkinson patients among the atypical depressions.

Removal of the depressive features in parkinson's disease has been seen by H. Strauss and many others, and akinesia was noticed to improve by Sigwald, *et al.* The authors' observations should encourage wider use of imipramine in similar cases. The depression in parkinson's disease, however, is far less frequent than akinesia, and it remains questionable whether akinesia and depression are actually related and expression of the same motor function. It is something entirely different, when a true depression in a parkinson patient clears up under antidepressant drugs, or, as we have seen in a fairly large number of cases, with ECT. It is true that in such patients removal of the depression also improves neurological function. The parkinsonian symptoms become worse, and the patient more rigid and often bedridden, when he develops a depression. He becomes mobile again when the depression improves. However, the same was seen in patients with paranoid psychotic episodes without depression. Furthermore, this effect on neurological functions is not limited to diseases of the basal ganglia. Other neurological symptoms such as hemiplegia are influenced in the same way during psychotic episodes.

Observations of this kind make it doubtful whether the authors' interesting studies can be used as evidence of a specific effect of antidepressant drugs as stimulating the arousal-motor facilitatory system as opposed to the striatal-thalamic inhibitory system. In a similar study Haase, who emphasized the direct effect of neuroleptic drugs on psychomotility, considers the effect of antidepressants on psychomotility as more indirect; he sees the psychomotor change as a consequence rather than the cause of the removal of depression.

The authors call their conclusions still unproven, but this does not diminish the value of the observations presented. I particularly regret this conclusion because it is my strong belief that a neurological approach to many psychiatric problems is most promising, and that it is being too much neglected by present day research. It is for this reason that I consider the authors' investigations a most valuable contribution.

THE JOINT COMMISSION REPORT ON MENTAL ILLNESS AND HEALTH: IMPLICATIONS FOR NURSING ADMINISTRATION

ANNIE LAURIE CRAWFORD, R.N., M.Ed.¹

The report has identified three problem areas: *Manpower*; *Facilities*; and *Costs*. These are problems common to many programs, with some special dimensions for programs dealing with mental illness and health.

Recommendations providing a suggested blueprint for action are offered under three major headings: *Pursuit of New Knowledge*; *Better Use of Present Knowledge and Experience*; and *Cost*. The report is an impressive document with implications for nursing which usually challenge but sometimes dismay.

The problems identified by the Joint Commission are known to every nurse administrator. The extent to which the nurse administrator can meet the challenge of the recommendations by finding new and better ways of dealing with the problems will determine the effectiveness, to a significant degree, of the nursing profession in this as in other health programs.

The first task of the nurse administrator is to assure herself and her staff at least a potentially friendly climate for practice. The nature of the professional nurse's role and function in mental health and the care of mentally ill patients is not as clearly understood nor is it at all times as sharply defined as it is in many other health promoting and conserving programs. The direct or indirect effect of policies and decisions of numerous governmental agencies and units, such as the budget bureau, the Civil Service System, the institution or agency personnel officer, and others, on the climate for professional practice cannot be ignored. This is equally true in many instances for her professional organizations. She cannot assume, even when the evidence seems fairly conclusive, that people lack understanding (which they may) or wish to deliberately hamper her. While she may not, because of the administrative structure of the agency, have any face-to-face con-

tact with the budget bureau director her knowledge of the processes can help her clear shoals when dealing with her immediate supervisor. In her communications with her professional organizations she must be prepared to defend objectively and expertly her conviction that certain of the organization activities support while others hamper her administrative efforts to provide optimum nursing care for patients.

Next, it is necessary to consider the objectives of the nursing service. Are these clearly defined and available in a concise, realistic, understandable, and *stimulating statement*, and apparent in the *working environment* of every nursing unit in the hospital and in the community nursing agency? How competent in the nursing care of mentally ill patients, support to the family with mental health problems, and as a participant in preventive mental health programs is the nurse administrator? This is a vital question, particularly to directors of general hospital nursing services acquiring psychiatric inpatient units and to directors of public health and community nursing services, where an agency assumes family supportive and patient follow-up service.

The problem of *manpower*, of persons who seek out opportunities to nurse the mentally ill, has been with us since the first human being became mad. Since it is apparent that workers in the field of mental illness and mental health have been beset or immobilized by manpower shortages even when there was a surplus of people wanting jobs, the current widespread manpower shortage should do little to comfort us. It may be that national attention to the needs in our field will finally mobilize more creativity and industry in dealing with it. However, there would seem to be a serious question about whether we may not be required to shift gears hurriedly to more careful selection and more effective and realistic training because of a flood of young workers, and an increase of older women, in the labor market. (The Bureau

¹ Florida State Board of Health, Jacksonville, Fla.

of Labor Statistics reports that we will absorb 29 million additional workers by 1970—most of them youths and older women.) There is already some evidence that some of these are nurses—and that others will be preparing for nursing in community colleges.

Large numbers of potential workers for this field were ignored in the 1930's. Nurses, most of whom had no training in psychiatric nursing, made the rounds of hospitals looking for work or sat by silent telephones awaiting calls for private duty, while thousands of mentally ill patients sat on dingy hospital wards, many of them tied into straight jackets, and from week to week did not even see a professional nurse. Even then some voices were raised, May Kennedy's, and your speaker often brought this question up at meetings. We believed then that it would have been possible to interest state hospital superintendents and the nurses in a cooperative effort to have hospitals offer housing and maintenance and plan educational programs useful to the nurses. If we reflect on the role of nursing in the development and expansion and in the excellence of general hospital patient care we can reasonably speculate that the Commission Report might be telling a somewhat different story if nurse leadership could have been mobilized then. We know that public health nursing expanded and became a tremendous force for health during that period, often through installation of community nursing services under WPA. With this second opportunity to assume aggressive leadership in providing a decent standard of nursing care for the mentally ill psychiatric nurses dare not fail to do so.

The manpower we need, and during the decade ahead will have a chance to get, will require the opportunity and tools to promote programs designed to prevent mental illness (with measurable results), to restore the mentally ill person to a healthy state, and to participate in rehabilitation which makes the person who has been sick a functioning member of society. The prestige and the remuneration which doing important work deserves will also be expected.

Nursing administration must recognize the enormous importance of volunteers, e.g.,

both the community worker and the summer college student for direct service to patients and for recruitment of workers. The patient's environmental climate is primarily the business of nursing. The psychiatric nurse in the mental health clinic, the public health nurse in the community, and the psychiatric nurse on the hospital ward, individually and collectively, have opportunity to promote immediate and long range goals for nursing service through productive contact with volunteers. These are the citizens of today and tomorrow whose knowledge of and tolerance for the ex-patient may mark the difference in whether he can survive at home during a crisis (for which the clinic is best equipped to help) or, following brief general hospital or extensive state hospital treatment, can return to a welcoming, not a rejecting family and neighborhood.

In addition to regular orientation, instruction, and guidance for volunteers, nurses can conduct classes for other community groups (*Mental Hygiene* classes taught in the evening by the director of nursing were attended by stenographers, beauticians, saleswomen and others, in Idaho, early in the 1940's). Florida psychiatric and public health nurses, employed by county health departments, are meeting regularly with relatives of hospitalized mentally ill patients, with the focus on understanding, tolerating and setting limits when a relative returns from hospitalization.

The Commission has said that we must pursue *new knowledge*. The nurse administrator must prepare and support her staff so that they too, no matter how busy, *tolerate and encourage* thinkers in their ranks. One of the characteristics which sets the nurse apart, not only to the public, but to herself, is that of being a *doer*. The public health nurse has perhaps reached a higher level of achievement in allowing for thinking, but she too is sometimes shaken by the "be you a talking nurse or a doing nurse" question.

The report speaks of venture or risk capital; the nurse administrator will need to indulge in a good deal of venture or risk policy and procedure—even to make better use of present knowledge and experience. This will take courage, and the willingness

to admit that the unworkable is, or for the time and place at least appears to be, unworkable. We have come a long way in recognizing the right and the *responsibility* of the physically ill person to participate freely in his own recovery process. We have not come even the first mile in many places toward allowing the mentally ill patient this right, nor preparing, even pushing him toward this responsibility. I do not believe that nurses should assume full credit for the *status quo*—we have distinguished friends and co-workers who share our failure to act. Let us be bold and imaginative now, and thus demonstrate that we have come of age professionally.

Nurse administrators will be expected in the *pursuit of new knowledge* and in the *better use of present knowledge and experience* to provide for more visible collaborative effort, in achieving and maintaining a healthy person and family, between the psychiatric nurse and the public health nurse, and among these nurses and others of the investigative and treatment groups (psychiatrists, public health physicians, behavioral scientists, and others).

The report suggests that we place more emphasis on the obvious that patients with major mental illnesses are different in significant ways from the physically ill. Almost everyone is aware that the mentally ill patient may at times behave impulsively and irresponsibly. This is not, I am sure, what the Commission is referring to. I would endorse wholeheartedly the suggestion that we give more thoughtful attention to the significant differences and to the similarities particularly in the orientation and training of students and new staff. Nursing administrators need to be sensitive to responses of staff members to, or even the stimulating of, bizarre behavior on the part of the patient. The manic is often charming—the paranoid patient a trouble maker, a convincing fabricator.

The diagnostic procedure and the planning of treatment for the mentally ill patient, in clinic or hospital (large state, small private, and to some extent in general hospital units) is one area where staff needs to understand certain differences clearly in order to participate appropriately in the

“team or multidisciplinary approach.”

Even as we emphasize differences we also need to be sure that the young staff nurse with traditional training is aware that there are some basic similarities between this and the approach which she daily experiences on the medical or surgical ward—the Lab report, the pathologist's findings, the result of x-ray reading, *etc.* This is a multidisciplinary approach but the emphasis for this “team” for whom the physician is undisputed captain is on presenting certain specifically confirmed information to the captain so that he can make a diagnosis and prescribe treatment.

In the case of the mentally ill patient, physicians, nurses, social workers, psychologists, occupational and recreational workers, aides and attendants sit around the table disclosing and discussing the most intimate aspects of the patient's life experience and relationships. Sometimes I have wondered a bit uncomfortably about how one could really distinguish a certain “staffing of a patient” from a general gossip session. I do not wish to imply that the staffing approach is inappropriate, but to emphasize the difference which I believe we must consciously prepare personnel to recognize and make use of in appropriate ways. We have at times emphasized the need for extensive information as a requisite for providing nursing to the point where nursing instructors and students feel frustrated and thwarted when the hospital's policy limits access to social and family history data and the psychiatrist refuses to sit down and discuss his patient with them. Until we have conclusive evidence that extensive information *gathered by others* about the patient facilitates nursing care success, we are on extremely tenuous ground when we demand this as an essential to demonstrate our nursing skills.

The nurse administrator might take the lead in planning staff conferences through which the nurse shares with her peers and co-workers what *she* has learned about a patient and how she has used this information to facilitate a nursing care plan which is contributing to the promotion and restoration of health for the patient or is helping him and his family to learn more effective ways of dealing with crises.

Considering yet another dimension, members of the nursing staff need to consider the economic and social significance that confining all diabetics or heart disease victims in large barn-like institutions would have, and in so doing be challenged to find ways to help the mentally ill patient return to the community as a functioning member of society. Thus we avoid the immobilizing effect of professional preoccupation with "curing" which is sometimes more of an unrealistic attempt to make the patient into someone we like than a realistic plan to help him mobilize his resources to deal with his environment in an acceptable way. Humane treatment is not necessarily incompatible with coaxing, pushing (even shoving a little) a patient toward self responsibility.

One of the more obvious places where nursing can begin is in providing patients with an opportunity to behave and work responsibly while in hospital. As an example of this we might ask how much latent energy for nursing is sitting idly about the wards of many state hospitals. How many physically healthy schizophrenic women could and would profit by the assumption on the part of the nursing administration that they too, at some time in their lives wanted to "nurse the sick." There are literally thousands of these women doing this work now—errand girls and aides on infirmary wards—and we can add a new approach for the already productive, working patient by taking steps to help her see her work as an ingredient of her health potential. She needs to view her work as a step toward becoming a functioning member of society rather than as a pass to a few state hospital privileges.

Many can be trained by nurse supervisors and instructors, and made to feel that they are accepted and respected enough to be accorded status and trust. This does not imply *unsupervised responsibility* for the well being of fellow patients. We might begin with lightly supervised or unsupervised responsibility for self, by providing living quarters where the duty and the freedom to report for work is given. Let this be the base on which assignment to nurse's aide work is established. This would make sense to the patient, and provide for her some

sense of orderliness in progression to healthy activity.

The nursing aide is only one of many illustrations of steps toward responsible achievement the patient can and should take in the hospital. Of all personnel, nurses are in the most strategic position to assess the patient's readiness to and interest in going forth into a life of productivity. Nurses must assume more professional responsibility for bringing these observations to the psychiatrist.

The opportunity for innovation, for experimentation, and for creative action in planning for and providing nursing care available to the psychiatric nurse has always been its greatest appeal to me as a field of practice. To make credible this difference, and to provide the atmosphere for creative practice, is the ultimate in administration of nursing services to the mentally ill. I believe this is in keeping with the Commission Report implications in its recommendation that we make better use of existing knowledge and experience.

As an immediate and long range response to the Commission Report I believe that nursing administrators in state mental hospitals should immediately assume aggressive leadership in requiring an acceptable level of preparation for all workers through pre-service, in-service and on-the-job training programs. The nursing administrator is the only person who can effectively demand and assume responsibility for requiring trained workers. This is only valid, however, if she has a plan. She will need to know what resources she can use, whether she can request assistance from vocational education, community colleges, and the extension service of the university. Many nurse administrators could begin by requiring that all schools of nursing sending students for instruction and clinical experience provide a faculty in this as in other clinical areas. Faculty members employed by the state hospital could then be released to instruct employed personnel, many of whom are at this time untrained workers assigned and paid to nurse the mentally ill.

The nurse administrator in the general hospital with a psychiatric unit or service often faces two inappropriate choices. If she can get a specialist she must often pay her

a higher salary than she does other supervisors, adding to internal stresses, or she cannot find a specialist available and must therefore select from her staff the best equipped person. In this situation she needs easy access to consultation, and an opportunity for some on-the-job training for the nurse selected. In Florida, nurse administrators have both resources available. Consultation is available in some areas through the county health department if the mental health worker is a psychiatric nurse, in others through the State Board of Health training and research program. On-the-job training is available in the psychiatric unit of the university hospital. (If the director of nursing has had no prior preparation in psychiatric nursing she should be the first to seek the on-the-job training.) It would seem that the specialist, when available, might best be used as a general nursing service supervisor, thus making her special skills available to all nursing service units.

In all types of facilities the nurse administrator should have specialist staff available to intensive care units so that the newly admitted patient can be continuously attended during the first days, or through crises. The modern general hospital considers an intensive care unit for medicine and surgery a necessity—expensively equipped, and staffed with expert nurses. The psychiatric patient does not usually need the expensive equipment, but is in equally urgent need of the expert nursing care if recovery and rehabilitation is to be assured.

In the Commission's discussion of facilities many areas have direct and far reaching implications for nursing administration. The suggestion was made that large state mental hospitals be converted to multi-purpose chronic disease hospitals, with more nurses, occupational therapists and

aides, and fewer psychiatrists. Is it to be expected that people, even chronically ill ones, will willingly submit to this type of isolation? What of the nurses and aides? There are hundreds of unfilled budgeted positions for professional nurses in isolated state mental hospitals now. There are few nurse positions unfilled in either general hospital or in mental health in public health. Outpatient departments and mental health clinics have too few psychiatric nurses, but this is because there are as yet few positions available to psychiatric nurses in these facilities.

I will only comment briefly on the *cost*, and not at all in terms of the cost of patient care as presently defined in all reports. Hospital insurance plans are constantly expanding, so today's figures are out-of-date tomorrow. I believe the nursing profession should put emphasis on the use of money where it seems most relevant—in recruiting, training and employing the nurses who will contribute significantly to abandonment of the need for large chronic disease institutions. We need particularly to expand our efforts in community nursing programs; we need to recruit talented youth and to strengthen preparation in psychiatric and public health nursing. In collaboration with psychiatric nurses, public health nurses can assume more responsibility in promotion of health, in prevention, in early case finding and referral, in support to individuals and families in time of crisis, and in support to the mentally ill patient who can manage at home on the job with this support. We need *enough* highly skilled psychiatric nurses to give direct care to patients when needed, and to instruct and supervise less skilled nursing personnel so that the patient is assured effective nursing care.

A RESEARCH PROJECT IN PSYCHIATRIC AIDE TRAINING¹

RUFUS M. VAUGHN, M.D.,² STANLEY TEITELBAUM, Ph.D.,³
AND HELEN KUMPAN, M.Ed.⁴

The shortage of personnel in mental hospitals is well documented. These shortages are especially acute in the ranks of professional personnel but less so in the ranks of psychiatric aides. Most direct care, therefore, falls to the relatively unskilled aide. On many chronic units, these employees carry almost total responsibility. It is apparent that professional ranks will not be expanded with any great speed. It has been often proposed, therefore, that the psychiatric aide could be utilized more effectively if he were trained. There have been many programs designed to accomplish this purpose but none has proved widely applicable nor has any been carefully studied as to efficacy. To be useful to many, a program should be of fairly short duration, not require a specific educational background and be so structured as to be applicable to a variety of situations. In view of the fact that formal didactic programs usually meet with limited success, a program should not rely solely upon this method of teaching. The program should also be evaluated to determine its usefulness.

In view of the above problems, a program was designed with an emphasis on learning through doing and on favorably influencing aide attitudes towards patient care. It was felt that an approach through on-the-job training would be most satisfactory since didactic programs, in general, have given disappointing results. It was also felt that aides would learn most through working directly with skilled professionals. It is generally accepted that superior aides have a favorable influence on those aides

with whom they work. It was therefore believed that these superior people should have a large role in the undertaking and could assume a fair amount of responsibility in the training of the lesser skilled employees.

In keeping with the idea of having a short program, a time limit of one year was set for the project. This year was divided into 3 periods of 4 months each. The total number of patients under the care of the research team was limited to 60 so that maximum time might be devoted to the problems of training. Obviously, in the time allotted little of a specific nature could be communicated and, indeed, it was not the purpose of the project to transmit "knowledge." Rather, it was the intention to influence attitudes of aides toward patients. It was hoped that custodial approaches might give way to more humanistic techniques of dealing with patients. The essence of the program, then, consisted of attempts to make attitude changes in a small number of trainees in 4 months through the direct action of the research team and charge (or superior) aides.

In order to judge the effectiveness of the program, a control group was selected and subjected to the same measuring devices as the experimental group. The same selection factors were used for experimental and control groups. The only difference was that the controls continued their regular hospital assignments without interference from the research staff.

Method of Project Operation. The subjects selected for the project included those employees assigned to the nursing service except for registered nurses and those nursing service personnel assigned to non-clinical duties (barbers, beauticians, linen room workers, etc.). Also excluded were employees who would be lost to follow-up in the near future due to such things as retirement, forthcoming resignation or pregnancy. Well over 100 subjects were selected for study but a variety of factors over a

⁴ Boston College, School of Nursing, Boston, Mass.

period of time resulted in a final sample of 79 including both experimental and control groups. Superior aides, selected by the director of the nursing service, were placed in charge positions.

The training setting consisted of a 60-bed two-story building housing 30 women upstairs and 30 men downstairs. The patient population included a fairly representative sample of the chronic population with the exception that some severe administrative problems, particularly escape and severe alcoholic problems, were excluded. The average hospital stay for the male patients was 17.98 years with a range from 1 year and 1 month to 34 years and 3 months. The average hospital stay for the female patients was 9.48 years with a range of 1 year and 11 months to 20 years and 1 month. Only 6 of the patients had been in the hospital less than 2 years. The hospital itself is a state hospital of some 2700 beds within a metropolitan area. The project staff consisted of the director psychiatrist, psychiatric nurse, occupational therapist, corrective therapist and psychologist, all of whom maintained offices within the building.

The physical arrangement permitted the assignment of 2 superior aides to the female unit and 2 to the male unit both morning and afternoon. In addition to these personnel were the trainees which consisted of 4 assigned to the men and 4 assigned to the women on both morning and afternoon shifts. The building was, therefore, more than adequately staffed for a chronic building with 6 attendants on each floor morning and afternoon. This relatively large number of employees, however, posed some particular problems.

Objective and subjective measures were taken on all subjects. The subjective measures included an Opinionaire which incorporated the Custodial Mental Illness Ideology Index(1), authoritarianism scales, self-deception scales, and self-esteem scales. In addition, the aide performance evaluation scale and aide-patient interaction scales of Ellsworth(2, 3) were also used. A separate Job Satisfaction Inventory devised by us was an attempt to clarify further custodial versus humanistic ideation in relation to patient care. All of these measures were given

prior to assignment to the unit, again at the end of 4 months (upon leaving the unit) and finally some 5 months after the end of the training period. Three sets of measures were then available on each subject. In addition, the experimental subjects were further studied with MMPIs.

The teaching program particularly emphasized the physical presence of the research staff on the ward itself. Except for the very late evening hours, one of the project staff was always available for assistance with problems or for individual contact with aides. In addition, the superior aides were always available. Twice each week for each shift, clinical meetings were held with the emphasis on discussing patient problems which the aides presented. Some attempt was also made during these meetings to provide some didactic or background material where appropriate but almost invariably this was not very successful. Each staff member was also assigned the responsibility of maintaining regular individual contacts with specific aides during their period on the research unit. Once each week, the aides had a group meeting with the focus on group problems rather than on patient problems. The occupational therapist had a regular weekly meeting with the aides to go over various programs and techniques. The corrective therapist worked intimately with the aides on various recreational projects. A number of patient group meetings were held on a regular basis and where possible the aides were encouraged and helped to assume group leadership responsibilities.

There was nothing unique about the teaching program itself. The prime emphasis was on providing an intensive experience with professionals for a 4-month period. The only thing that we felt was somewhat different was the encouragement of aide led ward meetings.

Problems During Project Operation. During various phases of the operation of the program, a number of problems arose. The first and most difficult was the resistance to change within the hospital structure. This was reflected in many areas. Physicians had some tendency to obstruct the program by not providing patients as requested and sometimes providing patients who were grossly unsuited to the program. They also,

at times, interfered with the easy transfer of an aide feeling that the individual was indispensable. Nurses, and particularly those in supervisory positions, were often reluctant to release aides from the unit and found a number of ways of preventing a rapid and smooth transfer. The aides themselves found innumerable objections to change. The particular hospital in which the project was carried out is, in many respects, a fairly progressive state hospital. In view of this, we were surprised to find a great degree of resistance to change which was directly opposed to the prevailing progressive philosophy of operation.

The resistance to change within the hospital is in itself a fascinating phenomenon but in our project nothing occurred which has not been previously described(4). There are a number of things, however, relating to the operation of the project which are of more particular interest. These have to do with the aide population itself.

Very early in the project, we discovered that our aides had great difficulty with abstract principles or dynamic concepts. It was particularly difficult for the aide to observe the same behavior in a variety of settings and formulate a patient's mode of operation outside of moralistic or judgmental concepts. To see, for example, that a patient's great need for attention or affection was motivated by something not immediately apparent was very difficult. The tendency was rather to take surface manifestations whether negative or positive and react to them directly. A patient seeking attention, for example, would either be given the attention or be rejected. It usually was the latter if the pattern was a frequent and pervasive one. There were, of course, some aides who did not respond to the patients directly but this seemed to be more a matter of familiarity with the patient rather than familiarity with the patient's problem or any dynamic understanding. The aide's failure to react would be described by the aide himself or by other aides as "oh, we know that patient" or "that patient is just that way" or "we're so used to him that he doesn't bother us anymore." The aide could not usually understand intellectually that a patient's cloying or obsequious behavior when couched in terms of attention seeking

and pleasant manipulative demands actually represented some underlying hostility. The aide, of course, would respond directly and immediately to the underlying hostility but had great trouble in seeing how the patient put the aide in a position to react. The social terms of good or bad were far more frequently used than we would have hoped or initially expected.

Another area of considerable difficulty was in limit setting. Limits could only be understood in terms of specific, concrete and sharply delimited administrative structure. On the other hand, flexible limits or less sharply defined limits or partial limits were seen as total lack of control. Especially during the early part of the project, aides seemed to operate on an all or none principle and had trouble comprehending the patient's inability to accept total responsibility for himself or his ability to accept only limited responsibility in some areas. The open door was seen early as overt permission for the patient to come and go entirely as he pleased. The aide felt impotent to intervene if a patient wanted to leave the unit inappropriately. In the early phase of operation, great difficulty was experienced in getting patients to bathe regularly or to meet appointments of various kinds. The aides felt that if patients were free to come and go, this represented also freedom to decide whether or not they would bathe or whether or not they would keep dental appointments. They felt that they had lost all control of patient activity. They were unable to see limit setting except in terms of actual physical restriction. As time went by, some of the more major problems diminished but it was our clear impression after a year of operation that the aide definitely requires a fairly structured job situation and should be permitted to use his own judgment only within prescribed and fairly narrow limits.

Another major difficulty was the aide's tendency to interpret recreational activities merely as fun, diversional or as leisure activities. It was difficult to inculcate the concept that a ball game or a picnic offered more than simply entertainment for the patient group. It was not easy for the aide to understand that these activities were actually work. Sometimes they felt guilty that

they were not doing their job as they saw it. Part of the problem seemed to be that the kinds of things which were done with patients were the same kinds of things which aides would do in their own private lives outside of the work situation. Sometimes aides tended to be punitive about this aspect of the program feeling that we were being "too good to patients" and that patients were "getting much more than they deserved." Probably this attitude arose partly from the fact that the research project engaged in a more active recreational program than the hospital at large. Aides were never reluctant to engage in an occasional party or assist with an occasional field trip or picnic but the concept of providing these things on a regular basis as a necessary part of the regular therapeutic program was foreign. The motivating factors which the research staff accepted were never totally embraced by the aide group. The research staff felt that there should be a slow and progressive transfer of increasing responsibility to the patient population for initiation of planning and program development. The aides' role was seen as one of assisting in this transaction and slowly withdrawing from a participating role to a supervisory or stimulus role for the patient group. The aide's tendency was, however, to assume a disproportionate degree of responsibility for both program planning and program participation. This problem was modified in time but the idea that patients could operate as responsible individuals at least in some areas was never totally accepted.

There were some problems which were particular to the project itself with respect to the number of staff available for ward operation. The work of Gutenkauf(5) in particular is of interest in this area. We discovered that we did not have the optimum number of employees working with patients. With our large number of employees, we had difficulty in appropriately dividing responsibility and in getting individuals within the aide group to accept their share. It was much too easy with a large number for responsibility to be shifted to the point that at times no work was done. Linen handling, for example, for a long while presented special problems. If an aide found this to be a difficult or unpleasant task, it

was easy for him to encourage the charge aide to find someone else to take care of it because, after all, there were plenty of people. The assigning of any task which was not popular posed this kind of problem. Without clear and unequivocal direction, floors were not swept, beds were not made, patient appointments were not kept and activities did not get started because "there were plenty of people to do the job." The idea of everyone pitching in never materialized in an adequate fashion. With a large number of personnel, it was also possible for more intense aide-patient interaction. This did not always work out favorably. Sometimes this interaction was inappropriate and unhealthy competition arose. There was also a greater possibility for manipulative behavior on the part of patients. There was yet another disadvantage to the patient. It was much more tempting for personnel to carry out tasks than it was to motivate patients to do them. We suspect that it requires particular persons with particular training to assist with the remotivation of the chronic patient. There are, then, very definite and particular problems in trying to operate with a large staff.

Problems Following Training. At the end of the 4-month training program, aides were sent to other units throughout the hospital. For 6 weeks, the research staff continued to follow the aides in their new settings. After an initial period of increased activity on each unit, there was a general leveling of performance to that previously existent in the building to which the aides were assigned. As soon as project staff support was withdrawn, former engagements in improving patient grooming and attempting to increase patient-to-patient interaction diminished. The tendency was for the aides not to continue to pursue these activities aggressively. This was a consistent finding with all three groups. There seemed to be a number of factors operating. The two most tangible ones were the need for support and structure and, secondly, the resistance to change within a hospital structure or the leveling aspects of the hospital culture.

Testing Results. The most revealing thing was that in the comparison of a number of attitudes, there was no significant statistical

difference between the control and the experimental groups. With respect to ratings of performance, however, there was one area which showed a change which is of interest. All aides, experimental and control, were rated by supervisors as to performance. These scores were dichotomized on the basis of highly rated and lowly rated. Of these four groups, then, it was found that the most highly rated experimentals showed the greatest change in custodial attitudes as compared to the other three groups. This change occurred, however, only in the post to follow-up period. Why this particular group should improve at this particular time after training is not clear. This particular observation, however, is of some importance in that it would indicate that supervisory ratings might be a sensitive indicator for screening out aides who will favorably respond to a program.

Also of interest are the MMPI findings within the experimental group. There tended to be a deviation in the Ma score and in the Pd scores for the experimental group. These deviations are increased above the normal for the general population. We also discovered that there is a very strong tendency for high Pd scores to correlate with poor performance. On the basis of the Pd deviations and the supervisory ratings, we would expect that poor performers ought to be available for identification within a short time after hiring.

CONCLUSIONS

Overall, we can clearly say this program was not an effective means of bringing about attitude changes or significantly changing work performance. We believe that the effectiveness of a program will probably be greatly hampered by the very nature of the aide group. There is such a diverse edu-

cational background as to make any program planning difficult. It is our feeling that the aide as now selected is a much less potent force in the growth of a positive program than is usually believed. Aides, in order to maintain adequate functioning, require aggressive nursing programs, staffed by properly trained nurses as key people. Although there is a great need for further study, there is a possibility that the good performer can be pre-selected. It may well be that hopes of upgrading patient care through in-service training of aides are not entirely realistic. Some more fundamental changes are probably needed in our concept of the job and in our concept of proper care of the hospitalized patient. This involves changes in educational requirements, selection procedures, pay scales and perhaps a total restructuring of responsibility within the hospital.

(Detailed statistical data on the study are available from the authors on request.)

EXPLORATIONS IN ALTERNATIVES TO HOSPITALIZATION¹

ROBERT F. MOORE, M.D., ROBERT S. ALBERT, Ph.D.,²
MARY JANE MANNING, M.S.S.W., AND BETTY ANN GLASSER, M.S.S.W.³

The primary goal of the Massachusetts Department of Mental Health is the treatment of the mentally ill "with the expectation that those who are hospitalized may be restored to productive community life and that those who are in the community may be restored without recourse to hospitalization"(1). This paper describes a demonstration project⁴ at the Massachusetts Mental Health Center that has explored some methods of achieving the second part of this goal—the prevention of psychiatric hospitalization. The project, based on a pilot study(2, 3) initiated in Jan. 1956, began operating in Sept. 1957 as a new research-oriented clinical unit of the hospital known as the "Community Extension Service."

In setting up the Community Extension Service as an integral part of the Massachusetts Mental Health Center (hereafter abbreviated as "CES" and "MMHC"), Harry C. Solomon,⁵ MMHC Superintendent, challenged it to show 1) that a significant number of the persons who are referred to MMHC for inpatient care could be adequately and safely treated by measures other than hospital admission; 2) that these alternative measures could be developed from existing community resources and professional techniques; and 3) that effective alternative measures could be less costly in time, money, and personnel than

hospital admission.

BACKGROUND

The parent institution, MMHC, the smallest by far of the 12 Massachusetts state mental hospitals, has been devoted to treatment of acute psychiatric illness, to education, and to research since its opening in 1912. It is located in Boston in the Harvard Medical Center, and is Harvard's principal psychiatric teaching facility.

By 1957, MMHC's growing facilities provided adult inpatient care on four wards⁶; outpatient care in the Southard Clinic (offering long-term, intensive psychotherapy) and the Community Clinic (treating only former inpatients); an active ex-patients' club; a privately sponsored Halfway House; a Day Hospital; a Night Hospital; and an intensive rehabilitation program(4). Most of these activities were initially oriented toward aftercare of inpatients, so as to shorten hospital stay and decrease readmissions. As the staff gained experience and confidence in aftercare, it was decided that the Day Hospital, which had served as a transitional stage between inpatient ward care and community life, ought to be able to admit seriously ill persons directly from the community. A number of patients, accordingly, were treated and discharged without ever staying overnight. A logical next step was an "extension" of the hospital into the community to provide preadmission treatment that might circumvent hospitalization entirely.

Another factor that encouraged the development of CES was the "waiting list" for admission to MMHC. The waiting period, commonly 10 to 14 days and occasionally 6 weeks or more, was often difficult for both patients and their families(5). CES would be available without more than a day's delay, and could offer 1) complete and definitive care, entirely on an outpatient basis, or 2) treatment that would con-

⁵ Principal investigators were Dr. Solomon, Dr. Milton Greenblatt (Asst. Superintendent), and Dr. Halim Mitry (Executive Officer). CES is also indebted to Stefan Kraus, M.D., Project Director for the first ten months.

⁶ Two new wards opened in Dec. 1958, increasing the adult beds from 130 to 165.

tinue on the ward when a bed became available, or 3) at least stopgap services or consultation to alleviate the distress of the waiting period.

Finally, the development of CES as an extension of the hospital into the community was stimulated by other experiments in home treatment and pre-hospital care in Amsterdam and elsewhere in Europe, and by concurrent work in this country(6). Although by 1957 the U. S. mental hospital population was decreasing, admission rates were still rising, pointing to the need for defining more exactly the indications for inpatient care and for exploring the possible alternatives to 24-hour ward care.

PERSONNEL AND PROCEDURES

During the 6 months covered by this report, the CES clinical team included 3 persons: a full time psychiatrist and psychiatric social worker, and a half time psychiatric nurse. Other personnel included a research psychologist, a secretary-receptionist, and, in 1959, a second clinical team and additional research staff. One floor of an old 3-story dwelling house across the street from MMHC was used as a suite of offices and reception room. This location, clearly separated from the hospital, helped to emphasize that the CES goal was extramural treatment.

The operating procedure, step-by-step, is as follows:

1. A CES psychiatrist reviews the MMHC waiting list daily, and selects from it the names of persons meeting these criteria—aged 16 or older,⁷ residing in Greater Boston,⁸ not currently an inpatient in any kind of hospital, and not currently in treatment in any unit of MMHC.

2. The psychiatrist then telephones the

referring physician to explain the CES goals and to offer immediate service to the patient and family.

3. If the physician rejects this offer, CES takes no further action. If he agrees to CES intervention, our psychiatrist then discusses with him in specific terms what CES proposes to do, and whether medical responsibility for the patient during the waiting period is to rest entirely with CES or with him, or is to be shared in some clearly understood fashion.

4. CES then contacts the patient or his family, having always obtained the referring physician's explicit permission to do so. As a rule, the social worker makes this contact by telephone, and schedules:

5. An interview between patient and psychiatrist, and an interview between a significant family member and the social worker, preferably at CES offices, but at the patient's home if necessary. During both these diagnostic interviews, CES is described as a service designed to help the patient find adequate treatment without admission to the hospital.

6. The psychiatrist and social worker usually confer briefly, and then all four—psychiatrist, patient, social worker, and relative—meet together to decide whether CES will begin treatment or recommend admission.

7. This decision is often postponed pending further diagnostic study, which may include physical examination, laboratory tests, x-ray, and psychological tests (the Minnesota Multiphasic Personality Inventory, the Leary Interpersonal Check List, and the TAT).

8. A diagnostic home visit, often the quickest and most accurate way to form a picture of the patient-family interactions, is usually worth the extra time and effort it requires. When the patient cannot or will not come to CES, or when we expect that the patient will need help with personal hygiene, housework, or baby care, the CES nurse usually makes the initial visit. When seeing the patient's family is the primary purpose, the CES social worker will visit. The psychiatrist visits only when the patient cannot be persuaded to come to CES. CES experience with the home visit will be reported elsewhere(7).

⁷ Persons under 16 are not treated on adult wards in Massachusetts. In Oct. 1958, MMHC opened an Adolescent Service for ages 14-17; since then, CES has excluded persons under 18.

MMHC has no strict upper age limit for admissions, but the referral of bedridden senile persons is discouraged. The oldest CES patient in the last half of 1958 was 62; only 6 others aged 60 or more appeared on the waiting list during this period.

⁸ CES defines Greater Boston as including the area within 45 minutes' travel from CES by automobile or public transportation.

9. The treatment measures CES uses most often are psychotherapy, drugs (principally chlorpromazine and meprobamate), EST, social casework with patients or relatives, special nursing care, day hospital care (supervised by CES), and provision of special services, such as vocational counselling. Whenever possible, the Visiting Nurse Association, a Family Agency, the family physician, and other community resources are brought into the treatment program.

10. Preadmission counselling (when hospitalization cannot be avoided) is usually handled by the social worker, who helps prepare the patient for the transition to hospital life and the family for the temporary loss of the patient. She might, for example, arrange temporary placement of a patient's children, or might introduce patient and family to the MMHC physician or nurse who will supervise inpatient care.

11. Finally, CES procedure includes follow-up of patient and family one year after referral, by persons other than those who made the initial contact. In addition, a CES psychiatrist has interviewed about a third of the referring physicians(8) in order to complete our picture of the events and feelings, as viewed by patient, family, and physician, that led up to the decision to hospitalize(9).

RESULTS

Our results have been encouraging. Preliminary figures show that alternatives to inpatient care were provided for 71 (52%) of the 136 persons seen in our first two years; the remaining 65 (48%) were admitted to MMHC or elsewhere for inpatient psychiatric care. This paper, however, discusses in detail only those whose initial contact with CES occurred during the 6 months from July 3, 1958 to January 5, 1959, since we have a one-year follow-up for this group.

During this period, the names of 185 persons were added to the MMHC waiting list. Table 1 shows that those not available to CES totalled 148 (80% of 185), including 114 who did not meet CES criteria, 29 whose referring physicians refused CES help, and 5 whose families refused CES help.

The outcome for the remaining 37 (20%)

persons, all of whom were 1) referred to MMHC by a physician specifically for admission to an inpatient ward, 2) interviewed by a CES psychiatrist, and 3) followed up 12 months later, was as follows: alternatives to hospitalization were found for 18 (49% of 37), and 19 or 51% were admitted for inpatient care. Two of the non-hospitalized group were treated by the CES staff in the MMHC Day Hospital, leaving 16 (43%) not institutionalized in any way.⁹

The interval between referral and admission for the 19 hospitalized persons was less than 30 days in 14 cases (74% of 19); 2 entered within 60 days, and 3 entered after 11, 22, and 23 weeks.

The alternatives prescribed for the 16 non-institutionalized persons were not unusual forms of treatment. Eleven received psychotherapy at CES for periods ranging from 6 weeks to 1½ years; 4 of these 11 also received drugs (see Case 1), and 2 of the 11 also received electroshock treatment. Of the remaining 5, 2 were referred to psychiatric outpatient clinics; one received case work at a family agency; psychotherapy by a private psychiatrist was arranged for the fourth; and the fifth was managed by "environmental manipulation."

ILLUSTRATIVE CASES AND COMMENTS

The following examples will illustrate the kinds of patients seen, the alternatives prescribed, and the results.

Case 1: This single woman of 46 had been briefly hospitalized in 1940 with a diagnosis of dementia praecox, catatonic type. Her family had removed her against advice, sheltering her at home ever since. Following her mother's death in late 1957, she became more withdrawn and bizarre, and finally the fire hazard of her careless cigaret smoking throughout the night led the family physician, with the father's reluctant approval, to put her name on MMHC's waiting list in August 1958. CES intervened, and after discussing the case with the referring physician, obtained his permission to telephone the father, who promptly agreed to bring the patient to CES for an interview. The patient obediently accompanied him, but remained mute, grimacing,

⁹ One of the 16 not institutionalized died of myocardial infarction 6 months after referral, as CES treatment was terminating.

and preoccupied throughout the initial meeting.

The father was delighted when CES offered to try to help him keep the patient at home. The patient remained mute and would not say whether she even understood what we planned, but she did not resist returning to CES with her father, and she took medication (chlorpromazine up to 800 mgm. daily) from him. At first the patient could tolerate only 5 to

10 minutes alone with the doctor each week. Meanwhile, the social worker met regularly with the father, and occasionally saw a married sister and brothers, while the CES nurse supervised weekly home visits by a student affiliate nurse, who would spend an afternoon with the patient, sharing with her the preparation of a meal or a shopping trip. Improvement was slow but steady, marked by gradually neater appearance and less inhibited

TABLE 1
Fate of the 185 Persons Awaiting Admission (7/3/58-1/5/59)

PATIENTS GROUPED ACCORDING TO IMMEDIATE OUTCOME OF CES SCREENING PROCEDURE OR TREATMENT	ADMITTED FOR WARD CARE WITHIN ONE YEAR	NOT ADMITTED WITHIN ONE YEAR	TOTAL ADMITTED AND NOT ADMITTED	
			NUMBER	% OF 185
1. Persons excluded in CES screening procedure :				
(a) Of the 185 persons awaiting admission, 104 did not meet CES criteria:				
Already hospitalized elsewhere	64 *	—	64	35%
Currently in treatment at MMHC	18	6	24	13%
Less than 18 years old	6	3	9	5%
Not within commuting distance	7	—	7	4%
And, 10 more were excluded for miscellaneous reasons :				
Administrative request	3	2	5	2%
Admitted before CES could act	4	—	4	2%
Patient spoke only Chinese	1	—	1	1%
Subtotal :	103 (90%)	11 (10%)	114 (100%)	62%
(b) CES sought the referring physicians' permissions to see the remaining 71 persons; 29 physicians rejected CES help, because :				
Patient "must have ward care"	13	12	25	14%
Admission no longer necessary	—	4	4	2%
Subtotal :	13 (45%)	16 (55%)	29 (100%)	16%
(c) CES offered help to the remaining 42 persons; the families of 5 of these 42 rejected CES and demanded admission :				
	5	—	5	2%
SUBTOTAL : Sum of (a), (b), & (c) :	121 (82%)	27 (18%)	148 (100%)	80%
2. Persons treated by CES :				
Outpatient care by CES staff	—	11	11	6%
CES-supervised day care	—	2	2	1%
Referred elsewhere	—	5	5	3%
Admitted for ward care	19	—	19	10%
SUBTOTAL :	19 (51%)	18 (49%)	37 (100%)	20%
TOTAL	140 (76%)	45 (24%)	185 (100%)	100%

* Of the 64 persons already hospitalized, 32 were subsequently transferred to MMHC and 19 to other mental hospitals, leaving 13 who continued as inpatients without subsequent transfer, and who were not, technically, "admitted within one year."

verbal communication, and by making the hour-long rapid-transit trip to CES alone. After 1½ years, she was well enough to talk of seeking employment. Subsequently, the psychiatrist had to discontinue contact with the patient, but she continues to take moderate doses of chlorpromazine, she comes to the hospital for regular talks with a graduate nurse, and the weekly visits of a succession of student nurses, each seeing her throughout the 3-month affiliation, have now gone on for 2½ years. Their educational value for the students is important, but aside from this, they seem to be meaningful enough to the patient to warrant continuing them indefinitely, as long as the patient's hospital admission can be postponed, if not prevented, with an investment of only two hours a week.¹⁰

Comment: The decision to attempt to treat this patient outside the hospital was based on the following reasoning. First, a basic CES assumption (or bias) is that outpatient treatment is, generally and relatively, better for the individual and the community than hospitalization. We recognize that some patients (e.g., those who may harm themselves or others) clearly need 24-hour ward care. We also believe there are others for whom hospitalization is clearly contraindicated (e.g., certain patients with extreme dependent tendencies). But most patients, in our opinion, fall between these two extremes; and they usually can be, and therefore should be, treated without hospitalization.

Second, CES reasoning is based on evaluation of the risks to all concerned and the probable outcomes of the various alternatives in comparison with hospitalization. In Case 1, we believed that the fire-hazard could be minimized, and we had no reason to expect violence or suicide; therefore, the only risk, if home treatment failed, was that her admission would be delayed. Hospitalization, on the other hand, carried the risk of being lifelong; even if she improved, her aging father's death or illness might leave no one willing to accept her on trial discharge. The chance that outpatient care

might strengthen the patient so that she could survive her father's death or become even a partly self-supporting citizen was admittedly small; but in our opinion the chance that inpatient care might achieve this outcome was infinitesimal.

Case 3: A 19-year-old boy was brought by his older brother to the family physician, who referred him for admission on hearing that he would not go to work, kept odd hours, talked strangely of religion, and was often argumentative. When the CES social worker telephoned the mother to arrange an appointment, she was asked to talk to the patient directly. He came to the telephone, agreed to an interview, and came alone to CES, arriving on time and neatly dressed. If he had not described himself as ill and eager for treatment, only the occasional bizarre word or phrase would have betrayed the severity of the illness during his interviews. He and his mother agreed to a trial of outpatient treatment, but the mother, whose behavior was puzzling at first, wanted the home visit delayed "till I can tell my husband." Further interviews with the mother brought out that two older children in this family had been institutionalized—one was mentally retarded and the other died in a mental hospital after surgery for brain tumor—and indicated that what initially seemed to be a casual attitude toward her son's illness was probably a reaction to feelings of depression and preoccupation with guilt.

Following the patient's third visit to CES, his mother telephoned to report that he had become argumentative and had thrown a bottle through a closed window, but had calmed down. She was given a night telephone number to call if there was further trouble, and agreed to use it. When the patient's brother returned from work that evening, however, and was told of the patient's actions, an angry argument ensued, ending with the brother escorting the patient to MMHC and demanding admission, which the doctor on duty arranged without informing CES.

Comment: CES failed in this case because it was assumed that the mother's attitude reflected that of the entire family; if she and the patient preferred outpatient care, we supposed other family members would agree. A home visit might have corrected our impression, and might have helped us to attach the proper significance to the two clues we overlooked: mother's

¹⁰ Some observers feared that object-loss recurring every 3 months would be harmful to a schizophrenic person. This patient perhaps viewed the succession of student nurses as a recurrent object-gain.

reason for delaying the home visit, and brother's original insistence that the patient see a doctor. A talk with the brother might have served the same purpose, but like the home visit, it too was delayed; in fact, neither patient nor mother had told anyone in the family of their visits to CES. It is possible that CES underestimated the patient's degree of illness or overestimated the mother's influence in the home, and it is certain that provisions for communication between CES and family, and CES and MMHC, were inadequate on the night of admission. These errors surely contributed to our failure to provide a "suitable alternative" to admission, but in our opinion they are less important than what must be called, in retrospect, the folly of attempting to treat any person without bringing all of the significant family members into common alliance with the patient and the treatment team. Our term, "failure," does not mean that CES considers this admission unnecessary or that the patient was out of place in the hospital; it implies, instead, our belief that we could have treated this patient in the community if we had more aggressively sought either an interview with the brother or a visit to the home.

Case 4: This 20-year-old woman started behaving strangely on the fourth day after her baby girl was born, but in spite of her overtalkativeness and refusal to stay in bed at night, she was discharged home with her baby. She was extremely concerned about the infant yet unsure of how to care for it and unwilling to follow the advice of her mother. Arguments with both mother and husband became increasingly loud, frequent, and uncontrolled, and the patient was hoarse almost to the point of muteness when the husband in desperation took her to a psychiatrist's office. The doctor at once put her name on the MMHC waiting list, and then called CES to suggest that we explore the question of whether or not a manic person can be handled without hospitalization.

CES promptly saw the patient, husband, and mother, who were willing to try outpatient care, primarily because they saw admission as disgraceful. There were frequent office visits thereafter, and numerous telephone calls, day and night, from all three. The patient agreed, after considerable persuasion, to take chlorpromazine in doses up to 150 mgm. q.i.d., and her overactivity diminished a bit. New crises

appeared frequently, and there would again be a flurry of telephone calls, which the staff handled more adeptly as their knowledge of the situation increased. The social worker was seeing both the mother and husband regularly in an effort to support them and also to aid them in gaining insight into how their behavior was affecting the patient. CES was without a nurse at this time, and therefore called upon the Visiting Nurse Association to instruct and help this young mother with the baby, and also to observe what was going on between mother and patient with regard to the baby.

At the end of a year, the patient was in good enough control to be able to arrange long-term psychotherapy at a local outpatient clinic; she successfully held a part time job, which was necessary because of her husband's behavior; and she dealt with both husband and mother in a more mature fashion. The husband had reacted to the birth of the child with jealousy, and to his wife's illness with anger and depression; he made it clear that he considered the illness a betrayal which voided the marriage. He displayed this anger through repetitive extravagances, by losing job after job, and finally by passing bad checks, and was persuaded to enter treatment himself only after narrowly escaping a jail sentence. In many ways the patient appears, after 16 months, the stronger of the two, and is currently the one who is less in need of help.

Comment: Treatment of this manic patient obviously occupied most of our staff at various times, and required round-the-clock availability at the beginning. This raises the question of the cost of CES service in such a case compared to the cost of inpatient care. Aside from this question, which is discussed below, we would point out the advantages, in dealing with an overactive patient and a manipulative family, of our limited staff, which was large enough to satisfy or "cushion" the constant demands, yet small enough to circumscribe the number of people the patient and family could become involved with, and the number of ways they could attempt to circumvent our prescribed regime.

Case 6: A 33-year-old mother of two young children rather suddenly developed crying spells, feared that she might harm the children, and took to bed, unable to care for her home or family. Her husband took her at night to

the psychiatric clinic of a small general hospital where the doctor recommended inpatient EST and telephoned MMHC, asking the doctor on duty to add her name to the waiting list. When told there would be a waiting period, the patient became even more disturbed, and pressed her husband to admit her elsewhere. The MMHC doctor on duty telephoned a CES psychiatrist about this referral, and CES was therefore able to intervene at once by telephoning the patient's husband and scheduling an appointment for the following day. The patient and her husband came to the CES offices convinced that immediate hospitalization was the only answer. Following a diagnostic interview, the patient was told by the CES psychiatrist that she would not harm her children, that she would get better and once again take care of her family, and that this might be accomplished without the need for EST. Patient and her husband were seen together by the psychiatrist and social worker, and these reassurances repeated. The response was immediate; both patient and husband accepted the opportunity to try to solve the situation with CES help and returned home with relief and hope. She came regularly to CES, despite a bus strike that isolated her part of town for 6 months, and made steady improvement. Much of the trouble centered around the husband's attachment to his mother, who had moved into the house to take over while the patient was ill; when the patient was encouraged to send her mother-in-law back home, she found herself able to do the housework that she could not manage before. Talking then of her feelings about her own parents and her fear of motherhood helped to clarify her feelings toward her children, and as treatment was terminated, she was fully in charge of her family and optimistic about the future.

Comment: This example demonstrates the therapeutic value of immediate aid at the time of crisis, especially in a situation that patient, family, and referring physician had pessimistically viewed as hopeless without hospital care. Just as the pessimism of one party reinforced the pessimism of the others, the husband's obvious pleasure and relief on hearing at CES that his wife might not need admission was immensely reassuring to her. CES' promptness and optimism were probably crucial in this case.

DISCUSSION

At the start of the pilot study, Robinson

(2) postulated that "immediate and effective treatment" of waiting list patients should enable many of them to circumvent hospitalization. If it is granted that our results support the possibility of preventing hospitalization, it is worthwhile to determine whether or not this was accomplished by treatment that was immediate and effective.

CES' *immediate* availability at the time of referral was a crucial factor in just one (Case 6) of the 4 examples given above, and it would be fair to state that about 5 of 6 of all our patients did not need our help on an emergency basis. It was important in nearly all our cases, however, that we be *promptly* available, meaning that we could intervene within 24 to 48 hours. In our experience, the swiftness of our response has been less important than the fact that we did respond, and that we declared our availability and our willingness to assume responsibility for the patient's care. Similarly, we have not found many cases in which our response had to be accompanied by action, such as immediately visiting the patient's home; very often, our telephoned statement that we will "take over" the case seems to diminish the urgency of the situation to the point that the patient and family will be able to await an appointment at our offices on the following day. In short, although we underline the necessity for *promptness* in making ourselves available, we have found little occasion for emergent or dramatic activity.

Our only measure of the *effectiveness* of our treatment has been the patient's ability to remain in the community for 12 months. On comparing mental status and social adjustment at the time of the follow-up interviews with similar evaluations at our initial contact, we can report a degree of improvement in most patients, but we have no way of determining whether more or less improvement might have resulted if the patients had been hospitalized. Reviewing our 4 case examples, it is our opinion that the treatment we provided, and the 12-month outcome, in Cases 1, 4, and 6 would not fall short of what hospitalization might have accomplished; in Case 3, our treatment attempt was abortive—this patient, incidental-

ly, was still on an MMHC ward at the end of a year.

Although we provided relatively long-term care for some persons, and often achieved definite changes in clinical status by means of EST, psychotherapy, or drugs, we also felt that symptomatic change, or situational change, was a satisfactory endpoint in many cases.

With each new patient, we attempted to assess the whole "patient-family situation" in order to determine what changes or losses had led to the referral for admission, and what needs would have to be supplied in order to prevent admission. Any measures that stabilized the situation or restored the *status quo*, and thereby forestalled admission, would, in our opinion, qualify as *effective* treatment.

It is in "assessing the situation" that the special skills of the nurse and social worker, especially as employed in the home visit, are invaluable; these staff members also have a major role in "supplying needs." In general, our efforts seemed to be effective in proportion to our flexibility in adapting ourselves to the particular requirements of each patient's situation. Willingness to assume the role that will be most helpful to the patient rather than a more limited role that might be dictated by professional training has been an asset in our staff members. It has also made it important at times for us to assign our personnel to patients or to specific responsibilities, such as a special home visit, on the basis of personality traits rather than professional training. In recruiting personnel to staff an "extension service," then, we would recommend as prerequisites enthusiasm for the prevention of admissions, ability to enter the patient's home and to participate, within limits, in the patient's life, and flexibility in attitude and outlook.

The cost of CES treatment during the last half of 1958 was \$7,600, which covered salaries for the clinical team, supplies, travel and telephone. This figure excludes research staff salaries and items furnished at no cost by MMHC, namely, drugs, EST, office rent and maintenance, and other overhead expense.

Dividing \$7,600 by the 37 patients seen yields an average cost per patient of \$205.

If it is argued that CES accomplished nothing for the 19 persons hospitalized, and that all expense should be charged to the 18 whose admission was prevented, the average cost of each successful alternative ($\$7,600 \div 18$) is \$422.¹¹

An estimate of the cost of the items furnished by MMHC could be added to the \$7,600, but we will assume that this added cost is offset by the fact that CES clinical staff did not devote all its time to the 37 patients described. Ten other persons were evaluated and treated in late 1958; they are excluded from this report because they were self-referred, rather than referred by a physician specifically for ward care. (We admitted 1 of these 10, and found admission alternatives for 9.) CES was also treating 15 patients referred before July 1958; 9 of these 15 were still being treated by CES in 1959. The \$7,600, therefore, provided clinical services for $37 + 10 + 15 = 62$ persons; it also pays for the time spent by CES staff in teaching and other non-CES activities at MMHC.

If it cost \$422 to treat a person referred for admission outside the hospital, how does this compare with the cost of inpatient care? In 1958, the average daily cost per patient in all 12 Massachusetts state mental hospitals was \$4.59, and the average patient stay was 180 days, giving a total cost of \$826 per admission (10). MMHC inpatients in 1958 were billed \$23 per day for ward care, but stayed an average of only 84 days, giving an average "cost" per admission of \$1,932.¹²

These unsophisticated calculations lead us to the conclusion that the cost of CES treatment is, at least, not greater than the cost of inpatient care. This opinion is supported by Hyde and Brennan (11), who found at the Butler Health Center that

¹¹ Follow-up studies now in progress may enable us to state whether CES treatment was of benefit to the persons whose admission we did not prevent (e.g., by shortening hospital stay).

¹² CES patients were not billed for treatment. Admission to MMHC would have meant a large bill for the family, and this may have provided an incentive for cooperation in outpatient care. Most families did not ask if we would send a bill, however, and we did not initiate a discussion of fees. Only one CES patient could afford private psychiatric care, and this one was so referred.

alternatives emphasizing "individual therapy on an outpatient basis show the least total cost to the community in the long run." Goshen(12) notes that the *per diem* costs of an inpatient alternative (day hospital care) exceed those of standard state hospital ward care, but that the total cost per patient of the briefer, more intensive day care is less than the total cost of inpatient care.

Table 2 attempts to show that the CES

list persons were admitted within 12 months, and incorporated the results in Table 1. In Table 3, we compare the 1958 waiting list group of 185-37 treated by CES and 148 not treated—with the 1957 control waiting list group, and show that the percentage of CES-treated persons hospitalized is significantly smaller than the percentages hospitalized in the other two groups.

A detail worth noting in Table 1 is that only 45% of the persons whose referring

TABLE 2

Personality disorders	227 *	33%	1	3%	—	1
Other non-psychotic disorders	8	1%	—	—	—	—
TOTAL: ALL DIAGNOSES	683	100%	37	100%	19 (51%)	18 (49%)

* The large number of diagnoses in this category is probably related to the large number (224 in 1958-59) of admissions each year of persons under indictment or charged with criminal offenses, whom the courts send to MMHC for observation.

patients were at least as "sick" as MMHC inpatients. Of the 683 MMHC inpatients admitted between July 1958 and June 1959, 286 (42%) were classed as psychotic; 23 (62%) of the 37 CES patients were psychotic.

To evaluate our results more precisely, we studied the "natural history" of the pre-CES waiting list, and found that 60% of the persons listed in early 1957 were admitted to MMHC and 20% to other mental hospitals, but the remaining 20% did not enter any federal, state or private psychiatric hospital in Massachusetts within one year after referral to the list(13). Since CES treated only 37 persons, or 20% of the 185 listed during 6 months, we try to show in Table 1 that our treated 20% are distinct from the 20% who would evade hospital admission in the natural course of events. From Department of Mental Health records¹³ we learned which of the 148 waiting

physicians rejected our help were subsequently hospitalized. All of these doctors, incidentally, were psychiatrists; general practitioners invariably agreed to CES intervention. Our data do not as yet explain how these referring psychiatrists achieved their 55% rate of "prevention." Perhaps these patients were less sick, or spontaneously improved, or responded to new or more vigorous treatment during the waiting period. Perhaps, too, the referring doctor's reason for rejecting CES help was his intense concern for and devotion to his patient, and this in itself turned the tide. This kind of determination to see the patient

tistics of the Massachusetts Department of Mental Health records admissions to all federal, state, and private psychiatric institutions within the Commonwealth except the psychiatric wards of general hospitals. CES is indebted to Thomas F. Pugh, M.D., Director of the Division, for aid and advice in this investigation, and to Miss Agnes K. Durkin and Mrs. Ruth D. Bluhm for their painstaking search of the Division records.

through to a solution of his problems is, we feel, a major part of what CES tried to offer.

SUMMARY AND CONCLUSIONS

During a 6-month period, the Community Extension Service sought alternatives to hospitalization for 37 persons awaiting admission to the Massachusetts Mental Health Center; 18 (49%) were successfully treated as outpatients, and remained in the community for at least 12 months, and 19 (51%) were hospitalized. It is concluded that alternatives to inpatient care can be provided for a significant number of persons who are referred for admission, and that the cost of these alternatives is no greater than the cost of ward care. Special personnel, unusual techniques, and elaborate resources are not required for these alternatives. What is required is a different view of the function of the mental hospital. When the treatment team decides that hospitalization often can and should be circumvented, and adopts prevention of admission as one of its primary functions, it will find practical alternatives to admission right at hand. The team will need a willingness to take responsibility for the patient's care promptly; a willingness to be flexible with regard to how and where treatment is to be given; and a willingness to consider together the patient, his family, and his environment in diagnosis and treatment.

ABSTRACTS

A STUDY OF CERTAIN PSYCHOLOGICAL ASPECTS OF VOCATIONAL (OCCUPATIONAL) DISABILITY

ROBERT L. BRAGG, M.D.¹

Since 1953 the Boston Welfare Department has referred some of its applicants for disability assistance on psychological grounds to the psychiatric clinic of the Massachusetts General Hospital for evaluation and recommendations. There has been, with the exception of one year, 1956, a gradual increase in the number of applicants so referred to the MGH. This group was studied in an effort to determine as well as possible the factors that disabled these individuals psychologically. The study consisted of: 1. A review of the records of the applicants seen for the 5-year period January 1, 1954 to December 31, 1958 with emphasis placed on determining the number of applicants seen each year for the 5-year period, the age, sex, marital status, the type of problem presented and the disposition; 2. A more detailed review of the records of the applicants seen in the calendar year 1958 with the classification of each applicant according to the nomenclature of the Diagnostic and Statistical Manual of the APA, and the further classification of the Boston applicants of this group into 1 of 5 groups, each such group having disability dispositional implications; and 3. The recording of a detailed history of those 5 applicants from the Boston area having primarily disorders of psychogenic origin without clearly defined tangible cause or structural change. This was accomplished by reviewing the records and several evaluative interviews with these applicants by the author in the psychiatric clinic, MGH.

For the calendar year 1958 these applicants accounted for 12% of all evaluations (775) all purposes, psychiatric clinic, MGH. For the same year disability assistance accounted for more than 12% of the total budget (over \$36 million) for the 4 categories of public assistance (aid to depend-

ent children, old age assistance, disability assistance and general relief) for the City of Boston.

An average of 83.3% of the applicants evaluated at the MGH psychiatric clinic for the 5-year period (a total of 177) were considered to be psychologically disabled by the examining psychiatrists. Thus it appeared that the decision that the applicants were disabled had already been made in practice by a community caretaker and the applicant then started in channels which would lead to official confirmation of this community decision.

The greatest number of applicants was in the age group 40-49 (33% of 177) with the next highest number in the age group 50-59 (31%). Of the 1958 applicants, 86% (93) were previously known to the various clinics of the MGH and 14% had their first contact with the MGH when they were referred to the psychiatric clinic for disability assistance evaluation. Of those previously known to the MGH, 23% had their first contact with the hospital through the medical clinic and 7.5% through the psychiatric clinic. The largest number of this group had more frequent contacts in the following clinics: medicine, nerve, psychiatry and orthopedics, in the order listed. The applicants were equally divided into male and female, except for the 60-69 category in which the number of females was twice that of the males. Fifty-six percent of the applicants were single and only 18% married. If the single, separated, divorced and widowed were combined, 81.7% of the group would be included. In the separated group, the females were twice that of the males. In the divorced group, the females were almost 3 times that of the males. Of the married applicants only 1 was a woman. The question is raised as to whether the married, psychologically disabled female is supported by her husband or family and the married,

¹ Dept. of Neurology and Psychiatry, Harvard Medical School.

psychologically disabled male is supported by agencies.

A close study of the 5 1958 applicants of the Boston area, having primarily disorders of psychogenic origin without clearly defined tangible cause or structural changes, led to the postulation of the following steps (they do not necessarily involve all the members of this group) which bring about psychological disability. These steps do represent a generic way of looking at the development of psychological disability. The steps are : 1. A stressful situation which may cause physical or psychological injury or both to the individual with subsequent development of a state of disequilibrium. During this state of disequilibrium the dependency needs of the applicant may be more obvious to an observer and are more readily and comfortably expressed by the applicant ; 2. The individual is most likely viewed by the family and friends as physically ill though the problems of our group of applicants are psychological. During this period family and friends mobilize to gratify the needs of the individual and are most interested in attitudes and opinions of examining physicians ; 3. A period in

which family and friends doubt the existence of a physical illness of the individual and, not being able to accept the concept of psychologically disabling illness, change their attitude towards the individual : "He is not sick, he is lazy." Hostility is then directed towards the applicant by family and friends ; 4. Loss of self esteem by the individual with a sense of role failure ; 5. Development of a hostile, dependent relationship of individual towards family and friends ; 6. Attempts at extrusion of the individual from the family unit ; and 7. A new level of equilibrium for some : complete unemployability.

As a result of the more detailed study of the Boston applicants for 1958 it seems that the greatest potentiality for reversibility of the psychologically disabling state rests with those applicants having primarily disorders of a psychogenic origin without clearly defined tangible cause or structural change. The infrequency with which rehabilitation measures were recommended and the chronicity of the problems presented suggests the need for earlier identification and evaluation of persons potentially disabled psychologically.

THE ISOLATED PSYCHIATRIST IN A MILITARY SETTING¹

INGRAM COHEN, CAPT., MC, AND I. LOUIS HOFFMAN, COL., MC²

Psychiatrists are stationed throughout the world with various military installations and function in a singular capacity, frequently without ancillary personnel. Isolation also comes to exist because the previous training and orientation of the psychiatrist before entering military service are directed toward the idea that his primary responsibility is to the patient. Upon entering military service, the responsibility becomes two-fold,

toward the patient, as well as toward the military mission.

The role of the psychiatrist may be divided into the following categories :

1. *Diagnosis and Treatment.* Since the population from whom patients are drawn consists of young adults whose prognosis is generally favorable, an attempt is made to use methods of psychiatric treatment which may be termed "short-term psychotherapy." In this way it is frequently possible to return military personnel who have suffered even psychotic reactions to active duty.

Military commanders are encouraged to discuss their problems, particularly as they relate to a given individual case. Frequently they are able to formulate environmental

¹ Presented at the Milwaukee Divisional Scientific Meeting of the American Psychiatric Association, Nov. 16, 1961.

The opinions expressed in this paper are those of the authors and do not represent the official views of the Department of the U. S. Air Force.

² Respectively, Chief of Psychiatric Service, Hospital Commander, Westover AFB, Mass.

changes which serve to alleviate maladjustment in some of their personnel. Most commanders have expressed their pleasure in being consulted. In return they frequently invite the psychiatrist to visit their installation so that he may become better acquainted with existing facilities and working conditions.

Treatment of individuals tends to be centered in the outpatient clinic except for the psychotic patients who are hospitalized. Use of psychotropic drugs is encouraged. These medications are used to control heightened anxiety, agitation, and severe forms of depression. Since the psychiatrist's time is limited, referral is also made to community agencies with mental health clinics, particularly for civilian dependents.

2. *Medical-Legal Consultant.* The military psychiatrist serves in a medical-legal capacity with regard to discharge actions brought against military individuals to determine their competency. These individuals have failed to perform satisfactorily in their work and are being discharged for their failure to adapt to military life. Consultations are also performed of individuals alleged to have performed criminal acts. Typical examples of the latter are the psychiatric evaluation of an individual charged with molesting a child or an individual charged with threatening to use a lethal weapon.

3. *Education.* This includes guiding others who deal with patients and providing information on the effective use of psychotherapeutic drugs. To assist physicians in making use of psychotropic drugs, the psychiatrist published a paper for local use which served as a guide to the use of these drugs(1). By utilizing the talents of other physicians who have an interest in psychotherapy and guiding them, it is possible to augment the existing psychiatric facility several fold. This is similar to the method of

supervision described by Balint(2).

4. *Military Security.* Because of the nature of the military facility, it is possible that an individual who is employed in certain classified areas may be suspected of possessing an emotional disturbance which might make him a poor security risk. If an individual appears to be emotionally disturbed his behavior will be immediately apparent to his co-workers and supervisor. It then devolves upon the psychiatric consultant to determine the nature of this disturbance and whether or not medical reasons exist for further security officer action.

Reevaluations are required since there is no fully adequate system for screening of individuals despite many attempts to do so. Instead, as in civilian practice, the psychiatrist employs his evaluation of the everyday functioning of the individual as a guide to the emotional stability of the patient.

5. *Community Liaison.* Since the establishment of the psychiatric clinic, community liaison has markedly increased. As a result, the psychiatrist is able to help supervise social service agencies in the care of patients whom he has referred following diagnostic consultation.

In conclusion it would appear that while a psychiatrist employed in an isolated area, such as a military setting, frequently must make use of his talents to devise an effective means of performing his work, it is possible within such a setting to derive the personal gratification so necessary in professional life. In such a manner, the psychiatrist plays a role in national defense.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinion of the Journal.)

THE EFFECT OF MP-809 IN DEPRESSIVE STATES : A MULTI-BLIND STUDY

H. AZIMA, M.D., DOROTHY ARTHURS, R.N., A. SILVER, M.D., AND
FERN J. AZIMA, M.A.¹

The search for identification of antidepressant substances other than monoamine-oxidase inhibitors and imipramine derivatives continues. The present note is to report on such a substance: MP-809,² a tryptamine derivative with the chemical formula: 4-Methyl- α -methyl tryptamine. In laboratory studies it has shown anti-reserpine activity, synergism with some central excitatory agents, seizure inhibiting effect and a very weak inhibiting influence on MAO(1).

The setting for this study is called "multi-blind" and has been described elsewhere (2, 3) and in the main consists of 1) a pharmacotherapeutically blind unit where many drugs and placebos are studied simultaneously (all blind), and 2) multiple observer assessment of change through a simple rating scale. Three groups of patients were compared: drug, potent (phenobarbital) and inert placebo groups, each consisting of 31 neurotic and 19 psychotic depressions (5 manic-depressives and 14 schizoaffectives in drug group; 12 manic-depressives and 7 schizoaffectives in both placebo groups). In the schizoaffective patients the main target symptoms were depression and apathy. Vital statistics of the 3 groups were relatively similar. MP-809 was administered with dosage regime of "gradual increase" with an average daily dose of 60 mgm. (maximum 100, minimum 20) for an average period of 21 days. Potent placebo was given with an average daily dose of 30 mgm. of phenobarbital, and both placebos for an average of 21 days.

Results. In MP-809 group, 26 patients

(52%) showed moderate to marked improvement. Slight improvement cases were not considered. Divided into sub-categories, 23 of 31 neurotic depressions (74.1%), 2 of 5 psychotic depressions, and 1 of 14 schizoaffective patients showed significant improvement. The drug seemed to have little effect in schizophrenic apathy and retardation.

In the potent placebo group, 15 patients (30%) showed moderate to marked improvement (10 neurotic depressions, 4 psychotic depressions and 1 schizoaffective).

In the inert placebo group, 11 patients (22%) showed moderate to marked improvement (7 neurotic and 4 psychotic depressions).

Statistical analysis of data using χ^2 method showed that when all patients were considered, comparison of the drug with inert placebo was significant at $0.01 > P > 0.001$ level, and with potent placebo at the level of $0.05 > P > 0.02$. In the subgroup of neurotic depressions, the comparison of the effect of MP-809 with both placebos was highly significant at the level of $P < 0.001$ ($\chi^2 = 11.16$ for potent, and $\chi^2 = 16.5$ for inert placebo).

Side effects were mild and consisted of fine hand tremors in 10 patients, drowsiness in 8, weakness in 6, dizziness in 5, fatigue in 4, nausea and vomiting in 5, generalized pruritis in 2, diarrhea in 2 and ankle edema in one. In potent placebo group drowsiness and signs of barbiturate intake appeared with doses beyond 50 mgm. daily.

Laboratory data (alkaline phosphatase, W.B.C. and differential, transaminase and urinalysis once a week) showed appearance of bile pigments in urine in 3 patients which disappeared while on the drug, and a tend-

¹ McGill University, Dept. of Psychiatry, Allan Memorial Institute, Psychopharmacology Section.

² Manufactured by Sandoz Pharmaceuticals.

ency towards neutropenia in one patient not requiring discontinuation of the drug.

SUMMARY AND CONCLUSION

1. A new substance, MP-809, a tryptamine derivative, was investigated in 50 depressed patients, as compared to two other groups of 50 depressed patients receiving inert and potent placebo, in a multi-blind controlled setting.

2. Clinically MP-809 had a significant (marked to moderate) antidepressant activity in 52% of all patients and in 74.1% of neurotic depressions. Statistically the results were significantly in favour of MP-809 as

compared with the two placebos, and this significance reached the high level of $P < 0.001$ in neurotic depressions.

3. Side effects were frequent but minimal in their intensity.

4. The final conclusion was that MP-809 is a potent antidepressant agent particularly in neurotic depressive states.

PLASMA IMIPRAMINE LEVEL IN SYNDROMES OF DEPRESSION¹

GEORGE G. HAYDU, M.D., ANDREAS DHRYMOTIS, M.D.,² AND
GERTRUDE P. QUINN, Ph.D.³

Imipramine, N-(γ -dimethyl aminopropyl)-iminodibenzyl, can substantially improve psychotic depressive syndromes (1, 2). Still, 25% of cases show no improvement (4). We thought that absorption or rate-metabolism of imipramine might be factors in such instances. Accordingly, plasma imipramine levels were determined following a single oral dose. During therapy this procedure was repeated. Excretion studies were also performed.

Materials and Methods. Hospitalized patients were selected with psychotic depressive syndromes regardless of diagnostic criteria. Before therapy 100 mg. of imipramine was given orally and blood plasma imipramine content determined 2, 4, and 7 hours later. Subsequent imipramine therapy consisted of 50 mg. t.i.d. After 4 weeks, plasma imipramine levels were determined again in the same manner. Twenty-four hours' urine and feces excretion of imipramine were also determined.

Imipramine determination was done through the fluorescence of the drug and its

extractability into heptane(3). The concentration was measured in spectrofluorometer using wavelengths of 290 millimicrons for activation and 400 millimicrons for fluorescence. The unknown samples were run concurrently with reagent blanks and with plasma plus known amounts of imipramine. The method measures also N-(γ -monomethyl aminopropyl)-iminodibenzyl, N-(γ -aminopropyl)-iminodibenzyl, N-(γ -dimethyl aminopropyl)-2-hydroxy-iminodibenzyl(6, 7).

Results. Two groups were formed. Group A constituted 4 patients who responded well to subsequent imipramine therapy. Group B constituted 4 patients who proved refractory. The plasma determinations 7 hours after the single oral dose differed in the two groups significantly at the 5% level. Responders had 6.00 μ g. mean with 2.24 SD, while the refractory group had 13.00 mean with 2.39 SD. This difference continued during therapy. Similar difference was obtained after a single intramuscular 50 mg. dose. The responders showed consistently lower plasma levels than the refractory group. Twenty-four hours' urine and feces excretion showed a similar trend, e.g., a responding type excreted 20 μ g. in the urine and 180 μ g. in the feces. A refractory type excreted 35 and 230 μ g. re-

¹ In cooperation with the staff of Creedmoor State Hospital, H. A. LaBurt, M.D., Director, and J. R. Whittier, M.D., Director of the Institute.

³ Geigy Research Laboratories, Yonkers, N. Y.

spectively.

Discussion. The finding that patients responding to imipramine therapy have lower plasma levels of the drug than refractory patients is interesting. A differential drug distribution and binding is a possible reason. It was shown in a case of suicide with imipramine(7) that drug concentration in the CNS was 50 times larger than in blood plasma. The different parts of the brain varied. The cerebellum contained 3 mg.%, the basal ganglia 13.1 mg.%. It is conceivable that the organ affinity of imipramine may vary according to the functional state of the CNS as modified by a particular psychopathology. Depression follows a variety of psychopathology and even after the lifting of depression the original psychopathology remains(4, 5). In this study the refractory patients showed schizoid pathology, while the responding cases a melancholic type. At any rate, the results show that insufficient absorption could not be the cause of refractoriness. Further clarification is attempted on larger groups.

SUMMARY

Imipramine plasma level was determined after a single oral dose. Patients who responded to subsequent imipramine therapy showed low plasma levels, refractory cases showed high levels. The low plasma levels of responders continued during therapy. Their imipramine stool and urine excretions were also low. A differential binding of the drug according to psychopathology was discussed.

CHLORDIAZEPOXIDE AS ADJUNCTIVE THERAPY IN CONVULSIVE DISORDERS¹

SIDNEY MERLIS, M.D., WILLIAM J. TURNER, M.D., AND SEYMOUR HALPERN, Ph.D.²

In the first symposium on the actions of chlordiazepoxide (Librium®) Rosenstein (1) described its anticonvulsive properties. Since then we have studied 86 epileptics for periods up to 16 months, using chlordiazepoxide alone or in combination with standard anticonvulsive medication. Twenty-six of our patients were severely ill mentally and were hospitalized at Central Islip State Hospital. Fifty-nine subjects were outpatients and were not classified as suffering from mental illness. Our patients included 43 females and 43 males ranging in age from 5 to 66 years.

Chlordiazepoxide was given orally in doses from 10 to 60 mgm. daily. In a small group of patients with mild or infrequent seizures, the compound was given alone after cautious withdrawal of other medication. In all but 9 patients, however, it could only be used as an adjunct.

Results. The effects of medication were evaluated both from an EEG and clinical standpoint. Serial EEGs were done in 30 of 60 patients. No specific predictable correlation could be shown between the normalization in the EEG record and clinical improvement.

Clinically, control of seizures was arbitrarily considered good if there were fewer than one attack per month; fair if no more than 2-4 per month; poor if they were more frequent than 5 per month. The total breakdown of clinical results is presented in

¹Supplies of chlordiazepoxide were obtained through the courtesy of Hoffmann-La Roche, Nutley, N. J.

²From the clinical and laboratory facilities, Research Division, Central Islip State Hospital, Central Islip, N. Y.

Table 1. It can be seen that the number of

TABLE 1

DIAGNOSIS	NO. OF PATIENTS	RESULTS BEFORE LIBRIUM			SEIZURE CONTROL WITH LIBRIUM		
		GOOD	FAIR	POOR	GOOD	FAIR	POOR
Grand mal	57	8	20	29	21	23	13
Petit mal	10	1	2	7	3	6	1
Mixed							
Grand mal & petit mal	9	0	1	8	2	4	3

Petit mal variant	2	0	1	1	1	1	0
Total	85	10	27	48	30	36	19

patients who had improved control of seizures was increased by the administration of chlordiazepoxide. Our findings, in general, are similar to those previously reported (2-5).

Side Effects. There were 43 instances of side-effects, which included: somnolence, 17 cases; ataxia and dysmetria, 7 cases; vertigo, 5 cases; irritability, 5 cases; restlessness, 2 cases; and fatigue, 2 cases. There was one episode each of headache, leucopenia, insomnia, facial flushing and jaundice (6).

CONCLUSION

Eighty-five of 86 patients starting treat-

ment were evaluated. One patient after 5 days of treatment developed clinical jaundice and was discontinued from the series. Prior to treatment 76 of 85 patients (89%) had fair or poor control of seizures. Following the use of chlordiazepoxide 56 of 85 patients (66%) had fair or poor control. The dosage used was 10 to 60 mgm. daily. Chlordiazepoxide appears generally to be compatible with the currently available anticonvulsive agents. Undesirable side effects, such as somnolence, ataxia and vertigo, were mild and relatively insignificant except at the highest dose. In spite of this chlordiazepoxide appears to be an effective adjunctive treatment in seizure disturbances.

ANTIDEPRESSANTS AND ELECTROSHOCK

PATRICK FLYNN, M.B., AND SOLOMON HIRSCH, M.D.¹

In reading many papers in psychiatric journals over the past few years, we have been impressed by the large number of exceedingly favourable reports concerning the efficacy of antidepressant drugs. Indeed, as far as this group is concerned, we have the impression that the published reports even outdo the manufacturers' advertisements at times! Recoveries, remissions or marked improvements of the order of 80% and over are usual (1-5), and it is not uncommon to find authors suggesting that electroshock as a treatment for depression is "almost superfluous" and should be con-

sidered obsolete (6). In our experience, favourable results with antidepressants given in the recommended dosages and for an adequate length of time (as suggested by the manufacturers) did not approach the percentages mentioned. On checking with about a dozen of our colleagues to learn their experiences we found impressions similar to our own—roughly half of the patients with depression who formerly would have had EST responded to the drugs: the other 50% did not respond in spite of adequate trial and often after a change in antidepressant medication. Practically all the patients who failed to respond to the drugs later had a successful outcome with EST.

¹ Respectively, Resident in Psychiatry, Assoc. Professor, Dept. of Psychiatry, Dalhousie University, Halifax, N. S., Canada.

We questioned then why our results contrast markedly with those reported in the journals, and in view of the obvious therapeutic response with EST, why it should be condemned out of existence. To be sure it may be criticized on its "alien" nature as one author describes it⁽⁷⁾ but harmful sequelae of EST are minimal in contrast with those of the antidepressants as a group. It is worth noting that 3 such antidepressants, Marsilid, Catron and Monase, which at times were hailed as giving "astonishing results" have been taken off the market because of toxicity. We suggest that the following factors may have contaminated the results as reported in the journals:

1. Many depressions are self limiting or episodic and may remit without any therapy. It is reasonable to suppose, then, that treatments which take more than a few weeks to produce their maximum effects will get many undeserved therapeutic credits.

2. Other factors besides drugs may influence the depression. Again if the patient is on a drug, it will get the credit rather than these other factors⁽⁸⁾.

3. We suspect that investigators who get good results with drugs tend to report the drug trials; those who get poor results do not usually bother to report them in the journals.

4. The type of rating scale used: In many studies, as has been noted by Smith⁽⁹⁾, patients who improve are graded as showing marked improvement, moderate improvement, mild improvement, and questionable improvement or no change. On such a scale the odds favour improvement.

5. Adequate follow-up studies have not been provided. The results within the first month or two may well have been "excellent" only to revert to "fair" a month or two later.

We do not dispute the fact that the anti-

depressant drugs play an important role in the therapeutic armamentarium of a psychiatrist, but we do question the large percentage of excellent results reported and the suggested obsolescence of EST. Many of our cases would have had a quicker recovery with EST, while for some patients it was the only therapy that was followed by a remission. We would like to emphasize that it takes from 6 to 10 weeks to complete a trial of two antidepressants allowing for excretion of a MAO inhibitor, should that have been used at first. We seriously question "the safety" of antidepressant medication which is often contrasted with "the dangers" of EST. From experience with our patients, half a dozen seizures suitably controlled appear to us to have relatively mild and transient side effects. Although it is understandable but most unfortunate, it appears that the literature tends to be biased by the fact that those who get good results from one given therapy tend to report the fact much more readily than those who do not. The writers hope that this note encourages further expressions of opinion on the efficacy of antidepressant drugs as compared to EST.

EXPERIENCE WITH CHEMOTHERAPY IN REFRACTORY PSYCHIATRIC DISORDERS

FRANK P. PIGNATARO, M.D.¹

Development of the new psychotropic

¹ Psychiatric Consultant, Monmouth Medical Center, Long Branch, N. J.

drugs has made it possible to treat on an outpatient basis, a considerable percentage of psychotic patients who, a few years ago,

would have been hospitalized. The author has previously reported his experience in treating private office patients with the monoamine oxidase inhibitor isocarboxazid (Marplan) and with the first of the benzodiazepine group of compounds, chlorthalidoxepine (Librium). An analog of the latter drug, diazepam (Valium), has recently been administered to a selected series of 67 private patients, 60 of whom had previously been treated over a considerable period with the parent compound, so that in effect they could act as their own controls in an evaluation of the new agent.

The diagnostic categories included 16 schizophrenics of various types, 9 other patients with psychotic symptoms, and 42 with psychoneurotic reactions of anxiety-tension, depression and panic, and personality and involuntional disorders. Almost every patient in the series suffered from a long-standing, severe and refractory emotional disturbance which had failed to respond to a succession of the indicated therapies. Several had been hospitalized for ECT or ICT.

Initial dosage of diazepam was usually 10 mg. two or three times a day, with maintenance intake 5 to 10 mg. daily. In 14 patients with severe depression isocarboxa-

zid was used adjunctively with diazepam, both drugs administered in the lowest effective amounts (the usual dose was 5 or 10 mg. of each drug per diem). Duration of therapy ran up to 11 months. A battery of laboratory tests was done in 32 patients, who were also given frequent physical examinations.

Good or excellent response was noted in 70% of the series, and symptoms were relieved over the whole range of diagnoses (Table 1). In the depressed patients combined therapy relieved all 14 patients, with good to excellent results in 12. Patients with comparable depression states on diazepam alone showed good or excellent results in only 7 of the 13.

Side effects were drowsiness in 5 patients, slight transient ataxia in 2, skin rash in 1, and stiffness of the jaw muscles in 1. Findings of the laboratory tests were well within normal limits.

While diazepam had a strong sedating effect especially desirable in tense and anxious patients, it did not cloud the sensorium; on the contrary, several patients remarked that the drug had "cleared their minds" better than any drug they had taken. Others were able to work well in

psychotherapy for the first time, and still others overcame phobias which had kept them housebound and were able to go away on trips or to find and keep jobs, something previously impossible for them.

The analog was felt to be more potent

than the parent compound, especially in the psychotic and borderline cases. In a few instances the patient and clinician agreed that diazepam was more than they needed, and the patient was put back on chlordiazepoxide.

COMPARISON OF TEMPORAL FACTORS IN DEPRESSIVE PSYCHOSES TREATED BY EST AND ANTIDEPRESSANT DRUGS

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

This study is part of a comprehensive investigation of manic-depressive psychosis. It is concerned with a comparison of temporal factors in depressive psychoses in females during a characteristic EST period and during a period in which antidepressant drugs² had largely replaced EST as the specific therapy. The first study period consisted of 3 years, from July 1, 1952 to June 30, 1955; the second extended from March, 1959 to June 30, 1960. The course of each patient during the 2-year period which followed her admission to the hospital was recorded and tabulated.

The results are summarized in Table 1. During the first period of study, 119 patients were admitted to the hospital; during the second, 72. Prorating the second period to an equivalent 3 years reveals that the number of admissions with depressive psychoses rose approximately 37%; this did not quite match the overall rise of 46% in total admissions of female patients.

Block 2 in the table reveals that only 6% of patients received EST during the drug period—all of these during the first few months. After Aug. 1959, EST was discontinued in the treatment of depressions on the female admission service of this hospital.

The figures in blocks 3, 4 and 5 indicate that the length of hospitalization was definitely shorter in the drug than in the EST period. As noted in a previous report,³ this reduction in duration of hospitalization in recent years may also be attributable to

changing administrative and professional attitudes. However, in earlier years patients were frequently retained in the hospital until EST-induced confusion and amnesia had subsided. This problem, of course, is not encountered with the use of antidepressant drugs. In the EST period, 60% of patients had a total hospitalization of more than 3 months during the 2-year period of observation, as compared with 31% in the drug era. Protracted individual hospitalizations (longer than 6 months) totaled 24% in the EST period, as compared with 10% in the drug period. The average length of total hospitalization during the drug era was only 37% of that observed during the EST period.

Block 7, which summarizes the patients' status at the end of 2 years of follow-up, reveals that 20% of the EST group were still hospitalized, as compared with only 6% of the drug-treated group. Mortality rate was approximately the same for both groups. It is pertinent to note that one patient in the drug-treated group committed suicide.

With respect to readmissions, there appears to be a slight advantage in favor of the EST group. Concomitantly, the average number of hospitalizations during the 2-year period of observation was slightly higher in the drug group.

It may be conservatively concluded, therefore, that the duration of hospitalization in female patients with depressive psychoses has not been lengthened during the current era of antidepressant drug therapy, even after due allowance has been made for certain recent alterations in administrative and professional attitudes concerning early release of patients into the community.

TABLE 1
Statistical Comparison of EST-Treated Depressions (1952-55) and Drug-Treated Depressions (1959-60)
During a 2-Year Period Following Admission to Hospital

		EST GROUP	DRUG GROUP
1. Total no. of patients		119	72
2. Specific treatment	EST	88—74%	4—6%
	Drugs	0—0%	59—82%
	Both	0—0%	1—1%
	None	31—26%	8—11%
3. Total time in hospital during 2-year period following admission date.	0- 30 Days	7—6%	11—15%
	31- 60 "	15—13%	20—28%
	61- 90 "	25—21%	19—26%
	91-180 "	25—21%	8—11%
	181-365 "	23—19%	12—17%
	366-730 "	24—20%	2—3%
4. Average total length of hospitalization (days)		205	75
5. Number of short hospitalizations (<60 days) (percentages in terms of total no. of hospitalizations)		34—22%	67—63%
6. Number of protracted hospitalizations (percentages in terms of no. of hospitalizations)	6 months-1 year	17—11%	9—8%
	1-2 yrs.	11—7%	2—2%
	2 yrs.	9—6%	0—0%
7. Status at end of 2-year period	Home	82—69%	60—83%
	Hospital	23—20%	4—6%
	Convalescent (or domiciliary)		
	home	4—3%	1—1%
	Deceased	10—8%	7—10%
8. Multiplicity of hospitalizations	1 admission only	91—76%	50—69%
	1 readmission		
	{ within 30 days	2	6
	{ after 30 days	19	9
		—18%	—21%
	2 readmissions	5—4%	5—7%
	3 or more readmissions	2—2%	2—3%
9. Average no. of hospitalizations per patient		1.30	1.47

CASE REPORTS

THROMBOSIS OF THE INTERNAL CAROTID ARTERY

R. NATARAJAN, M.D.¹

Angiography has taught us much about the symptomatology of occlusion of the internal carotid artery; it may produce no symptoms or may be followed by variable complications. Simple occlusion may produce no sequelae if the circle of Willis functions efficiently and if adequate collateral circulation is established. If the individual is a child or young adult, ligation of the artery usually produces no untoward effect. Progressive obliteration of the lumen by atheroma often causes recurrent transitory disturbances due to localized cortical ischemia, e.g., aphasia, confusion or contralateral paresthesia or weakness. There may also be transitory amblyopia in the ipsilateral eye.

A 39-year-old, white, married farmer was admitted to Yankton State Hospital at the end of 1961 on a regular commitment for an acute psychotic breakdown.

The patient suddenly became ill 2 weeks before admission when he was unable to give instructions to some boys on how to choose cattle. His words came out in a garbled fashion and could not be understood. When the boys made fun of him he became aggressive towards his children. He was aware that his sentences were not coming out as he intended, and that he could not find the proper words to communicate his ideas. He tried to pump a glass of water, felt his right hand weak and numb and could not hold the glass. The aphasic disturbance and paresis of his right hand lasted only a few minutes. His wife stated that the patient was in a confused and dazed state, was unable to remember dates, and misidentified people. These symptoms recurred on several occasions.

Previous illness. About a year ago he observed one day, while coming down the hill after hunting, that he suddenly lost his vision in his left eye, lasting 10 to 15 minutes. In

the last year he had been experiencing difficulty in naming familiar objects and his memory, especially of names, was impaired. These difficulties seemed to come on periodically.

Neuropsychiatric Examination. On admission the patient was a little withdrawn, irritable and not able to relate to his environment and his illness adequately; a complete neurological examination revealed: exaggerated reflexes on the right side of the body; a positive Babinski on the right side; the motor and sensory systems did not reveal any other abnormality and the cranial nerves were intact. Two weeks after admission his reflexes continued to be overactive, but the Babinski sign disappeared and, also, he gradually recovered from his aphasic disturbance so that he was able to name familiar objects, which he formerly could not do; there was no residual weakness in his right hand; he was no longer confused or disoriented and appeared more or less normal physically and mentally.

Arteriogram of the left internal carotid artery a month later showed an occlusion just distal to the bifurcation of the common carotid. The patient was operated on after a few days, "incision was then made over the bifurcation into to internal carotid to expose a yellowish, tough structure which completely occluded the artery."

Treatment is not yet agreed upon. Attempts at removal or replacement with graft have usually been disappointing. Whether sympathectomy in patients with recurring temporary symptoms will prove beneficial remains to be demonstrated. Milikan, *et al.*, have recommended treatment of the syndrome of "intermittent insufficiency of the internal carotid system" with anticoagulant drugs.

LOSS OF FEELINGS OF OMNIPOTENCE AND FORENSIC PSYCHIATRY

IRWIN N. PERR, M.D., LL.B.¹

A rather unique lawsuit² involving psychiatric testimony is herein presented. The facts of the case are those reported by the appellate court; the findings of the psychiatrists and the rationale for their reasoning is unknown to the writer. However, the material presented is that which is part of the legal record, spread now in various books throughout the land to serve as reference for future generations of lawyers and writers. It reflects the fact that almost every medicolegal case incorporates the opinions of the medical experts involved and that what is said in the sanctity of the courts remains forever (if commented upon by an appeals court) to serve as a memorial to the efforts of the participants. Every doctor who serves as witness must keep this in mind.

The court, before reviewing the facts, noted, "The insurer describes the claim as bizarre. If it is not that, it is an understatement to call it anything less than unique."

What had happened was this :

The truck of the defendant had swerved onto the right shoulder of a highway in order to avoid hitting school children alighting from a bus. The truck smashed several parked cars and finally hurdled into a gasoline station leaving a trail of widespread fire and destruction. The plaintiff, from Baton Rouge, was standing nearby and was not physically injured. "He was not touched in any way by anything. What happened to him, he says, was that on seeing this holocaust and the need for someone to rush in to help rescue victims, he suddenly became overwhelmed by fear and realized for the first time in his life that he was not the omnipotent, fearless man his psyche had envisioned him to be. His post-accident awareness that this event had destroyed his self-deceptive image of himself precipitated great

emotional and psychic tensions manifesting themselves as psychosomatic headaches, pain in legs and neck, a loss of general interest, a disposition to withdraw from social and family contacts, and the like.

"As it might have appeared to the jury of lay persons, the medical theory was that the accident had made [Mr. C] see himself as he really was, not as [he] had thought himself to be. In short, the accident had destroyed the myth. No longer was he the brave, invincible man. Now, as any other, he was a mere human, with defects and limitations and a faint heart. It was, so the [defendant] argued with plausibility to the jury, the strange case of a defendant being asked to pay for having helped [the plaintiff] by bringing him back to reality—helping him, as it were, to leave Mount Olympus to rejoin the other mortals in Baton Rouge.

"To this elusive excursion into the *id* of [the plaintiff], there were added many irrefutable, earth-bound events that made it sound all the more strange. At the time of the accident, he was a TV advertising salesman. Within a short space of time, he had changed employment. He became a president of a company, in which he was apparently personally interested, at a salary over twice as high . . . He bought and sold several pieces of real estate, had made \$25,000 in one trade, and had purchased . . . a new \$40,000 home. Within 9 months . . . he had successfully undertaken a campaign to become elected a city Councilman . . . The psychiatrists, acknowledging these external facts, then reasoned that this was a part of his struggle by which to recapture his lost self-esteem, and that while these things were most assuredly being accomplished, it was being done at further damage to [the plaintiff]."

This case was tried under the theory accepted in Louisiana and other states that one may recover for emotional damages not accompanied by physical injury. (In many other states, some physical injury is required as a prerequisite to such a lawsuit.) The court stated,

¹ Fairhill Psychiatric Hospital, Cleveland, O.

² C— v. Hardware Mutual Casualty Co., 264 F. 2d 152 (5th Cir. [La.] 1959).

The medical thesis was advanced with great earnestness by two psychiatrists, both of whom were apparently well regarded in the medical community. So that for our purposes here we may assume that on a proper showing of facts, or medical facts, or accepted medical theory as fact, the law may accommodate Blackstone and Freud to allow recovery for real psychic or psychosomatic harm.

The court continued.

The real controversy raged over the question whether [Mr. C] had really suffered any damage at all. The plaintiff said he was worse off and this episode had triggered this psychic mechanism. The [defendant], just as stoutly, claimed that [Mr. C] was better, not worse off, and that it was simply absurd to say that a truck owner should be held responsible for any such far-fetched consequences. This was the issue, then, of proximate cause. Finally, there was the question of the money award to compensate for the damages if any were found. From [Mr. C's] standpoint, this ranged from \$1900 covering numerous small items of medical, psychiatric, hospital bills, and car rental to a demand for \$75,000 to \$250,000 for mental pain and anguish. To the [defendant] the amount was zero.

The jury ruled for the defendant; this was upheld by the appeals court which reported the case.

As mentioned earlier, this case can be discussed only on the basis of the reported facts, and speculation as to other elements in the absence of definite knowledge is to be avoided.

Several medicolegal issues arise for our consideration. The liability for negligence is based on several elements—1. That the defendant had a duty to exercise a certain degree of care; 2. That as a result of a negligent act, whether of omission or commission, the defendant did not exercise that care with resultant injury to one entitled to such protection, and 3. The damage complained of was a direct and probable consequence of the injurious act.

The law as to psychiatric situations is oft unclear and confusing as unfortunately is the knowledge that we possess as to the relation of events and illness. As mentioned, in many states some degree of physical

contact is required before a defendant will be held liable for an "emotional injury." Nonetheless, a relation between a trauma and damage must be shown to be "probable"; mere possibility is not enough if one concedes a relation between a cause (a shocking accident) and an effect (a psychological reaction). Even though this be granted, this case raises the issue of what constitutes damage resulting from such an "injury." In what way was the complaining party damaged? To reduce the matter to absurdity, if a person undergoes a series of traumatic events and withdraws because of personality problems to a life of solitary and unhappy research culminating in a Nobel Prize, has the unhappy Nobel prize-winner been damaged or benefited? Or is it neither? Is he entitled to use one or more of the various psychological defense mechanisms without our worrying about moral or other judgments as to goodness or badness of the result. If lack of accomplishment is evidence of sickness and if accomplishment is a reaction to underlying sickness and is evidence of such, then the logical conclusion follows that innumerable life experiences are traumatic and detrimental. Probably, from the standpoint of society and our need to make a judgment in this regard, we cannot let such a philosophy (or medical theory or legal standard) be the basis of our regulating our society. However, this situation reflects one more instance where psychiatrists are forced into the role of social arbiters, a role that Szasz in his long series of articles feels inappropriate to psychiatry, but one which frequently is inseparable from the tasks clearly the responsibility of psychiatrists. It is hoped that cases such as these will stimulate discussion so that psychiatrists will, if nothing else, be better equipped to develop a more uniform attitude as to the nature of the testimony that we present to the courts. Perhaps too, reflection and study may help psychiatrists in formulating suggestions to our legal brethren so that both the law and psychiatry will synthesize to the fullest scientific knowledge and social responsibility.

PERIPHERAL EDEMA AND TACHYCARDIA DURING TRANLYCYPROMINE THERAPY

JOHN A. SOURS, LT., MC (USNR)¹

The use of tranlycypromine (Parnate) alone, or in combination with a phenothiazine, is well established. Its side effects, now well documented, include insomnia, epigastric distress, severe headache, palpitations, diarrhea, dermatitis(4, 5), hypertension, photophobia(2), constipation, leg cramps, nausea, anorexia(1), and ankle edema(6). A patient who developed hypertension, encephalopathy, pulmonary edema and coma while on tranlycypromine has been reported (7). Vogt has found that tranlycypromine aggravates the extrapyramidal side effects of trifluoperazine (Stelazine). In the following case, edema of the ankles, right knee and wrist, along with a tachycardia, appeared 10 days after starting tranlycypromine treatment.

A 28-year-old white, single male was discharged in January, 1962, from the hospital following medical treatment for an active, but uncomplicated, duodenal ulcer. In mid-February 1962, he again developed epigastric pain. Since his discharge from the hospital, he had been anxious, apprehensive, withdrawn, depressed, and prone to tearful outbursts. He contacted the physician who had cared for him during hospitalization and requested that he be readmitted. Physical examination was essentially negative. Urinalysis and CBC were within normal limits. A repeat GI series failed to reveal any evidence of a duodenal ulcer.

On examination, the patient was a thin, pale, youthful-looking man. His affect was quite constricted and, at times, inappropriate. He appeared depressed, stating that he felt guilty and inadequate about his "failures as a man." He readily acknowledged episodic suicidal feelings. He complained of difficulties in concentration, bewilderment, and pressure of thoughts. Several times, there were instances of blocking. Auditory hallucinations involved accusations that he was "homosexual." Primary and interpretative paranoid delusions were noted. He expressed concern with his bodily appearance and was preoccupied with somatic symptoms, especially epigastric distress. Mild obsessional traits were evident.

Higher integrative functions were fully intact. Diagnosis was schizophrenic reaction, acute, and psychophysiological reaction—gastrointestinal type. The patient was started on chlorpromazine (Thorazine) 50 mg., q.i.d.

On the 4th hospital day, chlorpromazine was increased to 75 mg., q.i.d., and tranlycypromine, 10 mg., q.i.d., was added. He was more agitated and depressed, feeling that he was "going to explode inside." Auditory hallucinations, however, had ceased on the 2nd day. Epigastric pain was no longer present. He expressed a great deal of apprehension about the possibility of a medical discharge from the U. S. Navy, and was particularly concerned with the prospect of having to return to his parents, toward whom he was quite ambivalent.

The patient complained, on the 10th hospital day, of swelling in both ankles, the right knee and wrist. He mentioned that he had palpitations which had persisted throughout the day. Physical examination revealed normal vital signs, except for a pulse of 130. There was 2+ edema of both ankles, loss of the contour of the right knee, and mild edema of the right wrist. Digits of both hands were puffy. No pain, heat or erythema was elicited in any joint. There was no hepatosplenomegaly. Repeat blood count was negative. Sedimentation rate was normal. Latex fixation test was within normal limits. An electrocardiogram demonstrated a sinus tachycardia. Tranlycypromine was discontinued and, within 24 hours, the edema and the tachycardia had completely subsided.

Although peripheral edema has been described with tranlycypromine and other antidepressant drugs(3, 8, 9), and palpitations have also been noted in association with tranlycypromine(5), there are no reports of both edema and tachycardia occurring simultaneously in patients receiving this drug. Edema occurs only rarely and responds promptly to withdrawal of the drug or a decrease in dosage, as does tachycardia, which is sometimes associated with hypotension. The side effects of tranlycypromine appear to be related to dosage; doses over 30 mg., q.i.d., increase the incidence and severity of the side effects(10).

SUCCESSFUL SUICIDE WITH TRANILCYPROMINE SULFATE

G. A. BACON, M.D.¹

The patient was a 17-year-old white female previously seen by the writer and diagnosed as a neurotic depressive reaction. Treatment with tranilcypromine was recommended to the referring physician who prescribed this drug. The prescription called for 50 10 mg. tablets. Upon returning home from the doctor's office the patient immediately ingested all 50 tablets, but the effect was not noticed by the parents until some two hours later. At this time the patient was agitated, talking incoherently and appeared to be markedly tremulous. She was brought to the emergency room for treatment of her agitation. The referring physician, at this time unaware of the number of tablets ingested, prescribed for the agitation 1 grain of sodium luminal IM and 2 grains of sodium seconal IM over a period of 4 hours. The patient gradually became less agitated, but lapsed into coma. At this time the writer was again called into consultation and the patient was seen to be critically ill. She was comatose, sweating profusely, with a pulse of 120 per minute, a pulse deficit of 2 to 3 to 1, a blood pressure of 40/0, and with marked fine tremors over her entire body. She was

transferred to the intensive care unit and was given intranasal oxygen and levarterenol bitartrate (Levophed) ampules 3 in 5% glucose in the course of 3 hours. She also received 2 units of plasma. A hydrotherapy apparatus was utilized in an attempt to lower the patient's temperature which had risen to 110° F. Her tremors subsided and the temperature dropped from 110° to 107°; her blood pressure remained between 70 and 40/0 but she did not regain consciousness. Gastric lavage was unproductive, but it is to be noted that because of technical error, it was not performed until some 5 hours after the ingestion of the drug. Death occurred approximately 8 hours after ingestion of the 50 tablets.

It is noteworthy that death, which was most probably caused by the hyperthermia and circulatory collapse, was merely an exaggeration of the side effects that are seen with this drug in standard and intensive treatment dosages. There is no specific antidote for overdosage with this drug, and treatment consists of 1) gastric lavage, 2) support to the failing circulation, and 3) treatment of the hyperthermia. In this case, moreover, treatment was to no avail.

COMMENTS

A "THAW" IN SOVIET PSYCHIATRY ? ¹

The death of Stalin in 1953 marked the end of a period in the Soviet Union that not only witnessed a succession of wars, but could be characterized itself as a protracted state of war against the many enemies of the new order. Centralized leadership, arbitrary rule, strict censorship, and suspension of many of the legal and civil rights to which we are accustomed marked this period. The present Soviet leadership accuses Stalin of terrible excesses and blunders. The Stalin period was also a time of restricted contact with the outside world. The present Khrushchev era coincides with the consolidation of Soviet power, a marked improvement in living standards and a corresponding relaxation of many of the restraints of the earlier period. During Stalin's time Soviet psychiatry, even more than other branches of science, preserved its ideological and national isolation, assailed the reactionary character of western psychiatry, and developed its own traditional Russian and Marxist methods and point of view, within a rather strict hierarchical administrative structure. An oversimplified philosophic materialism led to an almost total eclipse of psychology and psychotherapy as separate interests or sciences, associated with a very heavy concentration on classical Pavlovian approaches and a relative neglect or underestimation of other physiological, chemical, endocrinological, epidemiological, genetic, *etc.*, research in psychiatry.

Things are changing now, and Academician Parin's sweeping attack on past and present abuses should be read (Curr. Dig. Sov. Press, 14 : 22, 1962). I cite a few other examples :

In May 1962 an All-Union Conference on the Philosophical Problems of the Physiology of the Higher Nervous Activity and of Psychology was held in Moscow with the participation of leading representatives of all the interested disciplines. Professor

Bassin, the Moscow psychiatrist, in his report of this meeting (*Meditsinskii Rabotnik*, June 12, 1962), says that the conference endorsed the general aim of the Pavlovian conference called 12 years before, in 1950, but adds that the influence of this earlier conference in subsequent years was

adversely affected by the general conditions created by the cult of Stalin's personality. This bred dogmatism in the social and natural sciences, an uncritical attitude toward scientific authorities, and the resort to meaningless quotations as a substitute for independent research. Instead of solving scientific problems in an atmosphere of free discussion among competent specialists, the declaration of theoretical postulates became more or less the rule.

Among the consequences, said Bassin, was the neglect of psychology and the overemphasis of biology ; studies in higher physiological activity developed with too little contact with other approaches, and were especially remiss in neglecting cybernetics. In spite of the appeals of a few participants at the earlier conference the newer developments in psychopharmacology were not adequately pursued. It is not enough to criticize the Freudians, said Bassin, it is also important to cultivate Soviet research on unconscious forms of higher nervous activity. In spite of the productivity of Soviet Pavlovian work, he said,

The theory of the higher nervous activity should not be considered as the only possible method for the study of the functions of the higher regions of the nervous system. Other approaches to the problem must also be used.

Both method and theory should not only be developed through a variety of disciplines, but also "on the basis of diversified positions and from the point of view of diverse trends . . ." The conference also protested against a certain tendency to cling to scientific formulations that were new half a cen-

¹ Supported by NIMH Grant MY-2679.

tury ago but were now outmoded. A significant debate ensued, with distinguished names on both sides, on the desirability of revising some of Pavlov's original ideas on excitation, reinforcement, stereotypy, *etc.*, in the light of the newer physiology. The conference stressed the need for further theoretical discussion and emphasized the importance of the creation of multidisciplinary teams to work together on specific problems.

Soon after the conference a small multidiscipline committee including the psychiatrist Professor Fedotov met in the offices of *Meditsinskii Rabotnik*, the medical newspaper, to formulate more specific organizational proposals. This committee also stressed the need for the biological sciences to lean more heavily on the exact sciences of physics, chemistry, electronics and cybernetics. Professor Fedotov said Soviet scientists should publish more of their work in foreign journals. In again calling for more theoretical discussion in medicine, the committee noted that name-calling and labelling in the past had unfortunately discouraged theoretical discussion, and that this must now be avoided at all costs. According to the published account of this meeting² one of the members, Dr. B. Ia. Smulevich,

thought that the attitude toward foreign scientists was incorrect. They were being portrayed either as reactionaries or as vulgarizers of science. They are however often honest scientists who are seeking correct answers. Since it would be difficult for them to suddenly think along materialist lines, a friendly tactful attitude should be taken toward them, and their work should be analyzed and criticized with conscientious accuracy.

Dr. Smulevich also called for more attention to the social problems in medicine. The Soviet Academy of Sciences is accordingly planning a series of symposia on social hygiene, on the methodology of genetics, and on Pavlovianism and clinical medicine.

Unlike our American psychiatric literature, Soviet psychiatric journals have rarely given any attention to problems of psychology or personality. This lack is now

beginning to be remedied. Not long ago in Moscow a joint meeting of internists and psychiatrists was held on the subject of the psychology of patients. A recent little article by the Moscow psychiatrist and psychotherapist Professor M. S. Lebedinskii³ can be condensed as follows:

The patients' psychology must be understood by all physicians. Not only must the psychiatrist be a psychologist but the same is true of other medical specialists. As a matter of fact the cooperation of the physician and psychologist needs less emphasis in the case of the psychiatrist than in the case of other physicians. Soviet medicine has tended to neglect human psychology, but this fault must be remedied if we are to preserve the human dimensions in our medical practice.

In spite of the important fact that emotions can play an important role in very many diseases, our physicians too often either neglect or oversimplify this aspect of disease. All too often a medical procedure and even drastic surgical intervention has been prescribed for conditions that were basically neurotic. Moreover we have often induced iatrogenic illnesses because of our inept psychological understanding of a case. Even our recommendations for treatment must be adapted to the special sensitivities and susceptibilities of our patients. The whole hospital atmosphere should reflect a consideration of the psychological aspects of medical treatment. Courses in medical psychology should be required at our medical schools. Our medical journals and scientific societies should reflect much more interest in psychology. Medicine and psychology must be brought more closely together.

It cannot be said that Soviet psychiatry in recent years has changed its direction or abandoned any of its principle positions. Its tone however has become less dogmatic; it is more conscious of its ties to foreign science, more willing to give and take, and is beginning to show greater variety within itself. More specifically the recent period is characterized by a greater interest in psychology, personality and psychotherapy, by a belated but lively interest in psychopharmacology, and by an increasing interest in biochemistry. The supporting discipline of neurophysiology is very much interested in all aspects of modern technology and seems to be fascinated by cybernetics. Most important from our point of view is the

² Med. Rab., May 25, 1962.

³ Med. Rab., June 19, 1962.

eager interest of Soviet psychiatrists in reciprocal communication, interchange of personnel, and even in joint research. This should not be regarded as a mere tactic in the cold war: it reflects the serious conviction of Soviet scientists that they now must find their place in the international community of science.

Some of the old attitudes still persist.

There are also evidences of distrust and caution, and the slow and imposing machinery of government can produce functional blocks. Not all of the difficulties are on one side—but in spite of all this there is reason to believe that a thaw is here.

CORRESPONDENCE

PITFALLS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : I have read with interest the article "Pitfalls in Psychiatric Research" by Doctors Bigelow and Sainz. The authors cite Sauerbruch, the well known thoracic surgeon, as an example for the tendency of stating conclusions not supported by the findings or the presentation.

In 1930 I attended Sauerbruch's surgical clinics. I recall his examining four medical students in a crowded auditorium asking them to decide by inspection which of a child's hands was the sick one. The evidence was clear ; one hand was clean, the other hand was dirty. When the students failed to give the "right" answer, Sauerbruch became very angry and told them

authoritatively that the clean hand was the sore one because the child while playing had naturally not used the hand that hurt her. While everybody admired his sagacity, one of the students accidentally touched the dirty hand, and the child let out a yell. It was then revealed that this hand was so painful that it had never been washed. The professor fled from the auditorium, and for the next three or four days let the first assistant take over the clinic.

This experience apparently made no impression on Sauerbruch, as shown by his performance in 1945.

Spring Grove State Hospital,
Baltimore 28, Md.

FOLLOW UP OF THIORIDAZINE ADMINISTRATION

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : The report of Dr. Stanley L. Block entitled "Jaundice Follow Up of Thioridazine Administration" (*Am. J. Psychiat.*, 119: 77, 1962) points up transient minimal serum bilirubin elevation (1.20 mg. %) and serum transaminase activity increase, the amount of which is not stated. In view of the author's statement "There was no clinical jaundice . . .," it would appear that the title of the report is inaccurate, in as much as the report does not describe jaundice following thioridazine administration. Although serum transaminase (*Am. J. Med.*, 27: 911, 1959) elevations are associated with hepatotoxicity resulting from chemotherapeutic agents, it is, nevertheless, important to stress that not all serum transaminase elevations necessarily reflect hepatotoxicity. There is increasing evidence to indicate that, concomitant with the adminis-

tration of chemotherapeutic agents, minimal elevations in serum transaminase may reflect alterations in cellular permeability of liver cells and/or metabolic handling of the drug by the liver. In several instances, continued administration of a drug associated with transient minimal serum transaminase has resulted in the return of the serum enzyme activity to normal with no further laboratory aberrations and no manifestations of hepatotoxicity. It is important that a drug not be indicted as hepatotoxic barely on the basis of minimal changes in serum transaminase activity and minimal transient elevations in serum bilirubin, especially when the clinical aspects and tests of liver disease remain normal.

Felix Wroblewski, M.D.,
Memorial Hospital for Cancer
and Allied Diseases,
New York, N. Y.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : I wish to express my thanks to Dr. Felix Wroblewski and the others for their interest in my article, "Jaundice Following Thioridazine Administration" (Am. J. Psychiat., 119 : 77, 1962). I will attempt to answer the questions asked and must take issue with some of the points raised in the letters.

1. The title of my article is not, in my opinion, misleading. Jaundice may be clinical or subclinical. I chose to use the generic term "jaundice" in the title. I was quite careful to indicate its subclinical nature in the body of the Case Report.

2. I am aware that transient changes in serum bilirubin and/or transaminase may occur without clinical significance. The patient, serving as her own control, had shown a remarkable consistency in both serum bilirubin and transaminase until the sudden increase in both values some 9 months after the initiation of treatment. A laboratory test merely serves as a guide for a clinical judgement; it seemed valid to make a clinical judgement of early hepatotoxicity. The return to her previous normal after discontinuing thioridazine therapy would be a further confirmation of the correctness of the judgement.

3. Nicotinic acid cannot be implicated as a cause of the bilirubin and transaminase

elevation since it was given uninterruptedly, and the levels returned to normal.

4. Metastatic carcinoma cannot be implicated as a cause of the bilirubin and transaminase elevation since the patient is still living, quite well physically without any current evidence of metastatic disease or abnormal liver function tests.

5. I am aware of Dr. H. Brunold's reservations about the jaundice case cited in his report. My citing this case was for completeness in the literature survey that was made in my opening paragraph.

I agree that thioridazine is a valuable psychopharmacological preparation. I agree that it has proved its worth as an effective and relatively safe phenothiazine. I have used this drug extensively in the past and continue to do so. My purpose in reporting was not to "indict." Rather my purpose was to alert my colleagues to the *possibility* of hepatotoxicity from thioridazine administration, and to "suggest the wisdom of periodic liver tests" as a precaution, conservative as the precaution may appear to some.

Stanley L. Block, M.D.,
Cincinnati, O.

Editor's Note :—Several letters were received making similar comments on Dr. Block's Case Report. The one first received is printed above. Dr. Block's reply refers to them all.

MODEL PSYCHOSES AND SCHIZOPHRENIA

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : The paper by Luby, *et al.*, on "Model Psychoses and Schizophrenia" in your July 1962 issue may well prove to be one of the most significant contributions in its field. It suggests "the hypothesis of a disturbance in proprioceptive feedback mechanism in both the sernyl state and in chronic schizophrenia." May I as one who has done some work in this field be allowed the following brief remarks :

Hernandez-Peon, *et al.*, published in Acta Neurol. Latino-Am., 3 : No. 1, 1957, a

study on cats where electrodes were implanted in the visual and auditory areas of the brain and also in various subcortical locations. They were able to show that the responses to a flashing light recorded from the occipital cortex were almost abolished when the animal was given fish to smell. At the same time as this reduction was found in the cortical responses these authors state that the afferent leads in the optic tract and at higher levels in the optic pathway were reduced as well. The reduction in cortical activity is therefore apparently, in part at least, due to a reduction of afferent inflow.

Dawson (Proc. Roy. Soc. Med. Suppl., 531, 1958) now suggests that it thus seems that while the actual initiation of a switch in attention may occur at a high level, the process of reducing the inflow in one modality or in some part of that modality and of increasing the inflow through another modality is perhaps carried out at almost the lowest level in the afferent pathway.

Would it not appear that this work gives us a new working concept of the mechanism in a number of experimental and clinical states of psychological abnormality such as sensory deprivation, model psychosis, schizophrenia, conversion hysteria and hypnosis, all of which are conditions with an abnormal input at one level or another? In the two last mentioned conditions this abnormal input is localized while in the others

it is diffuse. Would not such a hypothesis be consistent with most of our clinical and research experience today, including the fact that some cases of schizophrenia appear easily understandable in psychodynamic terms while in many other cases this is not so, and an organic constitutional element must be assumed? Such a hypothesis also meets the requirement of being susceptible to experimental verification or falsification and indeed it is to be hoped that further neurophysiologic research with animals given LSD-25 or Sernyl and with schizophrenic patients undergoing brain surgery may cast further light on this problem.

S. E. Jensen, M.D.,
Newmarket, Ontario.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR: I am gratified by Dr. Jensen's response to our paper on "Model Psychoses and Schizophrenia." His comments on the relationship between psychopathology and the control and switching of sensory input and attention are most pertinent. The weird and terrifying body image disturbances of the schizophrenic patient may well have

their basis in defective screening of afferent inflow particularly from proprioceptors.

Our research is continuing in the direction of testing this hypothesis which, as Dr. Jensen indicates, opens many avenues of exploration.

Elliot D. Luby, M.D.,
Lafayette Clinic,
Detroit, Mich.

NEWS AND NOTES

BIOLOGICAL TREATMENT OF MENTAL ILLNESS.—A unique assemblage to consider the present status and prospects of therapy in psychiatry was the International Conference sponsored by the Manfred Sakel Foundation and held at the Academy of Medicine in New York City, Oct. 31-Nov. 3, 1962.

During these four days leading psychiatrists from twenty-one nations met to report the results of current studies and leads for the future fuller understanding of the physiology of the mind in health and disease. It was a momentous meeting.

The fine organization of the International Conference was facilitated by the worldwide personal connections of the chairman, Dr. Max Rinkel of Boston, who is Medical Director of the Manfred Sakel Foundation.

Mrs. Louis S. Gimbal, Jr., Chairman of the Board of Directors of the Foundation, graciously attended and assisted throughout the Conference, the "heart and soul" of the Foundation, as Dr. Rinkel so appropriately noted in his opening address.

Guest speakers at the banquet in the Starlight Room of the Hotel Waldorf-Astoria at the close of the Conference were Harlan Cleveland, Assistant Secretary of State, William H. Lawrence, Science Editor of *The New York Times*, and Linus Pauling, Nobel Laureate, who carried forward the conference theme of more precise definition of psychiatric therapy through expanding study of the biochemical, molecular and genetic basis of human behaviour.

A report of the salient features of the Conference will follow in the January issue of this *Journal*.

INTERNATIONAL ASSOCIATION OF INDIVIDUAL PSYCHOLOGY.—A directory of the International Association has just been received containing the history of the Association, the constitution, a list of the member societies in Austria, France, Great Britain, Holland, Israel, Switzerland and the USA, committees of the International Association and periodicals.

Dr. Alexandra Adler is president, and Dr. Victor Louis, Zurich, secretary general of

the International Association.

The next international congress will be held in Paris, Aug. 30-Sept. 2, 1963.

MENTAL HYGIENE WEEK IN ATHENS, MAY, 1962.—Marie Nyswander, M.D., of N. Y. C. who attended reports: It was truly an interdisciplinary program with equal participation by professors of public health, medicine, surgery, and psychiatry. In several of the meetings patients participated individually and in groups. This was made possible by the holding of several meetings in the mental hospital, Dromokaiteion, which is located just outside of Athens.

For the event a small booklet was issued with translations from the ancient Greek relative to public and mental health. This was prepared by Professors George Belios and P. Alivisatos. Central to all the meetings was Dr. George Lyketsos, medical director of Dromokaiteion Hospital, who functioned with characteristic Greek graciousness as host, lecturer and translator.

A. E. BENNETT AWARD.—The Society of Biological Psychiatry offers an annual award which was made possible by the A. E. Bennett Neuropsychiatric Research Foundation. The award will consist of \$500 part of which is to be used for traveling expenses to the meeting. It will preferably be given to a young investigator and not necessarily a member of the Society of Biological Psychiatry, for work accomplished recently and not published. The paper will be read as part of the program of the annual meeting of the Society and will be published with the other papers read at that meeting in the book: *Biological Psychiatry*, Volume VI. The honorarium will be awarded at the annual banquet. Please submit paper in quadruplicate to Harold E. Himwich, M.D., Chairman, Committee of Award, Galesburg State Research Hospital, Galesburg, Ill. Deadline for manuscripts is March 31, 1963.

ANNALES MOREAU DE TOURS.—The Society Moreau de Tours is the French Academy

which concerns itself with psychopharmacology.

An excellent compilation of the work of the past few years has just been published under the above title. This is edited by Drs. Baruk and Launay. Dr. Nathan S. Kline has called our attention to this book which American psychiatrists will wish to know about.

COLLEGIUM INTERNATIONALE NEURO-PSYCHOPHARMACOLOGICUM.—At the Third International Congress of the Collegium held in Munich, Germany from Sept. 2-5, 1962, Dr. F. A. Freyhan, Washington, D. C., was re-elected as secretary for the period 1962-1964.

The 1964 International Congress will be held in Birmingham, England, date to be announced.

Please direct any questions to Dr. F. A. Freyhan, c/o Saint Elizabeths Hospital, Washington, D. C.

INTERNATIONAL SYMPOSIUM.—An International Symposium will be held at the Galesburg State Research Hospital, Galesburg, Ill., March 1-3, 1963, on the subject of Developing Brain and Binding Sites of Brain Biogenic Amines. All interested are invited to attend. In addition to the formal participants other investigators with new data on either of these two topics are invited to submit brief discussions of five minutes by Jan. 15, 1963. In order to extend the opportunity to other institutions to invite one or more of the distinguished foreign participants, the following list is presented:

Dr. P. K. Anokhin, Moscow; Dr. H. Blaschko, Oxford; Dr. A. Carlsson, Goteborg; Dr. E. DeRobertis, Buenos Aires; Dr. N. A. Hillarp, Stockholm; Dr. P. Holtz, Frankfurt; Dr. L. Jilek, Prague; Dr. A. Pletscher, Basle; Dr. J. P. Schadé, Amsterdam; Dr. J. Scherrer, Paris; Dr. V. P. Whitaker, Cambridge.

For pre-registration please contact Harold E. Himwich, M.D., Director, Research Division, Galesburg State Research Hospital, Galesburg, Ill.

COLLOQUIUM FOR GRADUATE TEACHING OF PSYCHIATRY.—The American Psychiatric As-

sociation Committee in Liaison with the American Academy of General Practice is sponsoring a colloquium for teachers of post graduate psychiatry February 16 and 17, 1963 at Los Angeles. Participation in the colloquium will be limited, and early pre-registration is necessary. No funds are available for participants' travel and per diem expenses. There is a registration fee of \$15.00. Meetings will be held on the School of Medicine campus of the University of Southern California. Hotel arrangements should be made by participants themselves. The Statler Hilton Hotel in downtown Los Angeles will be most convenient to the meetings and is recommended.

For information write to Werner M. Mendel, M.D., 1934 Hospital Place, Los Angeles 33, Calif.

DR. SNOW TO DIRECT THE HUDSON RIVER STATE HOSPITAL.—Dr. Herman B. Snow, director of the St. Lawrence State Hospital since 1954, was appointed to succeed Dr. Robert C. Hunt at Hudson River who retired after 5 years as its director. Dr. Snow assumed his new duties October 11. He is a graduate of Syracuse University and received his M.D. from that university in 1933. Since 1934 he has been in the New York State service, and from '49-'51 was acting medical inspector. He received the Adolf Meyer Memorial Award in 1959 for his work in connection with the open door hospital at St. Lawrence.

DR. MARY M. WOLFE.—The death of Dr. Wolfe, a former president of the American Association on Mental Deficiency, occurred at her home in Lewisburg, Pa., October 18, 1962. She was a life fellow of the APA. A graduate in medicine from the University of Michigan, she received in 1933 the honorary degree of Doctor of Science from Bucknell University, which was founded by her great grandfather in 1846, and of which she had been a trustee since 1935.

Dr. Wolfe became the first superintendent of the Laurelton State School in 1914, retiring in 1940. She had served on the staff of Norristown State Hospital from 1899 to 1910. At the International Congress on Nervous and Mental Diseases at Lima,

Peru, in 1938 Dr. Wolfe was the only American woman delegate. She was a member of the American Association of University Women and of the Daughters of the American Revolution.

1962 MENTAL HOSPITAL SERVICE ACHIEVEMENT AWARDS.—The 1962 awards to institutions for notable contributions to psychiatry were given to The Lynchburg, Va., Training School and Hospital—APA Gold Achievement Award; The Reiss-Davis Clinic for Child Guidance—APA Silver Achievement Award; The D. C. Legal Psychiatric Service of the Bureau of Mental Health—APA Bronze Achievement Award.

The ceremonies associated with these awards are described in full in the Oct. '62 issue of *Mental Hospitals*.

THE GUTHEIL MEMORIAL LECTURE.—On October 28, 1962, in New York City, Dr. Leo Kanner, Professor Emeritus of Child Psychiatry, Johns Hopkins University, delivered the Gutheil Memorial Lecture under the title "The Scope and Goal of Psychotherapy with Children." Dr. Kanner was the third recipient of the Gutheil Memorial Medal, the first two having been Dr. Nolan

D. C. Lewis and Dr. John C. Whitehorn. The lecture was given at a conference sponsored by the Association for the Advancement of Psychotherapy, dealing with the general topic "The Acting-Out Patient—A Study of Biodynamic Mechanisms in Therapy."

ISRAEL S. WECHSLER LECTURE.—The 8th Annual Israel S. Wechsler Lecture is to be given on the evening of December 7, 1962, at 8:30 P.M., in the Blumenthal Auditorium of the Mount Sinai Hospital of New York City by Dr. Seymour S. Kety, Chief of the Laboratory of Clinical Science at the National Institute of Mental Health, Bethesda, Maryland. His subject is "Amino Acids, Amines and Behavior."

AAAS MEETING.—The research committee of the APA is sponsoring a session entitled "Human Reactions to the Threat of Impending Disaster" at the annual AAAS meeting in Philadelphia. Dec. 27-28, 1962.

BIOGRAPHY OF ADOLF MEYER.—The address of the authors of this biography listed in the November news items has been changed to Box 189A, Route 2, Owings Mills, Md.

BOOK REVIEWS

MILIEU THERAPY IN SCHIZOPHRENIA. By Lt. Col. Kenneth L. Artiss, M.C. (New York: Grune & Stratton, 1962, pp. 169. \$6.00.)

Dr. Artiss' second venture into publication is again a noteworthy event. His own personal experience translated into this brief monograph, with acknowledgements to the assistance of others, offers a challenge for psychiatrists to leave the security of established psychiatric theories and venture into a new method of treatment.

The author carefully reviews his experiences in establishing an experimental therapeutic milieu for treating schizophrenic military patients, organized as a separate entity within the psychiatric department of Walter Reed Army Hospital. One follows the evolution of the program as various hurdles are met and surmounted in the selection and management of patients and the organization and education of professional staff. Interpersonal relationships between all individuals concerned are explained.

Of 42 patients who were treated, 27 (64%) were returned to duty. Since the patients in this pilot study were selected without attention being paid to criteria of treatability, it is reasonable to assume, as the author suggests, that in a more select group a higher recovery figure might be attained.

One unique feature of this program is the emphasis on the ward aide personnel serving in an active psychotherapeutic role by being available for discussion in which the patient is directed to reflect upon his own feelings. Another innovation is the democratic "patient government" operation in which the group, the leaders of which are selected by the patient group, plans and decides the social activities for the evenings and all periods of time not reserved for patient psychotherapy.

Milieu therapy also becomes a prognostic tool. It enables the therapist to observe the psychologic functioning and adaptation of the patient and makes use of the resources inherent in group living. A cited example is the fact that the patient who can successfully assume leadership responsibility within the group is one whose prognosis is favorable for continued social adaptation and return to military duties.

The peculiar environment of a military setting, with its usual red tape and administrative

interference, is surmounted with aplomb. We are particularly fortunate that Dr. Artiss' high threshold of anxiety permits him to share with us some of his inner feelings and thoughts as the project progresses in its successive phases. While seeming to minimize his importance, we learn how one psychiatrist molds a group of nurses and particularly ward aides to obtain a therapeutic environment in which to treat schizophrenics. In doing this, note is made of earlier pioneering by Harry Stack Sullivan.

In discussing possible civilian application of this study, Col. Artiss emphasized three points:

1. The therapist or therapeutic agency should have a known goal for its treatment efforts.
2. Education in the rudiments of successful social behavior should be made a part of the treatment regimen.
3. Place the patient in a position where he has both a regular opportunity to interact with a healthy group and the responsibility to do so.

The author deserves credit for amply demonstrating that one may be a successful non-conformist even in the bailiwick of the military bureaucracy. One only regrets that the brevity of the book affords only a glimpse of how he accomplishes this feat.

INGRAM COHEN, M.D.,
New York.

ACCIDENT PREVENTION. American Public Health Association. (New York: McGraw-Hill, 1961, pp. 400. \$12.00.)

This is a unique book in many ways, not the least of which is the origin and sponsorship. It has been prepared under the direction of the Program Area Committee on Accident Prevention and is authorized for publication by the Technical Development Board of the American Public Health Association. It also makes the claim of being the only book written primarily to serve physicians and public health workers.

The primary objective of the book is "to provide a text for inclusion in courses dealing with accident prevention principles and concepts in the curriculum of medical schools, schools of public health, and other schools dedicated to the professional education."

As would be expected by the sponsorship this is a multiple author effort with some thirty writers gathered from medical, preventive medical, lay and official organizations con-

cerned with some aspect of accident prevention and control. The book has all the advantages as well as disadvantages of this technique of authorship. On the positive side is the gathering of information from a wide range of authorities. From the negative point of view is the variation in style and considerable redundancy, particularly in the presentation of statistics which are covered fairly comprehensively in the opening chapter and then repeated by many of the contributors.

Of special interest to psychiatrists is the attention to the personal factors involved in many accidents. This phase of the problem is given due but not excessive attention.

This book is of a calibre that it certainly should be included in the library of all workers and teachers concerned with the accident problem. It is not one that will have wide general appeal.

G. E. HOBBS, M.D.,
University of Western Ontario,
London, Ont.

BEFINDEN UND VERHALTEN. Edited by J. D. Achelis, and H. von Dittfurth. (Stuttgart: Georg Thieme Verlag, 1961, pp. 110. \$3.70.)

This book contains one symposium ("Gespräch") of the many recently arranged by pharmaceutical concerns, in this instance by Boehringer (Mannheim). Various papers were presented. Schleidt (Seewiesen) dealt with innate modes of behavior as influenced by drugs. v. Dittfurth (Mannheim) offered an orientation on the problems of pharmacopsychiatry. v. Holst (Seewiesen) expanded on the "psycho"-physiology (the quotes are v. Dittfurth's) of the thalamus of hens. Pluegge (Heidelberg) and Mappes (Munich) reported on heart-disease in children and tried to appraise its impact on the grown-ups. Bilz (Mainz) essayed to identify certain elements in hypnagogic experiencing with elements in psychotic experiencing.

In the discussion questions and comments made by v. Auersperg (Concepcion, Chile), v. Baeyer (Heidelberg), Lorenz (Seewiesen), Th. v. Uexkuell (Giessen) were challenging and impressive, although the discussions were not skillfully m.c'ed. Summaries were apparently deemed undignified. The prevalence of an anthropomorphic attitude in some quarters was considerable. "Aneinandervorbeireden" is not entirely avoidable under such circumstances.

EUGEN KAHN, M.D.,
Houston, Texas.

THE STAGES OF HUMAN DEVELOPMENT BEFORE BIRTH. By E. Blechschmidt. (Philadelphia: W. B. Saunders, 1961, pp. 684. \$23.00.)

This atlas of developmental human anatomy renders visible what has hitherto, for the most part, been available only in the form of tables. In so doing Professor Blechschmidt has provided the basis for answering the old question as to whether there is a natural interdependence of organs. He demonstrates that there is, and this soon becomes apparent in the concentrated treatment of the developmental stages of the first 2 months, though the book covers the whole period of intrauterine development, and this it does originally and admirably.

The illustrations are all beautifully clear, and the descriptive matter is equally so. The text is given in both German and English, a great boon to those who want to improve their German. This is altogether a most welcome contribution to the understanding of human development. I say human development, without limiting the value of the book to morphology, because if we are to understand human development we shall have to pay increasing attention to prenatal development. It is now well established that the prenatal organism is susceptible to every kind of environmental influence, and in order to understand the means by which such influences affect the morphological, physiological, and behavioral development of those influences, a good knowledge of the stages of prenatal development is indispensable. Hence, the importance of such a book as *The Stages of Human Development Before Birth*.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

DIE WISSENSCHAFT VOM VERBRECHEN. By Armand Mergen. (Hamburg: Kriminalistik, 1961, pp. 296.)

Dr. Mergen, who is Professor of Criminology at the University of Mainz and president of the German Criminological Association, has written this book, not as an elementary textbook of criminology, but properly as an *introduction* to this science and as a clarification of the basic concepts, principles and methods of criminology.

The first part of the book contains an interesting historical survey, a discussion of the main criminological approaches (biological, psychological, sociological) and discussions on "criminalistics," penology and methods of prophylaxis. The following chapters are devoted to

discussions of the various concepts of crime and of the criminal, illustrated with a number of cases from Dr. Mergen's own criminological practice (murder, theft, sexual offenses, etc.).

One of Mergen's main contentions is that criminology is a science in its own right, not just a mixture of chapters of sociology, psychiatry, penal law, penology, etc., more or less loosely patched together. Mergen emphasizes the autonomy and unity of criminology and describes its structure and subdivisions.

In the discussion of the basic concepts of criminology, Mergen tends to follow the principles of the school of "Social Defense," a school which looks upon the concepts of guilt, responsibility and punishment as "metaphysical"—a view with which many readers, especially lawyers and judges, are not likely to agree. Be it as it may, Mergen deserves credit for stating the problems clearly and without minimizing the difficulties. He displayed the same impartiality when he recently published his inquiry *Kriminologie Heute* ("Criminology Today") in which he gives side by side the opinions of a number of specialists belonging to divergent schools of thought.

STATISTICS IN PSYCHOLOGICAL RESEARCH. By William S. Ray. (New York: Macmillan, 1962, pp. 303. \$6.00.)

Although the author is a professor of psychology there is very little psychology in this book. It is really a text-book in statistical methods and satisfactorily performs its function. It does not clash with Aristotle's observation that what one is going to do after learning to do it is best learned by doing it; it provides exercises to that end. Nor will it tend to produce what Sir Ronald Fisher warned against, "boys with a lot of tables under their arms and fog in the place where their brains should be." The book can be recommended for students in statistical courses.

NEIL E. MCKINNON, M.D.,
University of Toronto, Canada.

MENTAL HEALTH IN THE UNITED STATES. By Nina Ridenour, Ph.D. (Cambridge, Mass.: Harvard University Press, 1961, pp. 146. \$3.50.)

It is difficult to think of any one who could have been better qualified than Dr. Ridenour to write such a book as this. She has been intimately acquainted with the history of the so-called Mental Hygiene Movement in the

United States and an active and knowledgeable participant in its later phases. It is an intriguing story that goes back to the publication, warmly supported by William James and William H. Welch, of Clifford Beers' autobiography *A Mind that Found Itself* in 1908, and the founding by Mr. Beers the following year of the National Committee for Mental Hygiene.

Dr. Ridenour gives enough references to the ways, at the beginning of the twentieth century, in which mental patients were regarded and handled to make clear the enormous labors Mr. Beers and the little group he organized laid out for themselves. The time was propitious. There were stirrings in professional circles toward better things, especially following Weir Mitchell's schoolmasterly lecture to the superintendents of American institutions for the insane in 1894. Notable was the record of Dr. George Zeller who in 1902 was conducting the Peoria State Hospital in Illinois on a completely open-door plan "without bars or locks or 'back wards.'" The contributions of Benjamin Rush, Kirkbride, Dorothea Dix to early mental hygiene and of William L. Russell, Thomas W. Salmon and George S. Stevenson to its later phases are duly recorded by Dr. Ridenour. Albert Deutsch's *The Mentally Ill in America* (1937) figures here of the greatest importance.

The author rightly dates the "emergence" of psychiatry to the turn of the 19th to the 20th century, but without taking note of the great stir following the bomb cast by Weir Mitchell into the camp of the American Medico-Psychological Association at its 50th annual meeting in 1894. Early trends in tangible form of the new movement are noted in the erection of "psychopathic" hospitals in connection with university medical schools, leading eventually to the recognition that no "general" hospital deserves its title if it does not provide full psychiatric service.

The leading influence of Adolf Meyer and his wholesome teaching of psychobiology during the early decades of the century are clearly recorded, followed by the epoch of the "new" therapies and burgeoning research.

Compactly but clearly, various vital developments initiated by the National Committee or in which it had an essential part are described. When the author comes to the subject of child psychiatry, she sounds a rueful note. At the time of signing the preface to her book she states that "there are not a hundred 'qualified' child psychiatrists in the United States." It is to be remembered that while the diagnosis mental deficiency—earlier often referred to in harsher terms—is ancient, the range

of other childhood mental disorders is of much more recent acceptance. Even the classification of grades of deficiency set forth by Goddard dates only from 1910.

Dr. Ridenour describes the fine work of Dr. Thomas W. Salmon, first director of the National Committee for Mental Hygiene, who volunteered for military service in World War I, when the United States entered the war. Dr. Salmon was sent to France as Director of Psychiatry of the American Expeditionary Force. This was the beginning of Military Psychiatry as we know it today. When Dr. Salmon became president of the American Psychiatric Association in 1923—the first in the Association's long history who was not a superintendent of a mental hospital—he initiated a movement, perhaps unconsciously, which led to the emergence of psychiatry from the closed walls of the mental hospitals into the general hospitals and the community.

Clifford Beers was one of those rare dreamers whose dream came true. His friends of 1909 were greatly impressed by his vivid and invaluable autobiography but reserved judgment of his long foresight as to the future of his plans for mental hygiene as a world movement. The year 1930 brought the answer. In that year Clifford Beers was the hero of The First International Congress on Mental Hygiene, assembled in Washington, attended by more than 3000 representatives of some 50 countries. The Proceedings of that meeting ran to nearly 1650 pages. In 1948 the Third International Congress was held in London, after which the work of the International Committee was taken over by the World Federation of Mental Health.

An especially notable period in the life of the original National Committee in New York embraced the depression years of the 1930s, when Dr. Clarence Hincks, director of the Canadian National Committee, was invited to assume the direction of the New York office. From 1930 to 1939, Dr. Hincks commuted between Toronto and New York, managing both headquarters. A major activity during 1930-1935 was a fruitful survey of psychiatric teaching in Class A medical schools in the United States and Canada. This survey was carried out by the New York Committee, supported by the Commonwealth Fund. It may be noted that Dr. Hincks, together with Dr. C. K. Clarke, the first director, founded the Canadian National Committee, and succeeded Dr. Clarke as director on the death of the latter in 1924.

This compact book traces the main transactions in the ever-widening domain of mental hygiene, now more suitably called mental

health. Under the general heading "Public Relations" the author deals with the extraordinary, continuing, even exaggerated publicity by all the media of communication, that has been given to this branch of medicine. One of the publicity peaks was the dubiously appropriate film "The Snake Pit." She seeks to note both pros and cons of the publicity obsession without pontificating.

Obviously there are areas in this vast field that require emphasis and amplification, others no doubt retrenchment, many further consideration. It is a fascinating story that Dr. Ridenour has written and we are grateful for her book.

C. B. F.

SENSORY DEPRIVATION. Ed. by *Philip Solomon, et al.* (Cambridge, Mass.: Harvard University Press, 1961.)

This volume reports the first major conference on sensory deprivation held in 1958 at Harvard Medical School. The participants were scientists from a wide variety of disciplines, including neurophysiology, psychiatry, psychology and engineering. Of the fifteen chapters, nine are reports of experimental work, two describe clinical applications, and the remainder discuss theoretical implications for sensory regulation, cognition, and the organization of the central nervous system in man.

The results of sensory deprivation, particularly with regard to aberrations of behavior, have been rather inconsistent. Some workers have seen remarkable changes in perception and cognition after a few hours of exposure to isolation; others have observed very few instances of gross distortion even after several days of isolation. Concern with these ambiguities has led several investigators to search for variables other than isolation which might be relevant to behavioral outcomes. Several such variables, important for all studies of human subjects, have been identified. Individual differences in personality of subjects and experimenters, differing instructions, explicit and implied, and the nature and amount of spatial-temporal structure in the environment are significant parameters. Thus results in this area of investigation are seen to be the product of the complex interaction of a number of factors of which sensory deprivation per se is but one.

The final chapter gives clear directions for further research. The differential consequences of two general techniques, absence of stimulation on the one hand, and unpatterned stimulation on the other, must be specified. Data

gathering must move from qualitative observation to quantitative measurement. More sophisticated assessment of the physiological and neurochemical correlates of behavior change is an urgent requirement. Longitudinal studies of adaptation to these and related environments are recommended.

The reports in this well organized and highly readable volume have implications for clinical medicine, public health, industry, and military operations, and the research gives promise of contributing to a revised conception of the organization of the central nervous system and behavior.

HAROLD L. WILLIAMS, MSC., Major,
Washington, D. C.

THE ETIOLOGY OF IDIOPATHIC EPILEPSY. By Harold Geist, Ph.D. (New York: Exposition Press, 1962, pp. 268. \$5.00.)

The first part of this book has a short section on the medical aspects of epilepsy, which is uncritical and in part in error. There is then a short review of some of the literature on psychological testing and on psychotherapy in epileptics followed by a section on the general principles of psychoanalysis. The remaining two thirds of the book discusses the technique of administering and the results in the author's series of epileptics of several psychological tests, e.g., MMPI, TAT, Rorschach, The Blacky Test, Draw-a-Person Test, Wechsler-Bellevue and Bender Gestalt. The descriptions of the various tests are often too involved for the individual who has not used the specific tests and yet inadequate for teaching others how to administer them. The results are presented with a psychoanalytic interpretation and almost always without giving the reader the slightest idea of whether 1 or 100 cases were examined.

The clinical material is divided into three groups: "A. knows" ("those cases where there is known to be a history of head trauma, laceration or cerebral disease and an EEG characteristic of *petit mal* or *grand mal*, with *petit mal* or *grand mal* convulsive seizures"—italics are the author's), "B. unknown," and "C. probable." There were 40 "unknown" cases, probably 5 "known" (although the author never specifically says so), and an unstated number of "probable" cases. Several of the clinical histories that are given make one sceptical of some of the medical diagnoses. However, the author feels competent on the basis of the various projective tests to offer for each of the three groups "... strands of psychoanalytic data which can be woven to make interesting comparisons with Freud's theories." It would

be unfair for the reviewer to attempt to summarize the characteristics of the various groups because of the many factors that Dr. Geist enumerates.

The author concludes that "... anticonvulsant drugs are, at best, controlling agents and do not completely remove the root of the disease. The answer appears to be in intensive psychoanalytic therapy." The author has neither demonstrated a very keen understanding of the organic basis of epilepsy, including medicinal therapy (which, of course, does not "remove the root of the disease") nor has he demonstrated to this reviewer, at least, that "the answer" lies in psychoanalysis. The title of the book, probably, is a misnomer; rather than *The Etiology of Idiopathic Epilepsy* it actually presents some psychoanalytic speculations on the results of psychological testing of an unstated number and probably mixed group of epileptics.

WALTER J. FRIEDLANDER, M.D.,
Albany, N. Y.

PSYCHOLOGY: AN INTRODUCTION TO THE STUDY OF HUMAN BEHAVIOR. By Henry Clay Lindgren, and Donn Byrne. (New York: John Wiley, 1961, pp. 429. \$6.50.)

This book is intended for use in undergraduate introductory psychology courses and deserves to be adopted by many schools. It is an informative and highly readable textbook, but it would be unfortunate if college sophomores were to be its only readers. It could, as well, provide an interesting overview of contemporary psychology for psychiatrists, psychologists, or others concerned with behavior.

The authors deal with all of the usual topics—learning, motivation, perception, intelligence—but save their best efforts for several chapters that rarely appear in introductory texts. These chapters on communication, group processes, business and industry, and world affairs are unusually well done, in that they present balanced surveys of the areas that are sensitively supplemented with cartoons and photographs.

It is the authors' aim throughout to develop a "scientific understanding of human nature." In pursuing this, they have developed each topic with abundant evidence from research studies. No consistent theoretical point of view is presented, but they are consistent in holding to research evidence. For example, the question of whether perceptual functioning is innate or learned is answered with brief summaries of studies by Hilgard, von Frisch, Tinbergen, and Sauer which effectively lead the reader to a clearer understanding of the nature-

nurture problem. The result is a book which presents a skeptical attitude toward theorizing and advice-giving, but which manages to convey a sense of quiet excitement about psychological research.

DALE L. JOHNSON, Ph.D.,
Houston, Texas

THE PEOPLE OF GREAT RUSSIA. A Psychological Study. By *Geoffrey Gorer*, and *John Rickman*. (New York: W. W. Norton, 1962, pp. 236. \$1.65.)

This book is a soft-cover reprint of a work originally published in 1949, with the addition of a new introduction by the surviving author (Gorer). The reissue is apparently based upon the interest which the work originally attracted. It developed out of the Columbia University Research Project on Contemporary Culture organized in 1947 under the late anthropologist Dr. Ruth Benedict.

The book's material consists of two parts. The first consists of ten sketches of Russian peasant life written by Dr. Rickman, the English psychoanalyst, who served as a physician in a Russian peasant community in 1916-18. These sketches are written with literary skill and psychological sensitivity to the people whom he served, and were originally published in various journals. The second and larger section presents a discussion of Russian psychology and, by implication, an analysis of Russian political history by Mr. Gorer. This section is based upon "three or four hundred interviews" with refugees, immigrants and visitors to Russia carried on at Columbia University by Russian-speaking interviewers. The author disclaims a personal knowledge of Russian, and his role was that of interpreting the interviews. Using Dr. Rickman's sketches as a base and the interviews and literary works as supportive data, Gorer devised a theory that "the majority of great Russians have a diffuse feeling of guilt which is largely or entirely unconscious and a diffuse feeling of fear, derived from the projection of their infantile hostility." This hostility derives, in turn, from the practice of infant swaddling which he implies was universally employed on all infants until the age of 9 or 12 months (both figures are given). The infantile restriction of movement results in the adult feelings of rage and hate, unfocused guilt, a feeling of separateness and a lack of "the internalized ethical control which

guides the conduct of most Occidentals." This explains both individual Russian psychology and the acceptance of both the Tsarist and Soviet systems by the Russian people.

These sweeping generalizations are presented with an apparently disarming modesty and with repeated statements that these conclusions are presented only as an hypothesis. In fact, however, the authors repeatedly interpret important historical events on the basis of their psychological theory.

This presentation raised many questions in the reviewer's mind. While rich in imaginative quality, the material presents few facts. It would make a very great difference, for instance, if swaddling occurred during the first 3, 9 or 12 months of infant life. On this basic fact, the authors are unclear. Swaddling is practiced among peoples as different as the French, the American Indian and the Italian, as the authors state. It is difficult to understand why similar practices should produce such dissimilar national characteristics and the explanations are unconvincing.

Many quotations from Russian literature are presented to describe the Russian character, but these have been chosen to support a theory rather than to investigate an hypothesis, and it would not be hard to find other Russian quotations which could lead to quite different conclusions.

Few students of infant development would deny the importance of early experience upon later psychology or that severe restriction of bodily activity could indeed affect psychological or physical growth. To justify these conclusions, it would, however, be necessary to bring together evidence that 1) such restrictions were universally applied and at an inappropriate age; 2) that the psychological effects upon the individual actually took place and that 3) the psychology of the individual is reproduced in the behavior of large political groups and can account for historical events. In the opinion of this reviewer, the authors have provided no such evidence.

A final quotation will give the reader a flavor of the atmosphere of this book:

"In the case of the Russians, I think the century-old complaint that other countries are keeping them from a 'warm-water port' probably has important psychological implications, but I have not, so far, been able to discover what these are." Perhaps readers of this review could assist with some suggestions.

HELEN WORTIS,
New York Medical College.

Proposed Amendment of the Constitution and By-Laws of the American Psychiatric Association

Approved by Council for consideration of the Membership under provisions of the Constitution and By-Laws

THE CONSTITUTION

Article I. Name

This corporation, founded in 1844 as the Association of Medical Superintendents of American Institution for the Insane, known from 1892 to 1921 as the American Medico-Psychological Association, and since 1921 as the American Psychiatric Association, is hereby continued under the last designation.

Article II. Objects

The objects of this Association are: (a) to further the study of the nature, treatment, and prevention of mental disorders; (b) to promote the care of the mentally ill; (c) to further the interests, the maintenance, and the advancement of standards of all hospitals for mental disorders, of outpatient services, and of all other agencies concerned with the medical, social, and legal aspects of these disorders; (d) to advance psychiatric education and research; and (e) to make available psychiatric knowledge to other branches of medicine, to other sciences, and to the public welfare.

Article III. Members

1. There shall be these classes of members: Fellows, Life Fellows, General Members, Life Members, Associate Members, Distinguished Fellows, Honorary Fellows, Corresponding Fellows, Corresponding Members, and Inactive Members. District Branches may establish parallel categories of membership not inconsistent with this article.
2. At the time of initial application, all except Honorary, Distinguished, and Corresponding categories shall be residents of countries of the western hemisphere, north of South America; or residents of the Caribbean Islands; or residents of dependencies of any of these countries.
3. An applicant for Associate or General Membership, if never before affiliated with this Association, will apply through the District Branch (if such District Branch

has jurisdiction and has been approved for membership processing) in the manner prescribed by the By-Laws.

4. If applicants are ineligible under Section 3, the application will be sent to the Secretary of the American Psychiatric Association, who will relay it to the Membership Committee for processing as a "member-at-large" in the appropriate grade, in accordance with the By-Laws.
5. The Committee on Membership will consist of six members who shall be either Fellows or Life Fellows. Each year the President will indicate which member of this Committee will be Chairman.
6. Associate Members will be physicians who have had one year or more of full-time training or experience in psychiatry.
7. To become a General Member, the physician shall either: (a) have been an Associate Member for at least one year, and have had at least three years of training or experience in psychiatry; or (b) if he has never before been of the membership of this Association, he shall have had three years experience in the specialty, and shall be recommended by the appropriate District Branch for direct election to General Membership. No physician will become a General Member (whether by direct admission to the Association or by advancement from Associate status) unless he: (a) holds a valid, nonprovisional license to practice medicine in the jurisdiction where he is working; or (b) holds an academic or research appointment not requiring licensure; or (c) is a full-time employee or officer of State, County, or National Government.
8. Fellows shall be chosen from those who have been General Members for at least two years, who have specialized in psychiatry for at least seven years, and who have made significant contributions to the field of psychiatry. The appropriate District Branch will be notified of applications for advancement from General Members

to Fellowship status, and consideration shall be given to the recommendations of the District Branch, if submitted.

9. Life Members shall be members who have had 30 years affiliation with the American Psychiatric Association, and who are not eligible for Life Fellowship. A Life Member has all the rights of a General Member.
10. A Life Fellow is one who is a Fellow after 30 years of membership in this Association. A Life Fellow has all the rights of a Fellow.
11. A Distinguished Fellow is a physician, not a member of this Association, or other scientist who has distinguished himself by contributions to psychiatry or related sciences, and who is so designated through the procedure described in the By-Laws. Physicians who had been designated Honorary Fellows will, at the time of the adoption of this Constitution, become Distinguished Fellows. A Distinguished Fellow will not be eligible to vote or hold office but will be invited to scientific assemblies of the Association and receive such publications as Council may determine.
12. An Honorary Fellow is a person other than a physician who has rendered signal service in the promotion of mental health and psychiatry, and who is designated "Honorary Fellow" through the procedure described in the By-Laws. Other than physicians, those previously classed as Honorary Fellows of the American Psychiatric Association will continue in that category. Honorary Fellows are ineligible to vote or hold office, but will be invited to scientific assemblies and will receive such publications as the Council may determine.
13. Any General Member or Fellow who, for ten years or more, has been in good standing, and who establishes inability to continue payment of dues as a consequence of hardship, illness, or retirement, may apply for inactive status. Such status will be granted in appropriate cases by the Council on recommendation of the Membership Committee. An Inactive Member will be entitled to register as a member at Annual Meetings, but will not pay dues, nor will he be eligible to vote or hold office. He will be entitled to the JOURNAL and such other publications as the Council may determine.
14. A person professionally qualified to be a Fellow and who lives outside the jurisdictional area of this Association, as described in Section 2 of this Article, may

be elected a Corresponding Fellow. A Fellow of this Association who moves permanently outside its jurisdiction may become a Corresponding Fellow or remain in previous status, at his option.

15. A Corresponding Member is a former Life Member, General Member, or Associate Member who has moved permanently out of the jurisdictional area of this Association, as described in Section 2 of this Article, and who has applied for the status of Corresponding Member. Such a member, if he prefers, may continue in his membership status.

Article IV. Officers

1. The officers of the Association are a President, a President-Elect, two Vice-Presidents, a Secretary, and a Treasurer. These Officers and an appropriate number of Councillors will be elected annually by mail ballot in the manner prescribed by the By-Laws.
2. The Council shall include the above officers, the Speaker of the Assembly, and twelve Fellows, of whom the retiring President shall be one.
3. Past-Presidents after three years of full Council service will thereafter be members of Council with full floor privileges but without the right to vote.
4. The President-Elect will be installed as President during the Annual Meeting next following the Annual Meeting at which his selection as President-Elect was announced. If the position of the President-Elect becomes vacant during the term, the Council will select a Fellow to serve as President-Elect and he will be installed as President at the next Annual Meeting.
5. The President-Elect, the two Vice-Presidents, the Secretary, and the Treasurer will assume their responsibilities at the time of the installation of the President. Incoming Councillors will assume their responsibilities when their election is announced.
6. The President, the President-Elect, each Vice-President, the Secretary, and the Treasurer shall each hold office for one year; Councillors will serve for three years. The President, the Vice-Presidents, and the four retiring Councillors are ineligible for re-election to their respective offices before three years have elapsed from the date of their retirement from such office.
7. (a) If the position of President becomes vacant, the Council will select a Vice-

President to become President for the remainder of the term.

(b) If any other position becomes vacant, the Council will elect a Fellow of the Association to fill that office for the unexpired portion of the term.

Article V. Privileges

1. The right to vote by mail, or in person, is limited to Fellows, Life Fellows, General Members, and Life Members.
2. Anyone with the right to vote also has a right to nominate candidates and to propose amendments to the Constitution or By-Laws.
3. Only Fellows and Life Fellows may hold elected office or serve as Chairman of Committees, Boards, and Commissions.
4. Every Fellow, Life Fellow, General Member, Life Member, Associate Member, or Inactive Member shall be entitled to the JOURNAL and such other publications as the Council may determine. Every such person shall also be entitled to register and attend the Annual Meetings as a member.
5. Every Fellow, General Member, and Associate Member shall be liable for the payment of dues and assessments.
6. Life Fellows, Life Members, Distinguished Fellows, Honorary Fellows, Corresponding Fellows, Corresponding Members, and Inactive Members will be exempt from payment of dues. Any persons in these classifications who attend the Annual Meeting will be entitled to register there on the same terms as General Members.
7. Any one of the membership of this Association (Article III, Section 1) may be appointed to a Committee.

Article VI. The Council

1. The Council will consist of the persons named in Section 2 of Article IV.
2. A majority of the voting members of the Council will constitute a quorum thereof.
3. Annually, the Council will elect, from its own voting membership, a Moderator of the Council.
4. The Council will meet during the Annual Meeting of the Association, and at such other times as the President or the Moderator may determine. By petition, one third of its members may call a special meeting of the Council.
5. Each year, during the Annual Meeting, the Council will organize an Executive Committee. This Committee will consist of the President, the two Vice-Presidents, the

Secretary, the Treasurer, the President-Elect, the Speaker of the Assembly, and two Councillors especially selected.

6. In the intervals between Council meetings, its Executive Committee has the powers of Council. All actions of the Executive Committee will be submitted to the Council at its next meeting for information, ratification, or modification.
7. The Council exercises all powers of the Association, not otherwise assigned, save when the membership is assembled in general meeting. Powers of the Council include:
 - (a) Fixing the date and place of each Annual Meeting of the Association.
 - (b) Determining the dues and assessments for the various classes of membership.
 - (c) Adopting a budget. This is solely the responsibility of the Council, and the budget, once adopted, shall be reported to the membership, for their information, at a business session of the Annual Meeting.
 - (d) Controlling the funds of the Association and designating its depositories.
 - (e) Making expenditures from the funds of the Association in implementation of its goals and purposes.
 - (f) Administering special funds, grants, and awards.
 - (g) Creating committees.
 - (h) Reviewing applications for District Branch charters after appropriate action by the Assembly, and making or approving recommendations for redistricting of branches when this becomes advisable.
 - (i) Processing applications for transfers within membership grades.
 - (j) Hearing and disposing of appeals from applicants rejected for membership.
 - (k) Directing the President to admonish or reprimand a member, subject to, and in accordance with, the appropriate provisions of the By-Laws.
 - (l) Expelling a member, or suspending a member, for a period of not more than one year, subject to, and in accordance with, the appropriate provisions of the By-Laws.
 - (m) Considering proposed amendments to the Constitution and By-Laws.
 - (n) Publishing the AMERICAN JOURNAL OF PSYCHIATRY, and appointing its editor, Editorial Board (or Publication Committee), and its staff.
 - (o) Providing for other publications desirable for carrying out the aims of the Association.
 - (p) Appointing such staff personnel as it

finds necessary to carry out the purposes of the Association, including professional auditors; and the setting of salaries.

(q) Doing all other things necessary to carry out the purposes of the Association and not inconsistent with the By-Laws or with this Constitution.

Article VII. Committees

1. There shall be the following Constitutional Committees: an Ethics Committee, a Nominating Committee, a Committee on Constitution and By-Laws, a Program Committee, an Executive Committee, and a Board of Tellers.
2. There shall be such Standing Committees, Boards, and Commissions as the President, the Council, the Executive Committee, and membership may designate.
3. Ad Hoc Committees, when appointed, shall act through the next Annual Meeting.
4. Unless otherwise specified, committee members will be named by the President. Each year the President then in office will indicate who shall be chairman of each committee. Anyone in any voting class of membership may be appointed to a committee; but only a Fellow or Life Fellow may be named as Chairman of a Committee, Board, or Commission. Persons not members of the Association may be designated advisors or consultants to committees.
5. Unless such power is specifically granted by Council or by the membership of the Association, no Committee will speak in the name of, nor encumber funds of, this Association.

Article VIII. District Branches

1. District Branches will be created in the manner described in the By-Laws.
2. Each District Branch will elect a delegate. The delegates, in the aggregate, constitute the Assembly of District Branches. The Assembly is authorized to consider any matters pertinent to the welfare of the Association or to the implementation of its objects.
3. The Assembly will annually elect a Speaker-Elect and a Recorder. The Speaker-Elect, at the conclusion of his service in that position, will become Speaker of the Assembly and a voting member of the Council.

Article IX. Amendments

1. Proposals to amend this Constitution may originate either (a) by a petition signed by fifty or more Fellows, General Mem-

bers, or a combination thereof, or (b) by resolution of the Council.

2. (a) Proposals to amend the Constitution by petition of fifty or more Fellows and/or General Members shall be received by the Secretary at least 30 days before the Annual Meeting. Such proposals shall be submitted to the Council and placed on the agenda for reading at the Annual Meeting.
(b) If at any time prior to the first day of the Annual Meeting, the Council passes a resolution endorsing a proposed amendment, the text thereof shall be read at the next Annual Meeting.
3. After a proposed amendment (no matter how originated) is read at the Annual Meeting, the text thereof shall be published in the JOURNAL (or otherwise made known to the membership) not later than January 1. The proposed amendment will be submitted to the membership for mail ballot, at the time of and in the manner provided in the By-Laws in voting for candidates for office in the Association. All Fellows, Life Fellows, General Members, and Life Members shall be eligible to vote. If more than fifteen percent of the eligible voters return properly marked ballots, and if more than two thirds of such ballots are favorable to the proposed amendments, then the proposal shall be considered adopted and the Constitution amended accordingly.
4. Proposals to amend the By-Laws shall be received and acted upon in the same manner as proposals to amend the Constitution except that the favorable votes of a majority of eligible voters shall be sufficient to enact the amendment to the By-Laws, provided that not less than fifteen percent of the eligible votes shall have been cast in this mail ballot, and also provided that not less than ten percent of those voting are in favor of the proposed amendment.

THE BY-LAWS

Chapter One. Annual Meeting

1. A general meeting of the Association will be held annually at such times and places as the Council may direct. In times of war or other grave national emergency, the Annual Meeting may be waived, but elections will be held by mail ballot and Council or its Executive Committee will carry on the missions of the Association.
2. Prior to each Annual Meeting, the Council will develop an agenda indicating what will be done on each day. The new officers

will be installed on a day, time, and occasion selected by the incoming President.

3. The President (or, in his absence, a Vice-President) will preside at each business session of the Annual Meeting.
4. One hundred and fifty voting members will constitute a quorum.

Chapter Two. Disciplinary Actions

1. (a) Any Associate Member, General Member, or Fellow who, for three consecutive years, fails to pay dues required by Council will be notified by registered mail by the Treasurer of the Association that he will forfeit membership if arrearage is not paid by a specific date. If full payment has not been made by that date, the Treasurer of the Association will notify the Council. Unless, at its next meeting, the Council waives the arrearage or remits the dues, the delinquent member's name will be stricken from the rolls of the Association. Thereafter, he may return to the Association only by being processed as a new Associate Member or General Member, unless the Council orders reinstatement with or without waiving the arrearage.
 (b) Any member of a District Branch (unless he be a Life Member or Life Fellow of this Association) who fails to pay District Branch dues for three consecutive years will be notified by the Treasurer of the Branch that this arrearage will, on a specified date, be reported to the Secretary of the American Psychiatric Association. If, by that date, full payment of District Branch dues has not been made, the Secretary of this Association will be so notified. The Secretary of the American Psychiatric Association will advise the delinquent member of the provisions of this section (Section 1. (b) Chapter Two of the By-Laws) by registered mail and, at the next meeting of the Council of the American Psychiatric Association, this delinquency will be reported to Council. Unless the Council directs otherwise, the delinquent member will be dismissed from both the Association and the District Branch. Thereafter, he may return to the Association only by being readmitted to the District Branch in accordance with its regulations.
 (c) No Life Fellow or Life Member of this Association will forfeit membership in a District Branch for nonpayment of District Branch dues.
2. The Ethics Committee shall hear all complaints filed against a member. It shall

consist of six Fellows, at least one of whom shall be a Past-President of the Association. The terms of the members shall be adjusted so that each year two seats become vacant, and in each succeeding year the incoming President shall appoint members to fill the vacancies of the Committee. The President shall designate, from the membership of the Committee, a Chairman whose term shall be for one year. Vacancies developing during the term of any member of the Committee shall be filled by the President, who shall name an *ad interim* member or Chairman for the unexpired term of the previous member.

3. Any complaint concerning behavior, *specified in Section 4 of this Article*, shall be in writing and signed by the party making the complaint. Any person, including any member of this Association, may make such a complaint. It shall be filed with the Secretary who shall forward it to Council for action.
4. When the Council receives, through the Secretary, a complaint that a member has been engaged in unethical or unprofessional conduct, or has knowingly refused to comply with resolutions or requests of the Council, or has brought discredit or dishonor on the Association or on the practice of psychiatry, or has been convicted of a crime involving moral turpitude, the Council may (a) dismiss the complaint if less than two thirds of the voting members of the Council agree, or (b) refer the complaint to the Ethics Committee for consideration and recommendation on approval of two thirds of the Council.
5. If circumstances warrant, the Council, by two-thirds vote, may suspend any member of the Association, without prejudice, (for not more than ninety days) from any or all privileges of membership. Such action may be taken by the Council when it is considered to be in the best interests of the Association pending completion of the adjudicative procedures described below.
6. Upon receipt of a complaint from the Council, the Ethics Committee shall designate a Fellow of the Association to investigate the basis of the complaint and report his findings to the Ethics Committee. Any member under investigation is entitled to thirty days' notice in writing advising him of the nature of the charges against him and of the date set for hearing thereon.

A member so charged may appear before the Ethics Committee and be represented by counsel. If the member is unable to travel to the place set for the hearing, he may, upon written request, appear before one or more examiners designated by the Ethics Committee, who need not be members of the Committee. All examiners shall be Fellows of the Association. Testimony of the member shall be recorded and all copies must be signed by the member and examiner, certifying the accuracy of the transcript before submission to the Ethics Committee.

7. Upon receiving the report of the investigation, the Ethics Committee shall hold a formal meeting at which, in addition to personal appearance, the member charged may be represented by counsel who may submit a brief on his behalf for consideration by the Ethics Committee and Council. The Committee may (a) determine the complaint to be without merit and recommend to the Council that it be rejected; or (b) advise the Council that one or more of the charges in the complaint have been sustained and recommend that the member be admonished, reprimanded, suspended from membership for a specific period of time, or expelled from the Association.
8. The Council shall have authority to act upon the recommendations of the Ethics Committee. A majority vote of the Council shall be required to admonish, reprimand or suspend, but a two-thirds vote of the Council shall be required to expel a member from the Association. The Council may, by a two-thirds vote, impose a more severe penalty than that recommended by the Ethics Committee. The Secretary shall promptly notify in writing the member charged of the action taken. The Council's action, in any case, shall be by resolution and recorded in the minutes.
9. The records of the Ethics Committee and the minutes of the final action of the Council shall be filed with the permanent records of the Association and may be inspected by any member having a legitimate interest therein. Unless the member charged requests it, in writing, the name of such member shall not be included in the Council's open report to the membership read at the Annual Meeting of the Association, nor in the minutes published in the JOURNAL.
10. A member may appeal a disciplinary measure taken against him by the Council

to the membership by filing notice of such appeal with the Secretary within ten days of receipt of notification of the action of the Council. On receipt of such notice, imposition of the penalty shall be held in abeyance. However, if expulsion has been directed by Council, the member shall be suspended from all privileges of membership pending the outcome of his appeal. The matter shall be placed on the agenda of the next Annual Meeting where it shall be heard at a session attended only by voting members of the Association and the necessary secretarial staff selected by the President. The member shall be given an opportunity to be heard and to be represented by a person selected by him. The matter shall be discussed, the member excused, and a closed written ballot taken. If two thirds of those present vote to reverse the action taken by the Council, the complaint shall be rejected.

Chapter Three. District Branches

1. When a group of not less than twenty members (not more than 20 percent of whom may be Associate Members), residing in a contiguous geographic district, desires to create a District Branch, they will submit a petition, personally signed by the proposed charter members, to the Recorder of the Assembly of District Branches, together with a proposed Constitution and By-Laws of the Branch, requesting a specific geographical jurisdiction. The Assembly will consider the application and make report and recommendation to the Council. If the Council approves, the proposal will be submitted to the general membership of the American Psychiatric Association for disposition. If the proposal is approved by a majority of members voting, the District Branch will be created.
2. Requirements for membership in a District Branch will be the same as for membership in this Association. A District Branch may elect, as Affiliates, physicians practicing or residing in its area who are not eligible for membership in the Branch. Affiliates are not members and will be ineligible to vote or hold office in the Branch or the Association, and will not be tallied in computing the voting strength of the Branch in the Assembly.
3. Subsequent to the adoption of these By-Laws, every Associate Member and General Member of the American Psychiatric Association will belong to the District

Branch, if any, having jurisdiction over the area where he resides and/or practices. If a member transfers permanently to another area, the provisions of Chapter 6, Section 11, will apply. Voting members of the Association, not affiliated with District Branches at the time of adoption of these By-Laws, may, at their option, become members of an appropriate District Branch or remain "members-at-large" and so designated by Council.

4. A District Branch shall be approved for processing American Psychiatric Association membership applications (a) when its boundaries have been defined in its approved Constitution, and (b) after certification by its officers of its ability and willingness to serve in that capacity.
5. A District Branch's approval for processing membership applications may be rescinded (a) by request of a majority of members of that Branch attending a regular or special meeting thereof, or (b) by resolution of the Council, or (c) a recommendation of either the Membership Committee or the Assembly and concurrence of the Council.
6. If the creation of a new District Branch would require alteration in the jurisdictional area of an existing Branch, this fact should be communicated to the Recorder of the Assembly by the Secretary of the existing District Branch. If there is objection to the alteration by the membership of the existing District Branch, this shall be noted in the communication to the Assembly and representatives of both groups will be invited to discuss the matter when it is considered by the Assembly and the Council. The Assembly will make recommendations to the Council and the Council will make recommendations to the Membership of the American Psychiatric Association at the Annual Meeting. Disposition will be made by a majority vote of those present and voting.
7. Each District Branch will elect its own officers, arrange its own programs, and provide for its own expenses. District Branch officers will assume their duties at the close of business of the Annual Meeting of the American Psychiatric Association next following their election. They may be formally installed within thirty days prior to or subsequent to that date.
8. Each District Branch will select a delegate from its membership. These delegates, in the aggregate, will constitute the Assembly of District Branches. The Assembly will

meet at the place of the Annual Meeting of the American Psychiatric Association and during the period of that meeting. The Assembly may meet at such other times and places as the delegates of their Policy Committee may determine. The Assembly shall (a) consider matters referred to it by the Council and advise the Council thereon, and (b) present to the Council suggestions and recommendations on any other matters pertaining to the objectives of the Association.

9. The presiding officer of the Assembly shall be known as its Speaker. At each Annual Meeting the Assembly will elect a Recorder and a Speaker-Elect. The Speaker-Elect will become Speaker at the Annual Meeting next following election. If the position of Speaker becomes vacant, the Speaker-Elect will become Speaker for the unexpired portion of the term and for his own full term thereafter. If the position of Recorder becomes vacant, the Policy Committee will designate a member of the Assembly to fill the unexpired portion of the term as Recorder.
10. The Assembly is authorized to adopt and, in accordance with its rules, to amend a procedural code. Nothing therein will be inconsistent with the Constitution, By-Laws, or resolutions of the American Psychiatric Association or its Council.
11. The Assembly is authorized to create a Policy Committee to function on behalf of the Assembly in the interim between Assembly meetings.

Chapter Four. Voting by Mail

1. General Members, Life Members, Fellows, and Life Fellows (and only these) shall be eligible to vote by mail on candidates, proposed amendments, or referenda.
2. Any Fellow or Life Fellow, nominated for office by a petition signed by fifty or more General Members or Fellows, shall be considered an eligible candidate and his name shall be included on the official ballot for the next general election, provided that such petition has been filed at the Central Office of the Association prior to January 21st.
3. A Nominating Committee of five Fellows will be appointed by the President within sixty days after his installation into that office.
4. The Nominating Committee will announce the selection of a panel of candidates, at least one for each vacancy, not later than October 31st.

5. The Secretary will prepare an official ballot which will include the names of all candidates selected by the Nominating Committee or nominated by petition. The official ballot will be mailed to all eligible voters between February 1st and February 15th. The date on which ballots will be tallied shall be announced in a memorandum accompanying the ballot. This date will not be earlier than four weeks, nor later than two weeks, before the opening of the Annual Meeting. All properly sent ballots received prior to the time of tally shall be counted and the person who receives the greatest number of votes for each single office will be certified as elected thereto. The candidates who receive the greatest number of votes for office as Councillors will be certified as elected to the Council. Results of this election will be announced at the Annual Meeting.
6. Between February 1st and February 15th, the Secretary shall mail an official ballot to each voting member.
 - (a) To each voter shall be sent a package containing (1) the official ballot, (2) a letter or memorandum of instructions, (3) an inner envelope, and (4) an outer envelope.
 - (1) The official ballot shall contain the name of each candidate selected by the Nominating Committee, and of each candidate nominated by petition, together with a brief biographic account of the candidate. Candidates for the same office will be grouped together. By symbol, word, or phrase, it shall be indicated for each candidate whether he was nominated by petition or by the Nominating Committee. The county, state, district, or province of each candidate shall also be indicated. The ballots shall be identical, shall not be numbered, nor shall there be any provision for the signature of the voter. The final return date shall be indicated clearly near the top or near the bottom of the ballot.
 - (2) The memorandum of instructions shall furnish the key to any symbols or abbreviations in the ballot; shall clearly state the final return date of the ballot; and shall give instructions for folding, marking, and mailing.
 - (3) The inner envelope shall have printed on its face a serial number and a certificate which the voter will sign, indicating that he is the person to whom

the ballot was issued and that this is the only vote he is casting at this election.

(4) The outer envelope shall be large enough to accommodate the inner envelope. On the face of the outer envelope shall be printed or written the words "Board of Tellers" followed by the office where the ballots will be counted so that further addressing by the voter will not be necessary.

(b) Prior to the mailing of the ballots, the President shall designate a Board of Tellers consisting of members and employees of the American Psychiatric Association, at least one of whom shall be a Fellow of this Association, and at least one of whom shall not be a Member or Fellow of this Association. The President shall likewise designate one or two employees of this Association as custodians of the ballots. Record shall be kept of the serial number of the inner envelope mailed to each voter.

(c) As the outer return envelopes are received by mail, the custodian of the ballots shall open the outer envelope and compare the signature on the inner envelope and its serial number with the name and number in the record. If these are in accord, the custodian will deposit the unopened inner envelope in a safe place. If a discrepancy is found in the name or number, the inner envelope shall be referred to the Board of Tellers for a decision.

(d) On the day fixed for the counting, the custodian shall open each inner envelope and remove each folded ballot in the presence of a Teller, and place it, still folded, in a ballot box. The votes will be counted after all inner envelopes have been opened.

(e) The Chairman of the Tellers, or some person designated by the President, will announce the results of the election at the Annual Meeting.

7. VOTING ON AMENDMENTS TO THE CONSTITUTION AND BY-LAWS. After a proposed amendment to the Constitution or By-Laws has been circularized or published in the JOURNAL, pursuant to the Constitution, the Secretary shall prepare an official text of the proposed amendment to the Constitution or By-Laws, preceded by those sections of the Constitution or By-Laws that would thereby be amended. Under this text matter

there shall be printed the phrase "Are you in favor of this proposed Amendment?" and the words "Yes" and "No" on separate lines with space to indicate the voter's choice.

8. **VOTING ON REFERENDA.** Whenever the Council, the Assembly, or members in formal session at the Annual Meeting direct, by resolution, that a matter be referred to the membership by mail ballot, this shall be done in the manner as described in Section 7 above. The Council shall, by an enabling resolution, indicate the day of mailing and the return date on which the ballots shall be counted. There shall be a period of at least twenty-one days between these two dates. The wording of the resolution shall indicate whether the resolution is to be binding or advisory.
9. **EFFECTIVE DATES.** Amendments, new By-Laws, and referenda shall be effective on the date of the certification by the Board of Tellers unless a different effective date is indicated within the text of the proposal.
10. **CERTIFICATION.** After the tally of each mail poll, the Tellers shall prepare a written certificate indicating (a) number of ballots counted, (b) number of votes cast affirmatively and negatively for each candidate, (c) number of ballots disqualified and the reasons therefor, and (d) net results of the election. The full text of the certificate will be filed in the Secretary's office for inspection on request by any Member or Fellow. The net results of the poll, giving only the names of successful candidates and the text of successfully passed Amendments, will be announced at the Annual Meeting and published in the JOURNAL.

Chapter Five. Scientific Programs

1. Subject to ratification by Council, the Program Committee will have final authority to determine the acceptability, or conditions of acceptability, of scientific papers offered for the Annual Meeting.
2. The Program Committee will determine the date, time, and room for the presentation of each accepted paper.
3. The Program Committee will select a chairman and a recorder for each scientific session.

Chapter Six. Membership Processing

1. A person not previously affiliated with this Association, and living within the jurisdic-

tion of a Branch, will apply for membership through the appropriate District Branch. If he resides outside the area of a Branch approved for membership processing or is not eligible for membership in the District Branch having jurisdiction, he may submit an application for membership-at-large to the Secretary of the American Psychiatric Association.

2. If an applicant is elected a member of a District Branch, notification of his election will be forwarded to the Secretary at least thirty days prior to the Annual Meeting. Upon receipt of notification of election from the Secretary, the applicant shall become an Associate Member or General Member of the Association, provided that the Branch has been approved for membership processing. The list of members so elected by the District Branches during the preceding year shall be presented to the membership at the next Annual Meeting.
3. If an applicant is rejected for membership in the District Branch of jurisdiction, the applicant may, within ninety days of being notified, appeal the action of the District Branch by sending an application to the Secretary of the American Psychiatric Association with a request for election to membership-at-large. The Secretary will refer the application to the Membership Committee and advise the Council that such appeal has been received. This Committee will investigate the rejection and, at the applicant's request, grant him a personal hearing at a place designated by the Membership Committee. Representatives of the Branch will be invited to such a hearing. The Membership Committee will then submit a confidential report to the Council. The Council may reject the application or may submit the applicant's name to the membership of the Association for election as a member-at-large as provided in Section 4 below.
4. If an applicant lives outside the area of a District Branch approved for membership processing, or is not acceptable for membership in the District Branch having jurisdiction, the application will be reviewed by the Membership Committee and forwarded to Council for action. Council shall then present the applicant to the membership of the Association for election in the appropriate grade at the next Annual Meeting. Members, so elected, will be designated members-at-large.

5. Promotions from Associate to General Member will be made by the Council in appropriate cases, after hearing the opinions of the District Branch having jurisdiction and the recommendation of the Membership Committee. The Council is authorized to establish more detailed criteria for such promotions for the guidance of the Membership Committee and District Branches. The Council's refusal to promote an Associate to General Membership will be without prejudice to the Associate's right to make subsequent application.
6. Promotions from General Member to Fellow will be made by the Council after weighing the recommendations thereon of the Membership Committee and District Branch. The Council's failure to advance a Member to Fellowship will be without prejudice to the Member's right to make subsequent application. The Council is authorized to establish more detailed criteria for Fellowship for the guidance of the Membership Committee.
7. Advancement to Life Membership or Life Fellowship will be upon the Secretary's certification that the Member or Fellow had been a member in good standing in the Association for thirty years, and further certification indicating present grade of membership or fellowship.
8. Any member may nominate a person for Honorary or Distinguished Fellowship. The citation will show the person's services in the fields of psychiatry, mental health, or the social or behavioral sciences. Each citation will be surveyed by the Membership Committee who will report thereon to the Council. The Council will determine whether to confer Honorary or Distinguished Fellowship or whether to defer this recommendation. A deferred recommendation will not be renewed until two years or more have elapsed from the date of the earlier nomination.
9. A General Member or Associate Member who permanently moves out of the jurisdictional area of the Association may, on application to the Secretary of the Association, be granted Corresponding Membership unless the Council directs otherwise. Such member may, however, retain his previous membership category if he so desires and continues to pay dues.
10. Any psychiatrist living outside the jurisdictional area of this Association whose professional activities are of Fellowship caliber may apply for Corresponding Fellowship, or such an application in his behalf may be made by any Fellow or Life Fellow. This will be studied by the Membership Committee which will report thereon to the Council. The Council will take dispositive action on such applications.
11. A member of a District Branch who moves permanently into the jurisdictional area of another District Branch will become a member of the District Branch into whose area he has moved; except that, if the governing body of that District Branch grants a waiver, he may, if he wishes, remain a member of his previous Branch. After adoption of these By-Laws, every Associate Member, General Member, and Fellow of this Association living in a District Branch area will be a member of the District Branch having jurisdiction, except: (a) under conditions stated above; (b) ineligible under Article III, Section 3; and (c) exempt by the Council as a member-at-large, as provided in Chapter 3, Section 3.

Chapter Seven. Affiliated Societies

1. When any psychiatric society of a geographic division or region within this Association's jurisdictional area shall desire to become an affiliated society, it will submit to the Council a copy of its Constitution and By-Laws and a list of its members. If the Council approves, the recommendation shall be submitted to the voting membership at an Annual Meeting. If the majority of those present and voting so determine, the society will thereupon be designated an Affiliate Society of the American Psychiatric Association, subject to the limitations of Section 3, below.
2. Any Society that has been designated an Affiliate of the American Psychiatric Association, prior to the promulgation of these By-Laws, will remain an Affiliate Society, subject to provisions of Section 3, below.
3. In every affiliated Society, all members must be physicians; at least 75 percent of the members must be psychiatrists; and more than 50 percent of the Society must be members in good standing of the American Psychiatric Association.
4. No affiliated Society will speak in the name of, nor encumber funds of, the American Psychiatric Association.

Harvey J. Tompkins, M.D.,
Secretary.

REVIEW OF PSYCHIATRIC PROGRESS 1962

HEREDITY AND EUGENICS

FRANZ J. KALLMANN, M.D., AND EDWARD V. GLANVILLE, Ph.D.¹

This year the task of compressing an ever-growing output of genetically pertinent publications into a concise progress review assumed disconcerting proportions. As Glass(34) pointed out, no longer could a single individual be expected to digest more than a fraction of the 100,000 articles extracted by *Biological Abstracts* each year from over 6,000 periodicals of potential genetic interest. The same thing might be said of having to attend the numerous meetings and special symposia bearing on the study of human heredity.

In addition to the regular programs of national societies, the list of specialized conferences included those held by the New York Academy of Sciences (evolution of man; tumor immunity; tissue transplantation; relatives of man, etc.), the anniversary program of the Institute of Cancer Research (Francis Delafield Hospital) in New York, and symposia organized by the Social Science Institute of Washington University in St. Louis (determinants of human sexual behavior), the Tissue Culture Association in Washington, the University of Missouri (genetics today), the Vanderbilt University Medical Center in Nashville (birth defects), the Eastern Psychiatric Research Association in New York (advances in radiobiology and biochemical genetics) and the Manfred Sakel Foundation in New York (biological treatment of mental illness).

Earlier symposia, the proceedings of which became available in book form, were concerned with mental retardation and its genetic components(51), congenital malformations(25), radiobiology(29), chromosomal aberrations(16), normal variation and natural selection in man(6, 38, 67), biological aspects of the psychoses(28, 76), and expanding goals of genetics in psy-

chiatry, the topic of the recent anniversary symposium of the Department of Medical Genetics of the New York State Psychiatric Institute(48).

The many new textbooks, published here and abroad, varied considerably in degree of specialization. Among them were volumes on general genetics(1, 49, 57, 60, 69, 72), the evolution of man(13, 18, 66) and human genetics(9, 11, 12, 32, 74, 83) including a particularly comprehensive one in German(79). Other valuable books dealt with radiation genetics(21, 44), the biochemical basis of psychiatry(42), pharmacogenetics(47), growth and development(80), animal behavior(5, 52) and twins(31, 71). In addition, the *International Review of Cytology*(8) contained excellent chapters on genetic coding, chromosomes, sequential gene action and cellular differentiation, while expertly annotated reviews of basic, clinical and psychiatric genetics, previously published in the *Journal of Chronic Diseases*, appeared in a single volume(56).

Chromosomal anomalies were described in numerous pathological conditions as well as in the phenotypically normal(33, 62). However, except for the aberrations observed in certain cases of abnormal sexual development, Down's syndrome, myeloid leukemia and the chromosome -17 syndrome, the precise nature of the defects seemed to call for further amplification and confirmation. At any rate, the frequency and somatic stability of chromosomal mosaics proved to be an important consideration in accounting for the wide range of variation seen in abnormal sexual development(10, 81) as well as in the symptomatology of mongolism(14, 39, 53). Of importance also were reports on an aberration identified as a self-perpetuating ring-chromosome in a case of gonadal dysgenesis

¹ 722 West 168th Street, New York 32, N. Y.

(54) and on two sisters with multiple malformations who were found to carry an apparently identical supernumerary autosome(37).

Another small extra chromosome was detected in an 8-year-old boy who on psychological testing showed schizophrenia-like symptoms(78), and a complement of 47 chromosomes was also reported in twin girls who appeared schizoid from the age of 5(4). However, the psychiatric diagnosis in these cases seemed to require clarification, especially since 10 other schizoid children in the latter study were found to have normal karyotypes.

Deletion of part of a Y chromosome in several members of a family with a combination of muscular dystrophy and hypospadias was assumed to be associated with the genital defect rather than with dystrophy(59). On the other hand, an extra small acrocentric chromosome was found in some cells from 5 of 7 cases of dystrophia myotonica(26). Even more startling was the report(30) that a human XX/XY hermaphrodite may have resulted from double fertilization of a single egg by two sperms.

Recognition of chromosomal duplication opened new avenues for linkage studies in man. It was shown that an extra chromosome may result in the cell's accumulation of excessive amounts of the products of the genes situated on that chromosome. Increased activity of leucocyte alkaline phosphatase in Down's syndrome seemed to indicate that a gene controlling production of this enzyme may be located on chromosome 21(77). However, no difference in erythrocyte glucose-6-phosphate dehydrogenase activity (which is controlled by a gene on the X chromosome) was detected in individuals of the XO, XX, XXX or XXXX varieties(36). The discovery of a sex-linked blood group(55) furnished a useful marker for tracing the transmission of genes on the X chromosome.

The search for a biochemical anomaly in schizophrenia continued with inconclusive results and with a surfeit rather than a dearth of observed aberrations(2, 28, 42). On investigating whether the children of psychotics show more neurotic symptoms than a control group, Cowie interpreted her finding of no increase as supporting

the hypothesis that the neuroses and psychoses are etiologically distinct(15). Also studied was the possible effect of communication stress on the development of schizophrenia in the presence of early total deafness, but no evidence of an increased frequency of this psychosis in the deaf as compared with the hearing was obtained(48). No gross chromosomal disarrangement was found in homosexuals(65, 73), although Slater reported that male homosexuals have an older maternal age at birth than controls, at the same time suggesting heterogeneity in the etiology of this condition(73).

Comprehensive reviews of genetic principles were presented in regard to aging(35), intelligence(40), drug-induced parkinsonism(61), phenobarbital idiosyncrasy(24), and congenital abnormalities(70). The deleterious effects of thalidomide in producing developmental defects of a highly specific nature were also explored(58).

Time as a dimension in the interplay of genetic and environmental forces, and the relationship between instinct and learning during growth and maturity were lucidly discussed by Eiduson(22). Perhaps equally worth mentioning was the fact that autoimmunization (the production of antibodies against the body's own proteins) received renewed interest, both in diseases with a strong genetic component such as Hashimoto's disease(17), and in those with a relatively weak predisposition such as multiple sclerosis(7).

Twins continued to be popular subjects of psychiatric research. Recent work included studies on intellectual subnormality(48), criminal behavior(84), schizophrenia(68), psychoneuroses(43), intellectual changes in aging(46), homosexual behavior(50), deafness(48), cancer(45), the correlation between mental and physical growth(3), infant vocalization(63), administration of hallucinogens(82) and a psychological study of identical twins with ovarian dysgenesis(64).

The extensive normal variation demonstrable within human populations(38, 75) was shown to be responsive to the forces of natural selection occurring within civilized communities(18, 67). The important point that biological variation and political

equality should not be regarded as mutually exclusive was eloquently made by Dobzhansky (19), and a stimulating work on the origin of the human races was written by Carleton Coon (13). With the mounting crisis in world population growth receiving more and more attention, it was helpful to have the dilemma succinctly stated by Dorn (20). The sort of medical advice given in premarital counseling (41) and the prognosis after therapeutic sterilization (23) also were expertly surveyed, and equally detailed was a description of the genetic implications of consanguineous marriages (27).

Once again, the 1962 Nobel Prize for medicine was awarded to geneticists, this time to Drs. Watson, Wilkins and Crick for their pioneering work on the molecular structure of DNA. The R. Thornton Wilson awards (Eastern Psychiatric Research Association) were presented to Dr. Blair Rogers for his systematic studies on the genetics of tissue transplantation and to Dr. Eugene Oakberg for his report on the results of experimental radiation genetics in man. The first William Allan Memorial Award of the American Society of Human Genetics was given to Dr. Newton Morton for his outstanding work in developing new techniques in statistical genetics.

Unfortunately, the discipline of genetics lost two of its grandmasters during the year, Sir Ronald Fisher at the age of 72, and Dr. William Castle at the age of 94. Death came also to the renowned anthropologist, Sir Ruggles Gates.

NEUROPATHOLOGY, BIOCHEMISTRY AND ENDOCRINOLOGY

ORTHELLO R. LANGWORTHY, M.D.¹

Basic studies may offer productive leads for studying demyelinating diseases, such as multiple sclerosis. Luse(1-4), using elec-

¹ The Johns Hopkins University.

tron microscopy, has shown that myelin is an intricate lamellar structure that is part of the sheath cell. Since all axons have at least a single cell membrane about them, it may be reasoned that all axons are myelinated. The small "C" fibers have multiple axons within a single Schwann cell rather than the single axon within the Schwann cell as a myelinated fiber. A metabolically active Schwann cell may manufacture the large amount of membrane necessary to form myelin by fusion of cytoplasmic vesicles. In the central nervous system nodes of Ranvier occur as in peripheral nerves. It may well be that more than one glial cell contributes to the sheath of a single segment of myelin. As glial processes insert themselves between the unmyelinated axons there is a predominance of oligodendroglial processes containing numerous vesicles. It is necessary to have both a neuron and a sheath cell before myelin will form. The integrity of both is necessary for the maintenance of the myelin sheath. Wallerian degeneration is a prototype of demyelination following an insult to either the neuron or the axon. The second type of demyelination is the result of an insult to the sheath cell, be it a Schwann cell or oligodendrocyte. The first changes are swelling of the cytoplasm and the cellular organelles in the sheath cells. Later the myelin disintegrates but the axon is unaltered.

Bornstein and co-workers(5-7) were involved with the living events of myelin formation as visualized directly by serial observations of cultured newborn kitten and rat cerebellum. During the phase of early myelin formation single neuroglial processes may be seen spiralling around the axon. Other axons appear to be involved with multiple glial cell processes, each seemingly contributing to the multiple layering. The internal structure of myelin may be produced by multiple neuroglial cell processes interdigitating about any particular axon.

Bornstein and Appel(6) exposed cultures of myelinated fibers to high concentrations of serum from animals with acute allergic encephalomyelitis. The first observable alteration appears as a swelling of the neuroglia. The myelin sheaths soon become disfigured by fusiform swellings at irregular intervals. The sheaths become indistinct

and finally fade into a background of neuroglia, neurons and small fat granules. Meanwhile some neuroglia have become enormously swollen. Their pyknotic nuclei frequently lie against the cell membrane with retracted elements of the cytoplasm. The main body of the cell is filled with fluid and particles in Brownian movement. At this time neurons seem little affected. The axis cylinders appear intact. The tissue is far from overwhelmed by the reaction. Removal of the foreign serum and its replacement by normal nutrient medium halts the process. Remyelination may occur after a short recovery period.

These workers also studied the first point of attack of the active agents on the neuroepithelium. Cultures of the rat or mouse cerebellum exposed for a suitable time to the rabbit experimental allergic encephalomyelitis serum were washed, fixed and then overlaid with fluorescein labelled duck anti-rabbit globulin. The preparations were then viewed in a microscope illuminated by ultraviolet light. Before demyelination is too advanced, the antiglobulin preparations attach to the neuroglial cell membranes and the myelin sheaths as demonstrated by the location of the fluorescence. If the demyelination is allowed to proceed, the globulins are no longer situated exclusively on the cell membranes but are found diffusely within the glial cytoplasm. Finally a culture washed free of experimental allergic encephalitis serum and returned to normal in vitro conditions for a number of days may reveal a very light trace of rabbit globulin still outlining the neuroglial cell membranes. It is possible that the first point of attack of the encephalotoxic factors in the experimental allergic encephalitis sera may be the neuroglia cell membrane and the myelin sheath which has been demonstrated to be composed of modified glial cell membrane.

Richter(8) has recorded rhythmicity in both organic and emotional diseases which he discusses as biological clocks. He has gathered over 500 cases from experience or from the literature. A remarkable example is intermittent hydroarthroses which he illustrates from 128 cases. This is a condition with no fever, no leucocytosis, no changes in pulse rate, no mental or emo-

tional symptoms. In most instances swelling of the joints constitutes the sole abnormal symptom. In any one patient the length of the cycles of swelling of a joint tend to be so constant over periods of months and years as to form a characteristic rather than an average length of cycle. The lengths of cycles for all this group fall within a narrow range of 7 to 14 days. Although in most patients with multiple joint involvement, swelling occurs at the same time in all joints, swelling may reach a maximum at different times in respective joints. The cycles then have the same length but they are out of phase.

Richter showed that in emotional illnesses mood variations, sleep and pulse may show rhythmical variations of remarkable constancy over months and years. In one patient depressed and normal phases each lasted about 20 days. One phase may be abnormal and the other normal or they may both be abnormal. These rhythmical changes may appear at any age. They may persist for months or years or be evident only for short periods. The well known biological clocks are the 24-hour clock of all humans and the 28-day menstrual clock of women. Many other timed mechanisms are present as becomes unmistakably clear under certain abnormal conditions. Cyclic phenomena are made more readily visible in lower animals than in man. Richter suggested that there are three types of clocks. One is peripheral as in the blood forming tissues of the bone marrow. Another is located in the brain, particularly in the hypothalamus and reticular formation. The third is homeostatic involving target organs and endocrine glands. It is assumed that the functioning units of every organ of the body have an inherent cycle characteristic of the organ. The units may be put in phase by such things as shock, trauma or allergy.

Several groups of investigators are studying hyponatremia and the antidiuretic hormone in relation to the nervous system. Hayward and Smith(9) stimulated various regions of the brain in trained conscious monkeys by means of stereotaxically implanted electrodes. The results were determined by various techniques including insulin and creatinine clearances and osmality determinations. Excitation of the

amygdaloid complex, the olfactory tubercle, the hippocampus and the diagonal band resulted in the release of antidiuretic hormone. Similar positive results were obtained from areas in the mesencephalic tegmentum. These investigations show that excitation of regions of the brain other than the hypothalamus can release antidiuretic hormone and indicate a more widespread control than has previously been demonstrated. The syndrome of cerebral hyponatremia also suggested to Hofer, *et al.*(10), the existence of pathways for primary central nervous control of antidiuretic hormone. A conditioning procedure was employed to investigate the possible physiologic role of such connections in modifying simple water diuresis. Five subjects on controlled diet, hydration and activity received 750 cc. of water by mouth in the same laboratory room for two weeks. After their conditioning a single 30 cc. swallow taken in this setting produced a substantial diuresis in each subject whereas 150 cc. taken in a different setting, but under otherwise similar conditions merely maintained control flow rates. Analysis of urinary composition showed marked change in free water clearance without alteration of excretory rates for sodium, chloride, potassium or creatinine, thus suggesting a conditioned decrease in circulating antidiuretic hormone. These experiments define certain circumstances under which nervous integration can alter neurohypophyseal secretion and reveal the capacity of this regulatory system to respond in terms of past experience even in preference to current homeostatic demands. Epstein, *et al.*(11), reported the case of a 16-year-old girl in whom chronic hyponatremia was associated over a period of years with excessive and paradoxical urinary losses of sodium. The neurological state was normal as long as the serum sodium was not allowed to fall. When the sodium did fall she developed mental confusion, tremor, weakness and positive Babinski signs and, on at least one occasion, a generalized seizure. Further study showed that hyponatremia and renal salt wasting resulted from inability to excrete a dilute urine after drinking water, probably owing to continued and inappropriate release of antidiuretic hormone. She has been success-

fully treated with the single and simple admonition to take liquids only when thirsty. Faris, *et al.* (12), reported a case of severe electrolytic depletion associated with coma and convulsions believed to be caused by chlorothiazide. On the opposite side Dodge, *et al.* (13), stated that irritability, restlessness and stupor are the usual neurologic signs of hypertonic dehydration in infants and children. Severe degrees of hypertonicity may be associated with irregular twitching, trembling, nystagmus, coma, respiratory failure and occasionally generalized seizures. High voltage slow waves and sometimes sharp spikes appear in the electroencephalogram with maximal hypertonicity but these changes correlate poorly with the twitching and trembling observed and recorded electromyographically from limb muscles. The hypertonicity interferes with functions of the central and peripheral nervous system at various levels.

Bard and Woods (14) showed that an intact hypothalamus was essential for the production of endotoxin fever in cats. Intravenous injection of a small quantity of typhoid vaccine produced an average rise in colonic temperature of 2.4° C in normal cats. This achieved an average maximum after 166 minutes and lasted from 5 to 12 hours. Similar thermal responses were obtained in cats which survived removal of all the forebrain except hypothalamus and preoptic areas, for periods of 8 months and in cats many months after decerebellation. All these animals maintained a normal core temperature during long exposures to extreme cold. Other cats were rendered poikilothermic by section of the brain stem below the hypothalamus and were studied after 24 to 349 post-operative days. When these animals were injected with the toxin, no trace of a febrile response was ever obtained. Like normal and hypothalamic cats they responded to the endotoxin with a transient leucopenia and yielded within 120-180 minutes a serum which produced a

typical endogenous pyrogen fever when injected into normal hypothalamic cats.

Harlow (15) studied the emotional growth of young monkeys. He suggested that the real mother facilitates social and sexual development but apparently normal relationships with peers can develop in spite of inadequate mothering if ideal conditions are provided for infants to develop affectionate relationships with each other. There have also been some exploratory studies to determine neurological mechanisms underlying social adjustment in monkeys. Bilateral lesions of the prefrontal and temporal neocortex have not been found to effect any affectional systems but bilateral section of the fornix has influenced the development of peer interactions.

ELECTROENCEPHALOGRAPHY

W. T. LIBERSON, M.D.¹

The purpose of this brief report is to indicate the trends which have emerged in

¹ VA Hospital, Hines, Ill.

this field during the past year, particularly in the areas of interest to psychiatry. Several new EEG books have been published :

Brazier(8) describes a detailed and fascinating story of the discovery of electrical activity of the brain (see also 7). A helpful atlas of EEG's of normal children was published(17). A brief summary of the present status of EEG in psychiatry will be found in *Clinical Electroencephalography* by Killoh and Osselton(28). A book on *Bioelectricity*(58) gives pertinent information; approximately 50 authors contributed to *Electrical Stimulation of the Brain*(57). Cohn presented his investigations on correlations between EEG, brain lesions and picture drawings(11).

Sleep. It has been generally accepted since the classical investigations of Bremer that high voltage, slow activity following a high transection of the cat forebrain (*cerveau isolé*) corresponds to continuous deep sleep in these animals, allegedly deprived by this operation of the centers of wakefulness. It is suggested now(59) that this observation is true only for the relatively short postoperative survival period. With a new technique overcoming the difficulties in postoperative care, the animals survived from 23 to 63 days. In such animals, alternation of sleep and wakefulness electrical activity in the permanently isolated forebrain was observed. The study of sleep deprivation and dreams have been numerous. A significant increase (from 6% to 26%) in the mean percentage of total sleep time characterized by EEG slow waves and a significant decrease (22.5% to 7.5%) in the mean percentage of total time spent in dreaming ("paradoxical" eye movement periods) was found during the first and second recovery nights after 108 hours of sleep deprivation(3, 4, 45). A major study showed that evoked responses to clicks characterise different sleep phases (slowing in stages 3 and 4; decrease in amplitude during the "paradoxical" stage)(60).

Mental Activity. Reaction time in normal individuals was shortened when the signal to respond was given during a spontaneous beta activity, but the difference was only 12 msec., much slighter than the advantage derived from a specific warning signal(13). Other investigators(14, 34) found that when such a signal caused alpha blockage, reaction times were decreased significantly

in normals but not in schizophrenics. Reaction times even increased in these patients when the warning signal was given 4 seconds before the signal to respond.

Evoked Potentials. Generally available averaging and integrating devices, permitting an easy recording of scalp evoked potentials, are responsible for reactivation of research in this field. Much effort to display the EEG effects of various sensory stimuli is being pursued with the aid of integrating devices and computers(41, 42). This technique results in an automatic mapping out of instantaneous electrical fields. This study will certainly activate other programs concerning computer analysis in EEG. As a by-product of this investigation, very slow 15-20 per minute low amplitude slow waves, independent from respiratory movements, were described(44).

A warning was voiced that some of the early components induced by auditory and visual stimuli, having an occipital predominance, may be of muscular origin(5). This is hardly the case, however, of somatosensory evoked potentials predominating on the side opposite to the stimulated nerve. Some of the components of this response are of very short latency (12 msec.) They predominate in the upper cervical region and are of unknown origin(33). A comparison of potentials elicited by various stimuli, derived from intracerebral electrodes, with the scalp ones(20), reveals two scalp components with particular topography and functional relations. One component arises chiefly in the limbic cortex as a general arousal response and is subject to rapid habituation or augmentation. The other involves frontal neocortex and is related to a laborious establishment of significant associations between stimuli(12). In the case of somatosensory responses, the following components were tentatively identified in the order of their increasing latency: component 1 is equated with a thalamo-cortical radiation response; component 2 with a primary positive response; component 3 and 4 with "secondary responses"; and component 5 with a "non-specific" classical V potential(1). The use of paired stimuli applied to the median nerve permits one to study the excitability cycle of the corresponding brain structures by

recording evoked potentials. According to the same investigators(1, 21) the early components recover in 50 msec. However, according to others, the initial recovery in normal individuals occurs within 20 msec. Two-thirds of mental patients showed less complete initial recovery than controls. These included personality disorders, schizophrenics, and psychotic depressives. Patients with "dysthymic" neuroses (anxiety, depression of psychophysiological reactions) did not differ from normals. This change is reversible after successful electrotherapy. It was also found that patients had higher amplitude evoked potentials than controls (47-55). The state of awareness influences sensory evoked potentials (increase in specific attention states, decrease in drowsiness, or when attention is directed to another sensory modality)(18, 60). The evoked responses to clicks and flashes were also studied in mental patients. It was concluded that in patients exhibiting violence and sub-normal intelligence, large responses were obtained at theta frequencies. Patients with "sadness" and agitation showed maximum responses to alpha and theta rates. Non-adaptive, tense and hallucinated patients had click responses at alpha rates only, and responses to flashes at all rates (10). Other investigators(6), who studied evoked potentials elicited by flicker found extreme variability of patterns within the same patient. The recording of intracerebral evoked responses was used for guiding neurosurgeons in localization of deep cerebral structures(23).

Rheoencephalography. This new technique deals with the recording of intracerebral impedance. It allows one to investigate cerebral vascular changes and, therefore, contributes to the study of vascular lesions(9, 27, 30). The application of the method to mental patients is still spotty and nonconclusive, although recently this method suggested abnormalities in schizophrenic patients(37, 56). Another application of rheometric method is its help in localizing the ventricles during stereotaxic surgery(43).

Psychopharmacology. A comparison of the effect of chlorpromazine, imipramine and placebo suggests that EEG frequency analysis provides quantification of neuro-

physiological changes with psychotropic drugs for psychiatric research(16). Anti-depressants, which frequently aggravate schizophrenic symptoms, accentuate pentothal effects on EEG when the symptoms are activated. A prolonged treatment in depressions produces no similar change(22). Chlordiazepoxide (Librium)(40 mg/kg for epileptic patients) elicited the following changes: 1) increase in fast activity (18-24 c/sec.3; 2) reduction of paroxysmal discharges; 3) reduction of background slow activity; 4) increase of alpha activity; 5) increase of theta activity(26). However, other investigators(19) found that with high dosages (90 mg. for several weeks) rapid rhythms disappear and the background activity slows down. Intravenous administration of chlorpromazine (3.5 mg/kg) in cats increased by 50% the amplitude of evoked potentials (elicited by sciatic stimulation) in the anteromedian hypothalamus. It also increased their latency up to 25%. The author believes that this drug affects multisynaptic systems responsible for these evoked potentials(15). Interesting results were found on oligosynaptic responses of the dorsal hippocampus following stimulation of the contralateral homologous area. Chlorpromazine did not change an average amplitude of the evoked potentials but did increase their variability. Still more pronounced increase in variability without change in average amplitudes of potentials was found following administration of JB-835 (monoamine oxidase inhibitor) and 5-hydroxy-tryptophane. It is possible that previous research has overlooked the importance of the variability of electrophysiological responses as a distinct and important physiological parameter of behavior(32, 35, 36, 39).

EEG and Clinical Psychiatry. A revival of the study of abnormal EEG in mental patients, free of any history of organic or epileptic disorder, seems to occur. The presence of paroxysmal discharges was again described in neurotic children(2); or in those with behavior problems; in some aggressive psychopaths, in somnambulism, and catatonics, particularly after an emotional "activation," (their presence is estimated at 2% in about 10,000 non-epileptics, psychotic patients)(46); in hy-

pochondriacal and hysterical patients with autonomic dysfunction, as an expression of a vicious circle between the somatic and psychotic factors(31); in psychiatric patients with neurotic and depressive states (left temporal foci), this abnormality being activated by hyperventilation and by 3 per second clicks and increased during depressive episodes (when they were associated with a peculiar sensitivity to anti-depressive drugs which can be used in only moderate dosages in these cases)(6); in schizophrenia (temporo-occipital abnormalities) with lowering of the metrazol threshold, this drug being capable of eliciting a temporal lobe seizure in some cases (40). However, other authors found that whenever mental patients showed either focal or diffuse dysrhythmic activity, even though they did not present any definite neurological signs, correlation could be established between the EEG findings and the results of pneumoencephalography(24). Still other investigators believe that the proportion of abnormal tracings in psychopaths is the same as in a normal population(29). On the other hand, the occurrence of slow posterior rhythms in adult patients (2.5-4.5 per second) without any definite neurological disease was once again analyzed. Seventeen cases were found in a population of 11,000 patients. A considerable spread of clinical diagnoses was found. A high incidence of mental and autonomic dysfunction was observed. Thirty percent of the cases had radiologically proven gastric or duodenal ulcers(38).

The presence of abnormalities in schizophrenic patients was considered from another point of view. In a population of 61 female adult patients, half of the patients had normal EEGs. The other half showed "dysrhythmic" and "abnormal" records. The patients with abnormal records showed a higher sensitivity to treatment, both from the clinical and EEG point of view. The authors believe that this type of record indicates a plasticity of the schizophrenic process(25). It seems to this reviewer that such an approach is more fruitful than the traditional comparison of the normal population with that of mental patients; namely, to determine in what way the presence of abnormality may affect an individual pa-

tient in a group of patients clinically diagnosed in a similar way. The incidence of a narrow pelvis is as high in pregnant women as in the general population; yet, its presence affects the type of delivery.

CLINICAL PSYCHOLOGY

OSCAR A. PARSONS, Ph.D.¹

In this review the contributions of both clinical and non-clinical psychologists to a variety of problems of relevance to psychiatry are presented.

Pregnancy and Birth. In Grimm's(15) extensive study of tension and pregnancy there was a significant positive relationship between the index of tension and amount of weight gained during pregnancy and length of the second stage of labor. Mc-

Connell and Daston(23) found that positive versus negative attitudes toward the pregnancy were significantly related to Rorschach barrier and penetration body image scores. Davids and DeVault(10) found significant differences in anxiety, on a number of measures, between groups of women who had normal versus abnormal (complicated) deliveries. The only measure on which the groups did not differ was the patient's own direct rating of anxiety.

Personality Development. In view of the

¹ University of Oklahoma Medical Center

recent widespread interest in the effects of maternal deprivation upon subsequent personality development, Yarrow's (35) critical review is of some importance. The one finding of which there seems to be little doubt is that sensory deprivation over a sufficiently long period during the first year of life is likely to be associated with severe intellectual damage.

How children get along with their peers is of predictive importance for later conduct. Child guidance cases who had difficulty in peer adjustment, compared with cases who did not, had significantly higher "bad conduct" ratings while in the military, Roff (27) reports. An experimental investigation of the process of identification by Bandura and Huston (4) indicates that subjects who experienced a previous rewarding interaction with a model (adult) imitated the model to a much greater extent than did subjects who experienced a cold and distant relationship.

In view of the importance accorded to the development of conscience or superego in psychodynamic personality theory, an extensive study of moral responses to transgression in children by Aronfreed (1) is noteworthy. The responses of the children to a projective test were studied in relationship to social class, sex and mother's punishment practices. All three were found to be significantly related to the children's moral responses. The strong effect of social class led Aronfreed to the conclusion: "The marked social patterning of the moral responses . . . should be treated as distinct moral phenomena and not as equivalent reflections of an underlying unitary phenomenon such as conscience."

Normality and Adjustment. While most workers would agree that preoccupation with the abnormal has provided a one-sided emphasis for theories of behavior, studies of "normal" individuals have been rare. One such by Bonny (6) indicates that 30 "normal" undergraduate psychology students, who were nominated by their peers as "good representatives of your conception of a normal personality," had many unfavorable objective conditions in their developmental histories, e.g., severe parental rejection, broken homes. Twenty-six described one or more rather serious psy-

chological stress or social conflicts which they had experienced or were still involved in. Trauma, early unhappiness and stress are not sufficient explanations for the development of behavior disorders.

In another important study, a representative sample of the resident population of adults in the United States was interviewed about their feelings of distress in different life areas. Veroff, Feld and Gurin (31) identified four factors of distress common to men and women in their everyday life: felt psychological disturbance; unhappiness; social inadequacy; lack of identity. The emphasis is placed upon different areas of distress varied as a function of sex role and education, the latter being one important index of social class.

Learning, Perception and Awareness. An important contribution demonstrating the long-term retention of a conditioned response is provided by Edwards and Acker (13). A group of navy veterans responded to the battle stations signal with a significantly greater galvanic skin response than a control group of army veterans. To account for the results, the authors refer to Gantt's conception of schizokinesis, that is, the persistence of inappropriate conditional visceral responses long after the somatic motor components disappear.

The psychological literature for 1962 is replete with studies of verbal reinforcement which have implication for clinical interaction. For example, Marlow (22) reinforced, by "saying Mm-hm in a flat monotone," positive self-references in the responses of subjects to four general questions about their life situation. Subjects who were previously rated high on need for social approval produced significantly more positive self-references than a comparable group who had a low need for social approval. Further, in answer to a series of questions at the end of the interview none of the subjects were able to state the contingency, i.e., the relationship between the experimenter's "mm-hm" and the nature of the content which was being reinforced.

Salzinger and Pisoni (29) found schizophrenics responsive to the reinforcement of statements of affect within a 30-minute session. Ten or more reinforcements were necessary in order for the conditioning effect

to be manifest in their schizophrenic groups. Waskow(32), on the other hand, using "reflection" of feeling, a combination of feeling and content, and content only, with groups of college students found that only the group who had the latter condition responded to the reinforcement. While differences in method and subjects may account for these different results, the moral is rather clear: easy and glib generalizations cannot be made from verbal conditioning studies to psychotherapy.

A continuing debate is present concerning whether subjects who respond to reinforcement are aware or unaware of the relationship between the content being reinforced and the reinforcing agent, *i.e.*, the contingency. Behavior, awareness and a number of other issues are discussed at length in an important symposium edited by Eriksen (14).

Assessment Process and Techniques. One of the most vexing problems to clinical psychologists is the discrepancy between the subjective certainty of the experienced clinician concerning his interpretation of his assessment techniques and the lack of objective demonstration of predictability when put to experimental tests. Horowitz's(18) study is an example of the dilemma. She found that skilled clinical psychologists were able to predict therapists' descriptions of patients significantly better than naive judges, and that clinicians using test materials plus biographical information could predict significantly better than clinicians using biographical materials alone. However, their best predictions were not significantly different from the base rate predictions! Holt(17), in a thoughtful article, concerns himself with aspects of this troublesome problem. He believes that the essence of clinical work lies in interpreting verbal meanings and considers a number of methods for doing this; the title of his article, "Clinical Judgment as Disciplined Inquiry," reflects this emphasis.

An example of the type of study which seems promising for the unraveling of the process of clinical judgment is that of Mahrer and Young(21). Over a thousand judges, psychiatrists and psychologists in the VA made a diagnostic statement on the basis of sentences serving as cues or cue

combinations. The results suggest that the utilization of combination of cues is a complex and multi-determined process, but has predictable characteristics.

A new 20-minute standard interview is reported by Wittenborn, *et al.*(34). In addition to content latency, duration of speech and non-verbal behavior are recorded. Wittenborn found the latter variables significantly related to anxiety, hysteria, hypomania and depression. Such a tool should have use in a wide variety of research contexts. A "Minimal Social Behavior Scale" has been demonstrated to be reliable and valid in differentiating regressed from non-regressed patients and should be useful as a criterion measure in research with chronic neuropsychiatric patients(12). Aumack(2) devised a useful rating scale which deals with two aspects of psychiatric patients' social adjustment: work level and socialization level.

The issue of test response bias or set, that is acquiescing or presenting self in a favorable light (or the obverse) on the personality-type questionnaires, has received extensive investigation throughout the year. McGee(24) reviewed many of these articles.

Behavioral Change and Psychotherapy. The application of learning theory to problems of behavioral change and psychotherapy appeals to many psychologists. Boardman(5) presents an interesting case study of a child in whom remission of symptoms was achieved by application of "simple learning theory principles." No psychotherapy was given; rather, the parents were instructed to reward desired behavior immediately while important gratifications were to be withheld during periods of misbehavior. In the case example, the parents essentially applied punishing procedures. Both Bandura(3) and Miller(25), who comment on Boardman's approach, point out that much of the literature, in both the animal and human areas, indicates that reward is more effective in changing behavior than punishment. Murray(26) in an invited study of Rosen's direct analysis technique finds that, from a learning theory point of view, Rosen punishes psychotic symptoms, extinguishes anxiety about family conflicts through encouraging the expression of culturally prohibited family feelings

and positively rewards transference statements. Again, as in Boardman's approach, Rosen's punishment practices are questioned. Wolpe's systematic desensitization techniques were applied in group treatment of phobic disorders by Lazarus(20). Follow-up studies and comparison with groups treated by interpretive psychotherapy revealed a striking effectiveness of the sensitization technique.

The importance of the therapist's reaction to dependency statements in the initial interview is noted by Winder, *et al.*(33). A group of terminators in psychotherapy had significantly higher avoidance of their dependency statements by their therapists than a group who stayed in psychotherapy. A second aspect of the study indicates that approach and avoidance responses to dependency statements by the therapist elicit more and less, respectively, subsequent dependency statements by the patients, a finding typical of verbal reinforcement studies.

Cartwright(8) replicated an earlier study which found that patients after psychotherapy showed greater consistency in the self-picture. While controls (not receiving therapy) also increased in consistency over time, the psychotherapy group showed qualitative changes in self-concept while the controls merely seemed to be consolidating previous impressions.

An interesting study by Carson and Heine(7) noted a curvilinear relationship between improvement as a result of psychotherapy and degree of similarity of personality of the therapist and the patient. Extremely similar or dissimilar therapist-patient pairs had significantly lower therapeutic gains than those pairs who were medium to slightly above average in dissimilarity.

The orientation of psychotherapists on a number of different scales related to psychotherapeutic practice was evaluated by Sundland and Barker(30). Psychoanalytically oriented psychologists and Rogerian psychologists differed on most aspects of the therapeutic process. The interpersonally-oriented (Sullivanian) psychotherapists tended to fall between the two. Experienced psychotherapists were more similar to inexperienced psychotherapists of their own school than to therapists of the other schools

of thought. While this finding seems to contradict the commonly held belief that experienced therapists of all schools are more similar, it should be noted that the present study dealt with attitudes rather than the therapeutic protocols.

Psychopathology. In a clear, well-reasoned paper, Zigler and Phillips(37) evaluate the logical status of psychiatric diagnosis as a classificatory system. They state that if psychiatric diagnosis is approached with assumptions that prognostic and etiological statements are necessary correlates of such description, then the present diagnostic system may be considered faulty and vague. They suggest that such assumptions are premature and that diagnosis is eminently justifiable when viewed as a way of classifying symptoms. They call for an open and expanding system of classification.

In support of their position, Zigler and Phillips(36) provide a tripartite classification of symptomatic behavior: 1) "self-deprivation and turning against the self," 2) "self-indulgence and turning against others" and 3) "avoidance of others." While there is some relationship between the symptoms and traditional psychiatric classifications, the amount of information conveyed about symptomatology by assignment to diagnostic category is minimal. Further, Zigler and Phillips(38) find their classification of symptomatology to be highly related to premorbid social competence scores. Perhaps a combination of the traditional diagnostic system, without its etiological and prognostic correlates, and the symptom cluster analysis of Zigler and Phillips would be a more meaningful approach to the problem.

The process-reactive distinction in schizophrenia has received much attention. Heron(16) reviews much of the research in this area, especially studies which utilize the following scales as criteria: the Kantor, Wallner and Winder items, the Elgin Prognostic Scale and the Phillips Scale. He concludes that while the process-reactive studies have succeeded in explaining schizophrenic heterogeneity in a more meaningful manner than traditional diagnostic groupings there remains considerable work to be done in quantification on these scales. Chapman, Day and Burstein(9) point out that

both the Elgin and Phillips scales, although providing quantification of premorbid factors, do not consider sub-cultural and regional sociological differences and accordingly are limited in their application. Kantor and Jackson(19) review a number of findings relating life history variables to symptoms and prognosis.

Zigler and Phillips(38) conclude that the process-reactive distinction in schizophrenia is reducible to a social maturity-competence dimension; they suggest that the social maturity dimension is applicable to all psychopathology. In support of their position are the findings of Rudie and McGaughran(28). The most significant differences between "reactive" and "essential" alcoholics were found on variables similar to those constituting the social competence scale of Zigler and Phillips. If social maturity is the fundamental variable, then certainly Chapman's critique of the present scales, *i.e.*, the fact they may not be valid for certain subcultures and societies, must be considered.

In conclusion it might be noted that the frequency with which the phrase "varied as a function of social class" (or its equivalent) has appeared in this brief survey emphasizes the importance of the social psychological approaches to the theoretical and empirical study of human behavior.

CLINICAL PSYCHIATRY AND PSYCHOTHERAPY

NOLAN D. C. LEWIS, M.D.,¹ AND PAUL H. HOCH, M.D.²

CLINICAL PSYCHIATRY

Since a considerable proportion of publications in the field of clinical psychiatry is involved with or centered in pharmacodynamics, a subject which is reviewed elsewhere in these progress reports, our focus is limited to the selection of a few contributions which we consider to be informative in terms of mental mechanisms and psychotherapy. The following selected samples are not intended to imply that there are not many others, among the great mass of published studies deserving of special notice if space permitted.

Atkin(1) in discussing mental disorders and external stress believes the concept that these disorders are increasing is only an impression. He holds that indirect external stress has been given an unjustified importance as an etiological factor. In fact, it is a normal aspect of living. Degrees of stress may be pathological for a certain individual, but there is no evidence that its quantity has increased. Anxieties about "wearing out" and "nervous collapse" are greatly exaggerated. He points out the fact that tranquilizing drugs are being prescribed in a rapidly increasing fashion, and that an iatrogenic disorder called "stress phobia" may be in the making.

Ward, *et al.*(2), of the University of Pennsylvania Medical School in a study of the psychiatric nomenclature to ascertain reasons for disagreements in diagnosis utilized a series of psychiatric outpatients. These were interviewed separately and diagnosed independently by random paired psychiatrists so that each patient was seen by two different diagnosticians with a few minutes interval between the interviews. There was diagnostic disagreement in about half the cases. The authors give nine separate reasons for this, but the items fall into

three categories: 1. Inconstancy on part of the patient (5%); 2. Inconstancy on part of the diagnostician (32.5%); and 3. Inadequacy of the classification system (62.5%). The inconstancy on the part of the interviewers was frequently due to the differences in obtaining covert material and identifying the predominant pathology. The chief difficulties with the APA *Diagnostic and Statistical Manual* were the

requiring impractically fine distinctions as in the diagnosis of psychophysical reaction as opposed to conversion reaction; requiring unnecessary decisions of weighing as in the forced decision of predominance between neurotic and personality disorder when both are present; the lack of clear criteria as in distinguishing certain reactions now labeled schizophrenia from neuroses or schizoid personalities.

A rather extensive theoretical article was published by Arieti(3) entitled the "Microgeny of Thought and Perception." It is held that thoughts and perceptions pass through several unconscious stages before reaching consciousness. These are called "microgenic" (Werner) stages. The existence of these is inferred by the study of pathologic phenomena such as acute and chronic schizophrenia, some psychoneuroses, aphasias, agnosias, and certain brain injuries. Some experimental investigations dealing with subliminal perception and with stabilized images have contributed to the concept. Thus there is some accumulated evidence that thoughts and perceptions tend to reach consciousness before they have completed their microgenetic development. The relationships of these processes to neuroses and psychoses are discussed.

A study of the reactions of psychiatric patients to danger, particularly to mental hospital fires, was made by Schooler and Parkel(4). "The objective of this study is to determine whether the presence of immediate danger reactivates relatively normal modes of behavior in chronic mental patients." The reactions were evaluated by analysis of the hospital fire records, and data from interviews with the patients who

¹ Formerly Director, State Bureau Research, Princeton, N. J.; Hon. Prof. of Research Psychiatry, Jefferson Medical College, Philadelphia.

² Commissioner of Mental Hygiene, State of New York; Prof. of Clinical Psychiatry, College of Physicians and Surgeons.

had been in the fire situation. The reaction was found to be related to the length of hospitalization and to the diagnosis. The longer the hospitalization the more likely the patient will be relatively unconcerned about his personal safety or that of others. Chronic schizophrenics showed the lack of initiative, in keeping with the usual ward behavior, even in the presence of immediate danger.

Disturbances of body image have been recognized as present and important by many authors. The concept has been extended to include sensations from inside the body. Bruch(5), in her study of the falsification of bodily needs and body concept in schizophrenics, points out that these patients, to various degrees, are unable to identify bodily sensations in the same way as normals. They become falsified and distorted. Bodily sensations, thoughts and feelings are experienced as coming from outside themselves and thus from others in the environment. Therapy is rarely effective, if at all, in the absence of self-initiated activity. The therapeutic aim is to create an awareness in the patient of the origin of his bodily sensations. Multiple somatic complaints as a precursor of schizophrenia is the subject of a report by Offenkrantz(6) which is a part of a larger study based on a review of the medical records of 455 Veterans Hospital patients. The aim of the study is the attempt to determine the premorbid characteristics of those persons who later develop the recognizable disorder. He presents evidence to indicate that a high proportion of these patients showed clinical evidence of a mental disorder while in military service prior to the onset of an obvious schizophrenic process. Also the findings indicate that the disorder was characterized in part by multiple somatic complaints which may represent classical hypochondriasis.

As to background factors in schizophrenia Pokorny(7) studied 40 white male veterans with schizophrenia at the VA Hospital at Houston, Texas, using a detailed interview covering 9 areas of family background and life adjustment. These findings were compared with those of two control groups of patients suffering from tuberculosis (a "regular discharge" group and an "irregular dis-

charge" group). There were no significant differences in family background, but as compared with the "regular discharge cohorts, the schizophrenics showed poorer childhood health, poorer adjustment in school and in social relations at all periods, and showed more religious participation in childhood, more alcoholism, more military maladjustment and greater difficulty in adult occupational adjustment." The author concludes, "It may be that these represent factors leading to schizophrenia—but equally likely—they may be the early symptoms of schizophrenia." To investigate the factors related to outcome and social adjustment in schizophrenia, Mandelbrote and Folkard(8) followed 171 outpatients after their discharge from a mental hospital during periods from 2-4 years. There were 96 (31 men—65 women) considered "well" and 75 (29 men—46 women) "not well" as rated at the time of interview. Stress situations where the patient's behavior upset the family are described for various combinations of situations in conjugal families and parental families. The article would seem to be of particular value to those psychiatric social workers concerned with the family care of patients.

A follow-up study of the course and outcome of 109 patients with pseudoneurotic schizophrenia was reported by Hoch and coworkers(9). The period of study was 5-20 years. Sixty percent of the patients had been seen first at the New York Psychiatric Institute and 40% in clinics or private practice. Two-fifths of the group had had previous episodes of mental illness (inpatients, 42%—ambulatory, 31%). There was a significant incidence of subsequent hospitalization. Approximately 40% of the entire group were rehospitalized 1 to 9 times; 10% attempted suicide but only 2 patients succeeded. At the time of the follow-up study approximately two-thirds of the patients were found to have a good or fair adjustment. A comprehensive discussion of several factors involved in the diagnosis, evaluation and results in this type of schizophrenia are presented. Cowden and Ford(10) presented a method of systematic desensitization with phobic schizophrenics. In a previous study the authors demonstrated in a laboratory situation that schizo-

phrenics respond to systematic desensitization. In the study they have applied the technique to the clinical symptoms of two paranoid schizophrenic patients with fixed phobic reactions. The technique is described and illustrated by the case histories. As a result, they conclude that desensitization is an effective technique for some subjects, which neither supports nor contradicts theories regarding biochemical or physiological etiological factors, but shows that learned behavior can be unlearned even with psychotics.

Schwartz(11) presents 3 cases to illustrate a type of paradoxical remission that can occur in a severe psychotic disorder. All 3 patients were hospitalized and the remissions occurred immediately after a part of the treatment program was abandoned, which abandonment was characterized by a change from hope to hopelessness on the part of the medical and nursing attendant. The hypothesis is expressed that the surrender of therapeutic endeavor confronted these patients with a threat of disaster in the face of the lack of ability of others to protect them. In response they apparently found latent ego strengths within themselves to meet the situation. The mobilization of several ego defenses led to the remission.

Perpetual distortion as an etiological factor in certain paranoid reactions is the subject of a report by Sarvis(12) who states that marked interference with accurate perceptual evaluation of the external environment such as that from sensory deprivation, overload, or distortion occurring in experimental situations, in temporal lobe disease or constitutionally, tends to create psychic mental reactions. The author presents the hypothesis that this perceptual distortion tends to force the individual into a paranoid reaction which may then be segregated, become identified with an aggressor, pass into an autistic reaction or develop into a paranoid character. Levy and Grigg(13) made a study of the early memories of 21 patients utilizing a thematic configurational method of analysis. No clinical material other than the sexes of the subjects was used. The attempt was made by each of the two authors independently to match their formulations with those

from the therapists. They found it possible to predict preconscious themes from early memories and that the thematic configurational method of analysis as applied is a reliable one which can be communicated. The study is a preliminary one to test the predictive value of early memories, and the results invite additional work with a larger number of patients.

Stephens and Kamp(14) report an interesting survey of the various aspects of hysteria including the clinical manifestations, factors of immaturity, dependency and childhood affectional deprivation, and the libido theory. Examples are given from the literature and from personal experience where the basic reaction turned out to be schizophrenia. Their review of the whole situation does not support the belief that conversion reactions are disappearing. Diagnosis is probably faulty in many cases. Their summary states

The records of 100 inpatients diagnosed as hysteria, after study and treatment at the Henry Phipps Psychiatric Clinic between the periods 1913-1920 and 1945-1960, were studied. The admission rate was not found to be appreciably different in the two periods nor were the reported symptoms significantly different.

They suggest the "need for further research integrating recent developments in ego psychology and concepts of hysteria." Recently interest has been expressed regarding the incidence of color in dreams; for example, Kahn and associates(15) studying immediately recalled dreams found that color was present in 82.7% of dreams of 38 subjects (28 males-10 females), college students and others, ranging in age from 18 to 35 years. Careful questioning close to the time of dreaming apparently brings the color incidence considerably higher than has been previously reported by several investigators using questionnaires and other procedures.

The complex problems of psychiatric management of intersexed patients are discussed by Stoller and coworkers(16). They describe a heterogenous group with ambiguities of the external or internal sex organs or with conflicts between the appearance of the external genitals and sec-

ondary sex characteristics. Most of the patients were diagnosed as pseudohermaphrodites. The type of therapy naturally depended upon the correctability of any anatomical defects, the age of the person and the possibility of changing a sexual identification. They found it difficult to change the sexual identity of children after $2\frac{1}{2}$ years of age. Where supporting psychotherapy is used it should include the family. Psychoanalysis was thought to be not indicated.

Suicide has become a major medical problem. There were 16,760 cases reported for the United States for 1957, not taking into account the number reported as "accidents" that were actually suicidal in nature. At present the rate is much higher, and suicide is now considered to be the fifth most frequent cause of death in the U. S. The ratio of unsuccessful to successful attempts is not known, but some authors have placed it as high as 5 to 1. The subject of suicidal attempts in adolescence and childhood was approached by Bergstrand and Otto(17) who reviewed the case notes of patients under 21 years of age, from 465 hospitals in Sweden. There were 1727 cases (351 males and 1376 females) in a 5-year period (1955-1959). It was found that the frequency of suicidal attempts increased with age. The majority (83%) of attempts were among those in lower income groups. The most frequent cause given was love problems (30%), a number of incidences were apparently due to alcoholism, mental disorder in the parents and to broken homes. Girls were in the majority in the above categories. Boys constituted a large percentage of those with school problems, and were largely in the group with mental and character disorders. Ingestion of drugs was the method in 87% of total incidences, but violent methods and repeated attempts were more frequent in boys; they more often required continued psychiatric therapy. Attempted suicide by adults was studied by Tuckman and associates(18). The investigation was concerned with 1,112 attempted suicides by persons 18 years of age, or older, who came to the attention of the Philadelphia Police Department from 1959 to 1961. This includes persons who died as a result of the attempt, as well as

some of those who were doubted as to a serious genuine attempt. Information was sought for any relationship of the event to sex, race, marital status, educational background, occupation, employment status, location of residence, circumstances leading to the attempt and method used, previous patterns of adjustment or reactions to the various life situations, motivation and attitude toward death. Naturally many important factors were not obtained, related or due to unconscious forces. This report will require reading to obtain the details of a wide sweep of material.

PSYCHOTHERAPY

The number of schizophrenics treated with various forms of psychotherapy, which vary considerably in their theoretical aspects and clinical application, is increasing rapidly. Arieti(19) emphasizes the establishment of the patient-doctor relatedness in terms of transference and the equally important counter-transference, with the creation of mutual trust. The development of insight into the psychodynamics of the patient's life situation and into the manner in which conflicts and distortions have taken place, and a general participation in the patient's life with assignment of tasks and suggestions of activities for the purpose of developing gains in self-evaluation and capacities, are the major issues involved. Meares(20) in an article entitled "What Makes the Patient Better? Atavistic Regression as a Basic Factor" points out that a notable number of patients have been known to lose their symptoms during vastly different medical and non-medical procedures, such as talking freely with the family doctor, abreaction, suggestion, a variety of organized psychotherapies, prayer, yoga and Zen practices, autosuggestion, *etc.* The author holds that suggestion, insight and doctor-patient relationships are not fundamental as the universal therapeutic mechanism, but that atavistic regression which is described as a return to a primitive mode of mental functioning is the important thing. This may be induced in the mentally troubled in the absence of insight and with little suggestion. Normal persons experience this type of regression in states of reverie. Lidz(21) describes how family studies in

psychiatry have received a strong stimulus from psychoanalysis and how some of these have operated or been used and thought about by previous workers; and, moreover, what seems to require reorganization of thought and practice in this field.

The fear of vocational success is a reaction which has been studied by Oversey (22) who reports interesting case histories to show that this particular fear is a phobic extension of paranoid reaction. His paper describes the adaptational psychodynamics of success phobias and shows a practical application in the conducting of the psychotherapeutic procedure in terms of the choice of therapeutic goals. Not all patients benefit from the attempt to overcome these fears; some lack sufficient "ego strength" and may collapse. The therapy can be seriously handicapped in those cases complicated by depressive reactions, even by suicidal attempts, alcoholism, drug addiction, acute anxieties and paranoid hallucinatory states. It may become necessary to institute pharmacologic aids, ECT or temporary hospitalization. In a paper on transference dynamics of group therapy Farrell (23) asks the question "What is therapeutic in group psychotherapy?" The hypothesis is "that the understanding and resolution of the multiple transference constellations which arise and exist among group members and therapist is the therapeutic experience." The author develops his concept in four parts describing which transference reactions occur; how the group in the character defense interactions of its members personifies and dramatizes the conflicts of the members; why the transference reactions follow an outlined pattern; and the final part dealing "with the qualitative and quantitative differences of transference in group psychotherapy as compared to individual therapy, and the inherent therapeutic advantages of these differences." The termination of therapy as a problem in a community outpatient psychiatric clinic is discussed by Schiff (24) who points out that the phase of termination, above all others, in the psychotherapeutic process is the one which may produce the greatest difficulty and create complicated problems for both patient and therapist. He describes the outpatient clinic setting and its role

as contributor to the difficulties. Problems unique to this phase of therapy for the patient are pointed out as well as the difficulties encountered by the therapist.

There has been a marked increase in experimental interest in hypnotic phenomena but very few quantitative studies have been made on perception during hypnosis. Kliman and Goldberg (25) record the result of a pilot study of 10 healthy males with a special method for measuring visual recognition thresholds of words seen in the hypnotic state as compared with the waking state. The findings suggest that visual recognition occurs at a lower illumination in the hypnotic state and that the range of recognition thresholds is narrower. Words requiring the highest illumination for recognition in the basic waking state are recognized with less illumination in the hypnotic state. This last mentioned is very pronounced. It is suggested that "attention cathexis" is more impartially available when perception defense avoidance is suspended during the hypnotic state. Barber (26) in an extensive, pertinent article criticizes hypnotic research methodology. He deals with referents of the term hypnosis, subject variables, the "good" hypnotic subject as his own control, the use of control groups, the interpersonal relationship, motivational factors and the definition of the situation, and Sloane and associates (27) have made a critical review of "hypnotic age regression" challenging some of the interpretations of previous authors on this subject. The attitudes of psychiatrists to the use of hypnosis have been outlined by Auerbach (28). To determine the extent of the use of hypnosis in psychiatric therapy a questionnaire was sent to 828 psychiatrists in California; 469 responded who had had experience with the method; only 13% still used it in selected cases. Several reasons were given for abandoning hypnosis. Among these were unpredictable, inconstant and non-lasting results; doctor-patient relationship may become impaired; untoward results occur with poorly trained hypnotists, commonly precipitating a psychotic episode, a panic state, a depression or even suicide. There has been really very little added to the knowledge of hypnotic states for the last 200 years despite studies by medical socie-

ties over the major civilized countries; and it is rightly emphasized that much research is needed to delineate the proper areas of application of hypnosis and the limitations made more definite.

The usual large number of generally helpful psychiatric books has appeared during the past year, but we may list only a few of these that seem pertinent to this section on Clinical Psychiatry.

PSYCHOPHARMACOLOGY AND PHYSIOLOGICAL TREATMENT

JOSEPH WORTIS, M.D.¹

Thalidomide : In this annual review two years ago a British report was cited which described a new drug thalidomide as a

safe non-toxic sedative. Under the trade name Contergan it had been sold freely without prescription in Germany where it quickly became a most popular tranquilizer(1). Soon afterwards it was available

¹ State University of New York, Jewish Hospital of Brooklyn, Brooklyn 38, N. Y.

in Britain as Distaval, in Canada as Talimol, and was distributed for clinical trial here as Kevadon(2), though the Food and Drug Administration held up its license because it was reported to produce polyneuritis(3). In 1961 Lenz in Germany and McBride in Australia independently and almost simultaneously related the drug to the occurrence of a severe fetal malformation of the limbs called phocomelia, a relationship soon confirmed by Spiers in Scotland, and others. The drug was thereupon withdrawn from the market, but not before thousands of deformed infants had been born in Germany, England and elsewhere(4). A single dose early in pregnancy is sufficient to induce fetal death or damage: in animal experiments all gravid rabbits fed thalidomide produce stillborn or deformed offspring(5). Widespread concern in this country hastened the enactment of a number of new laws proposed by the Kefauver Committee to safeguard the public interest in the drug trade: the Food and Drug Administration now has far greater authority to halt or recall drugs, can insist on fuller safeguards, and can supervise advertising(6).

The thalidomide affair has directed interest to the special problems of insuring drug safety for human beings, particularly in sustained use; acute toxicity for animals is no longer an adequate criterion. Large populations under chronic medication now must be surveyed to detect low grade, sporadic and fetal toxicity. From this point of view it can be recalled that several years ago Roux showed that prochlorperazine (Compazine) can induce fetal death or malformation in laboratory animals(7). It can also induce fatal bone marrow aplasia in man(8). In a series of reports Werboff and his associates have demonstrated that various psychotropic drugs administered to the gravid rat not only increase neonatal mortality, but also effect the development, behavior and neural responsiveness of the offspring, with changes persisting into adult life(9). There is some evidence that chlorpromazine and other neurotropic drugs may sometimes cause irreversible brain damage, especially in predisposed subjects(10). Prolonged administration of certain MAO inhibitors to dogs can also produce CNS

lesions, indicating "the danger of delayed toxicity with chronic administration of some drugs"(11). Chlorpromazine (Thorazine) and promethazine (Phenergan) definitely hamper the development of the rat(12). The significant amount of glycoprotein serum change found in patients under chlorpromazine is noteworthy, even if unrelated to clinical signs(13). Attempts are now being made to review the patterns or morbidity found among patients under chronic medication(14).

Overdosage of reserpine can induce gastrointestinal hemorrhage and ulcers in animal and man(15, 16). Pheniprazine (Catron), nialamid (Niamid), and phenelzine (Nardil) can all induce hepatitis, which can be fatal(17). Imipramine (Tofranil) can cause agranulocytosis(18). Five cases of visual impairment, including two cases of optic atrophy, from pheniprazine have been reported(19). Among the remote effects of the newer drugs may be mentioned the dangers of faulty deglutition and fecal impaction(20). Addiction to many of these drugs is a continuing concern. Kiloh and Brandon(21) estimate that in a British urban community approximately 1% of the population use amphetamines, and about one-fifth of these are addicts who find ways of getting the drug on a continuing basis.

Reviews and Comparisons: Several brief reviews on psychopharmacology can be recommended(22-25); Lehmann's(26) is especially clear and authoritative. Many of the new reports attempt to compare the efficacy of the varied physiological agents now in use or to define their indications. Although statistical groupings of depressed patients may show the same responsiveness to either drugs or electroshock treatment, some patients still need EST(27), and the quality of remission varies with each agent. Oltman and Friedman(28) believe remission in neurotic depression is better maintained with drugs; Witenborn, *et al.*(29), also think imipramine benefits total behavior more than EST. But where drugs cannot supplant EST, they can shorten it(30). For quick and intense effect EST appears to be the method of choice(31-33). Cannicott(34) finds that unilateral stimulation produces less confusion and memory loss. H. G. Alexander(35) claims a very

high response rate in both acute and chronic schizophrenia to a combination of the very potent (and sometimes toxic) fluphenazine (Permitil or Prolixin) and intensive daily EST(36). On the other hand, the combination of EST and imipramine often induces a bad manic state(37).

In a large predominantly schizophrenic population treated with various phenothiazines, mepazine (Pacatal) and promazine (Sparine) did poorly(38). Trifluoperazine (Stelazine) is said to be especially effective in paranoid schizophrenia(39, 40), and is one of the few drugs which can favorably influence compulsions(41). Chlorprothixine (Taractan) is reported to be a quick and effective initial sedative in all types of psychomotor agitation, including delirium tremens(42, 43). A large number of reports on thioridazine (Mellaril) endorse its value and ease of administration in both acute and chronic psychoses(44-47), including senile disorders(48), though leukopenia(49), impotence(50), and jaundice(51) have been noted. Another series of reports confirms the value of chlordiazepoxide (Librium) in a wide variety of neurotic and milder disorders(52-54), though it may induce curious *absences* or sleep attacks which can cause accidents(55, 56).

Carphenazine (Proketazine) is said to be superior to other phenothiazines for the hypodynamic chronic schizophrenic. Side effects of parkinsonism, akathisia, tremors, agitation and perspiration are relatively mild; occasional leukopenia, liver dysfunction and visual disturbances have also been reported(57-59). In an interesting and well-planned regional study in Scotland(60) involving three hospitals no significant changes in behavior were found among patients treated with chlorpromazine (Thorazine), prochlorperazine (Compazine), and placebo, though another group here(61) found prochlorperazine effective for acute psychoses and for maintenance treatment. Favorable reports on trifluoperazine are noted(62), but a severe protracted extrapyramidal motor reaction was encountered in a child after administration of two 35 mg. suppositories in a 12-hour period(63).

Amitriptyline (Elavil) is said to be at

least as effective as imipramine (Tofranil) for endogenous depression, but less effective for reactive depression; it has fewer side effects (except possibly seizures), induces improvement more rapidly, and has fewer relapses(64). In another carefully documented study it was easier to demonstrate the value of imipramine for endogenous than for neurotic or schizophrenic depressions(65). In agitated depressions a combination of imipramine and promazine (Tofranazine) is recommended highly(66). The common occurrence of withdrawal symptoms after imipramine treatment deserves more attention(67). Nialamid (Niamid) is being widely and successfully used for depressions(68, 69), can be given intravenously(70), and is well tolerated by the aged(71). Nevertheless some observers report that phenelzine (Nardil) is better suited for the older patient, and nialamid for the patient under 40(72).

The MAO inhibitor tranlycypromine (Parnate) is attracting considerable attention. In a thoughtful report Bartholomew(73) concludes that EST is still indispensable for the severe depression that demands prompt relief, but "that people with minor depressive states might well receive Parnate as an adjunct to supportive psychotherapy." In agitated and neurotic depressions it can be combined with a tranquilizer such as trifluoperazine (Parsteline)(74-77). Several favorable reports have appeared on the use of haloperidol (R1625) for manic states, including post-operative excitements, agitated hallucinosis, toxic alcoholism or impending delirium tremens(78-80), though it is of limited value in chronic schizophrenia(81).

New Drugs: Among the many new drugs may be mentioned: acepromazine (Notensil), found effective and well tolerated in acute schizophrenia(82); propiomazine (Largon), which induces rapid sleep lasting 2-3 hours after intravenous administration(83); protipendyl chlorhydrate (Dominal in France) for chronic cases, for acute alcoholic disorders and for relief of anxiety-tension states(84, 85); chlorproethazine (RP4909) with an action similar to other phenothiazines, but with a paradoxical anti-parkinsonism effect and a selective action

on certain motor symptoms(86); the very potent new phenothiazine SKF 7261(87); a thioxanthen analogue of perphenazine (Clatyl or Sordinol in Europe) said to be very effective in chronic schizophrenia(88); acetophenazine (Tindal), useful in ambulatory and old schizophrenics, but with very marked somnolent action(89, 90); butyrylperazine, with contradictory reports from here and abroad(91, 92); thioproperazine (Dartal), said to be useful(93), though a sudden death from respiratory paralysis has been reported(94); butyrophene carbamide (R3345), a dipiperon related to haloperidol with a pleasant hypnotic action and an anti-psychotic and anti-anxiety effect(95); the mild piperazine phenothiazine MDS92(96); cyclopentimine (Cypentil), which reduces aggressiveness and induces euphoria at the cost of distressing side effects(97); tetrabenazine (a Roche product), which is said to relieve acute excitements as well as neurotic and reactive depressions(98); the benzhydryl derivative KT-5(99); the benzoquinolizine derivative P-2647(100); and benzquinamide (Quantril)(101)—all of which relieve anxiety. A recent issue of *Acta Neurologica Belgica*(102) was devoted to dixyrazine (Esucos), which combines a phenothiazine nucleus with the hydroxyzine side chain, and can be best described as an autonomic sedative useful in various neurotic and psychosomatic disorders, especially those associated with agitation.

The following new antidepressants or stimulants also claim attention: Ensidon, a sort of combination of imipramine and perphenazine(103); RP 8228(104), good for narcolepsy and asthenic depressions; the hydrazine Dicatron(105); trimpropimine (RP7162)(106), used with chronic resistant schizophrenics and psychopaths; a new MAO inhibitor PC603(107), said to be effective in neurotic and reactive depressions and obsessions; etryptamine acetate (Monase)(108), a mild but effective antidepressant; RO4-1575(109), structurally close to imipramine and chlorpromazine; the theophyllin derivative called Captagon (110) in Germany (Homburg 814); the hydroxybutyrate S 186(111); a close relative of imipramine and amitriptyline N7001(112); Desipramine (G35020)(113);

and Abbott's new MAO inhibitor MO-911 (114), described as "one of the most effective antidepressant agents available."

PSYCHOSURGERY

WALTER FREEMAN, M.D.¹

$N=3,000$; Chi square=160.5; Df=7; $P<.000001$; $C=.37$.

"In other words a highly significant decline of good results with increasing duration of illness." Roth and Garside(24) continue: "A great advance would be registered by the introduction of some form of treatment less transient in its effects than ECT, less irrevocable in its consequences than operations on the frontal lobes."

Renewed interest in psychosurgery has developed in England as a consequence of the ineffectiveness of electroshock and of the psychotropic drugs in many emotional disorders. Pippard(21), in a survey of 525 operations performed in various hospitals in 1960-1961, notes that the reduced number of operations from the previous decade is almost confined to the "standard" leucotomy. "The standard or its anterior modification still accounts for nearly one-fifth of all operations; it is on its way out, but all too slowly, and should be finally abandoned."

At the same meeting of the Royal Med-

ico-Psychological Association, Sargent(26) dealt particularly with the indications for leucotomy, stressing the need for limited incisions in the inferior medial quadrants in order to avoid the personality changes consequent on extensive cuts. If the patient, before his illness, "had a good, conscientious, driving, obsessive and overanxious personality, leucotomy may have a very gratifying and sometimes completely unexpected success." Obsessively held memories, which are the basis of so much chronic neurosis and psychosis, "may sink back into relative insignificance . . . [Leucotomy] is one of the best means we possess for deconditioning abnormal behavior patterns arising from strongly held memories." Sargent cites anxiety hysteria, recurrent depressions, psychosomatic disorders and even well preserved schizophrenics with paranoid, catatonic and pseudoneurotic symptomatology as suitable for operation. With the vicious circle broken, these patients are more amenable to other therapeutic methods and will willingly take ataraxics that they had previously refused.

Freeman(9) reports success in 6 of 7

¹ Sunnyvale, Calif.

adolescents after transorbital lobotomy, all of the patients having shown alarming trends toward fixation. In a larger group of depressed and agitated patients over 65 (10) the results were particularly gratifying, similar findings being reported by Scoville(29) and by Smolik and Nash(31) after incisions limited to the orbital areas. These older patients are more likely to regain effective life than younger ones since they have a half century or more of productive existence behind them.

Schizophrenia. In certain patients, lobotomy is remarkably effective, in others a complete failure. The average is close to 35% discharged. Thus Ambrumov(2) finds it valueless in patients hospitalized 10 years or more, Schulte(28) considers it superfluous except in extraordinary cases. Torres(32) uses it only for better management in the home or ward, and Witton and Ellsworth(34) state: "In comparison with the lobotomized group, the non-lobotomized group showed the same release pattern which was apparently dependent on the rehabilitation efforts more recently adopted in this hospital."

This gloomy picture is offset by Brinegar's(4) report of 68% discharged. Freeman's(12) follow-up of the West Virginia lobotomy project shows 65% discharged after less than 5 years of hospitalization, and 35% in the 5-10 year group. He comments: "The personality changes brought about by lobotomy definitely increase the chances of discharge from the hospital even after confinement there of 2, 5, or even 10 years. These changes consist predominantly of lowered sensitivity and decreased preoccupation with the self. Losses in intelligence, memory and other measurable psychologic abilities are due to the psychosis, not the lobotomy." In another paper Freeman(13) compares prefrontal with transorbital lobotomy showing preference for the latter. Patients with affective disorders or psychoneuroses showed a discharge rate of 90%. Schizophrenics operated on in general hospitals showed 80% at home 10 years later, while those operated on in state hospitals showed only 35% at home. After one year there was little change in the social status of operated patients. Hirose(17) obtained a discharge rate of one third with prefrontal

lobotomy, but, with his own operation, he raised this to one half. He speaks of "psychosurgery as a kind of plastic surgery of mental states rather than a cure for the disease itself."

Psychology. Ackerly(1) has concentrated upon mentally healthy patients whose frontal lobes were unavoidably sacrificed, and probably extensively, in the treatment of tumors and injuries. He emphasizes the decreased complexity of their lives . . . the enforced involvement with the "here and now" . . . the automatic and perseverative aspects of behavior that make it more difficult to shape one's "set" and to engage in novel and planful behavior involving yesterday, today and tomorrow. "Man as man cannot long prevail without frontal lobes, can he prevail with them? This is civilization's greatest challenge."

De Mille(7) compared prefrontal and transorbital patients, 22 of each, closely matched, and concluded that the prefrontal patients scored higher. "Two tests which confounded [?] verbal comprehension and social intelligence factors differentiated the groups significantly." Hamlin and Kinder(16) found vocabulary deficits 10 years after operation (topectomy) in comparison with controls, but conclude that: "familiarity with a test may serve to decrease unpredictable and irrelevant schizophrenic behavior. Unless the idiosyncratic capriciousness of schizophrenic behavior is taken into account, relevant differences may be readily obscured." Nemiah(20) reports on a paraplegic whose pain was unrelieved by cordotomy, studied before and after radiofrequency leukotomy. "The patient could now talk about the meaning of being paralyzed without an overwhelmingly painful affect, and there no longer existed the need for the psychological mechanisms of suppression, denial, displacement and conversion which had protected him from these painful affects, at the same time, resulting in the complaint of pain." If this is devious, how else explain some of the life-saving effects of lobotomy in other intractable psychosomatic conditions as reported by Freeman(11)? Porteus and Diamond(23) state that psychosurgery brings about defects in planning capacity and find the maze test the most reliable indicator.

Incidentals. Crow, Cooper and Phillips (6) insert many thin gold needles into the frontal white matter, leave them for several months while studying the effects of gentle currents applied for 15 minutes to 24 hours. When the most effective spots are found, a strong current is used to produce electrocoagulation. An abbreviated procedure is reported from Ranchi, India (18), where a patient underwent transorbital lobotomy in the morning and played on the winning soccer team in the afternoon, much to the horror of the surgeon.

Studied by pneumoencephalography, the anterior horns and third ventricle cease enlarging in favorable cases at the end of the second year, but continue in the worst cases. Five of the 35 patients had cavities communicating with the anterior horns. The surgical operation starts a complex dynamic process that continues for years and may explain the delay in clinical improvement (22, 25).

Visual and auditory hallucinations may be triggered by frontal lesions (27). The authors describe the uncinate fasciculus. The reviewer believes that interruption of this bundle may be the next advance in psychosurgery, as a means of suppressing hallucinations. This is more than a guess (13).

Interruption of the cingulate fasciculus has resulted in confusion and memory defect similar to the Korsakoff syndrome. Whitty and Lewin (33) state that this might be expected since memory and emotion are indissolubly linked in normal life.

Baker (3) noted improvement after leucotomy in a patient with Gilles de la Tourette syndrome. Cobb (5), in some reminiscences of John Fulton, recalls showing a picture of Becky, the famous lobectomized chimpanzee, with the caption: "Was this the face that lopped a thousand lobes?"

CHILD PSYCHIATRY ; MENTAL DEFICIENCY

LAWRENCE SHARPE, D.P.M., AND LEON EISENBERG, M.D.¹

The diagnosis of childhood psychosis, despite increasingly frequent usage, still lacks suitable definition(1). The proposal of nine "cardinal criteria" for childhood schizophrenia, arising out of discussions among British child psychiatrists(2), represents an important effort to order the field, although the criteria remain somewhat imprecise. The question remains: Is the diagnosis to be made when specified pathology in behavior is detected, whether or not organic signs are in evidence?

The characteristics of the childhood schizophrenic in adolescence have been contrasted with those of (a) adolescent schizophrenics and (b) adolescent behavior disorders in a paper by Colbert and Koegler(3). The authors report more marked poverty of thought; sexual confusion; an obsession with the properties of space, time and movement; and marked distortion of body image—factors that may in part relate to the chronicity of the disorder. The same authors(4) have stressed the significance of abnormalities in vestibular function in a group of children they describe as schizophrenic. Starting from these clinical observations, Scheibel, *et al.*(5), have explored cat brain stem and caudate for regions modulating nystagmus. Manipulation of caudate tissue resulted in phenomena "reminiscent" of postural patterns seen in schizophrenic children. A comprehensive survey of "infantile schizophrenia" has been made by Delage(6) with detailed clinical reports on 20 cases. Cunningham has carefully analyzed the language of a 7-year-old autistic child(7) in comparison with the language of a normal 2½ year old. Among the differences noted were that the autistic child used language less for conveying information, more as mimicry, and had an excessive use of nouns compared to pronouns.

Valerie Cowie investigated the children of psychotic parents(8). She drew her *propositi* from the children of psychotic patients admitted to the Maudsley Hospital

in London and took her control group from the children of mentally normal parents admitted to a general hospital. She found no significant differences between the two groups of children and found, surprisingly, that the children of schizophrenics were remarkably free of neurotic symptoms. How many children seen in Guidance Clinics eventually develop a psychotic illness? From Norway comes a partial answer to this problem(9). From Child Welfare Board material from the years 1929 to 1933, 1863 children were followed up by checking mental hospital records. Sixty-one cases were discovered to be psychotic in hospitals, a rate of about 3%.

Two papers on suicidal attempts in children and adolescents throw some valuable light on the epidemiology of this condition. In 1727 cases under 21 collected in Sweden (10), 1376 were girls and 351 were boys; 83% of these cases came from the low-income group; 87% attempted suicide by the ingestion of drugs. The "reasons" for the attempt at suicide were given as "love problems" in 30% and as "family problems" in 25%. One hundred cases analyzed in this country(11) show a high association of suicidal attempts with family disorganization and delinquency. The authors postulate that both suicidal bids and delinquency are aspects of "acting-out" phenomena. According to Toolan(12), children and adolescents with depressive illness are referred to pediatricians rather than child psychiatrists. He points out that the symptoms of an underlying depression are different from those in the adult and alertness for these symptoms is necessary if suicidal attempts are to be forestalled.

Bowlby has reviewed theories of separation anxiety from William James through Freud, Rank and Melanie Klein(13). He lucidly states his own position as a belief in what he terms "primary anxiety." He feels the child is bound to his mother by a number of instinctual response systems, which have a high survival value. "Primary anxiety" is an elemental experience which, upon reaching a certain intensity, is linked

¹ The Johns Hopkins Hospital, Baltimore, Md.

directly with the onset of defense mechanisms and should therefore be distinguished sharply from states of anxiety dependent on foresight. Recent reviews of the concept of maternal deprivation(14-16) show that rigor in definition has been lacking; many of the studies suffer from methodological inadequacies; insufficient attention has been given to distinguishing between maternal and "non-maternal" variables (such as amount of environmental stimulation, differential sensitivity, *etc.*). The questions of reversibility and of "critical periods" remain to be answered.

Williams(17) compared a group of 54 children between 5 and 11, who had re-entered a Reception Center after failure in foster placement, with a group of 74 children of the same ages, who had entered because of a sudden family emergency. There were significant differences between the two groups on the WISC subscores and on the Rorschach. These differences are interpreted as indicating damage in personality growth and in interpersonal relationships.

In a 30-year follow-up of 524 patients originally seen at a Child Guidance Clinic in St. Louis(18) it was found that 20% of the cases originally seen met criteria for sociopathic behavior as adults compared with only 2% from a comparable control group. The incidence of divorced parents, failure to supervise the child's behavior, non-support of the family, and sociopathic behavior by the father were all higher in the group that were to become sociopaths.

Precht and Stemmer(19) have investigated 50 children referred for poor school achievement and behavior disturbances at home. In these cases, they observed brief, jerky and arrhythmic muscular movements, most readily seen under stress. In all cases the muscles of the tongue, face, neck and trunk were involved and in 92% the eye muscles were also involved, resulting in disturbances of conjugate movement and fixation. Of the group, 90% had reading difficulties of varying severity. EEG records showed, in addition to movement artefacts, epileptic discharges in 14% of the cases. In all but 22% of the cases some history of obstetrical or post-natal complications was elicited. The authors speculate that the

etiology of this condition is early minimal brain damage, probably to putamen or caudate. If this syndrome can be delineated early in life, it has important implications for remedial education and neuropsychiatric treatment. This work merits careful efforts at replication.

MENTAL DEFICIENCY

The most significant single event of the past year has been the issuance of the report of the President's Panel on Mental Retardation(20). Scholarly in presentation, the report avoids both "crash program" mentality and pious non-specificity. It emphasizes steps to acquire new knowledge while it proposes measures to apply the best in current principles. Recognizing that progress in research is dependent upon scientific manpower, the Panel has called for federal aid to higher education via scholarships for qualified undergraduate as well as graduate students and facilities grants to expand institutional capacity. Stress is placed upon the need for basic research in both the behavioral and the biological sciences. At the same time, the repeatedly demonstrated association between marginal socioeconomic status, poor health care, and neuropsychiatric disorder leads to proposals for (a) the provision of comprehensive maternity and infant care to disadvantaged families; (b) pre-school and after-school programs of cultural enrichment for the slum child; (c) improved hospital, foster care and counseling services to mitigate maternal deprivation; and (d) a Domestic Peace Corps to enlist volunteer community support to rehabilitate and reeducate the marginal families in our society. Space precludes discussion of the many other salient proposals. Suffice it to say that the Panel has issued a distinguished document that can become the basis for mounting an effective attack on mental retardation if it receives widespread public support. In this, we, both as individuals and as APA members, have an important role to play.

Increasing concern has been expressed as to the inadequacy of training in mental deficiency provided in pediatrics, neurology and psychiatry. Now, the various specialties are displaying a distressing tendency to attempt to establish hegemony in this newly

respectable field. None of us has a glorious record of past performance to boast: it is to be hoped that the staking out of claims will give way to a more sober effort to define what it is that each speciality has to offer. The need is surely great enough to absorb for the foreseeable future all of the professional energy any of us is willing to devote. In a survey of psychiatric outpatient clinic service patterns in relation to diagnostic category, Bahn, *et al.* (21), noted the infrequent provision for the retarded of any service beyond diagnosis. Unless the needs of these patients and their families are being adequately met elsewhere in the community (an unlikely assumption), this finding suggests failure of the psychiatric clinic to accept full medical responsibility for defective children.

The study of chromosomal abnormalities continues to yield a rich harvest. New clinic entities have been reported (22-25). In mongolism, an interesting report by Forsmann and Lehmann (26) of 11 families with more than one affected member found only 3 with translocation of 15/21, 21/22, or 21/21 types and hence a hereditary disorder; the other 8 displayed a non-transmitted basic trisomy 21. The same authors (27) have described a family with hereditary mongolism of the 15/21 translocation type in which one son had the chromosomal deficit but was phenotypically normal. Whether or not this child will prove to be fertile, this is the first reported example of a male carrier. Occasional cases of mongolism appear to have the normal complement of 46 chromosomes (28); the interpretation of these findings remains uncertain. Measurements of enzyme activity in mongolism have shown minor abnormalities compared with controls (29, 30); further investigation is required.

After a long period of relative neglect in the English literature, the classic work of Piaget is being re-examined and largely finding confirmation (31-33). Reflecting this trend, Piagetian methods have been applied to the study of the defective (34) and the educationally subnormal (ESN) child (35). Systematic examination of the concept of time in 50 ESN subjects as contrasted with 50 normals reveals a severe retardation of time concept in the ESN, with the ESN of

I.Q. about 65 displaying at age 15 the time understanding of a normal 9 year old.

The training of defectives is being examined experimentally in order to determine what methods of training would most help the subnormal to take a place in the world at large and to find out how subnormals compare with normals in learning abilities (36-39) and in the study of language development (40, 41). This basic research will be necessary before rational methods of training for the subnormal can be defined.

The etiology of mental defect has been considered in Lundstrom's masterly follow-up study of rubella in pregnancy (42). Microcephaly and the group of encephalomyelocoele, myelocoele and meningocele are among its consequences. Apart from the incidence of congenital cataract and deafness, long known as sequelae, subclinical deafness is common and may result in apparent retardation. The high incidence of immaturity, institutionalization and difficulties in school are planned to be the subjects of an independent longitudinal survey. On the basis of a lower overall incidence of congenital defects than others have reported, Lundstrom suggests that the indication for therapeutic abortion following rubella in pregnancy should be less automatic than it has become.

A comparison of 50 male premature babies with 50 male normals (43) has shown superiority of the normals on I.Q., perceptual tasks, developmental tasks and the Lincoln-Oseretsky Scale. The concept of intrauterine growth retardation has been put forward by Warkany, *et al.*, in a paper (44) in which, of 22 cases of prematurity, 15 showed subnormal intelligence often related to a specific mental syndrome, such as microcephaly.

The thalidomide tragedy (45) illustrates the need for the greatest vigilance in giving drugs during pregnancy and thus exposing the fetus to potential hazard, just as earlier misfortunes had warned of special susceptibilities in the neonate (46). Federal legislation, assured passage only because of the ghastly German experience (almost certain defeat had been predicted before the thalidomide news broke), empowers the F.D.A. to require more extensive screening

for toxicity as well as to demand demonstration of efficacy before drugs are released for general use. But, despite all this, major responsibility will rest with us as clinicians. *No drug* should be prescribed without sufficient indication and without weighing expected benefit against potential toxicity; *no new drug* should be preferred to a time-tested older one without convincing evidence of superiority rather than mere equivalence in effect. *Primum non nocere* remains the first precept of the physician (47).

OCCUPATIONAL PSYCHIATRY¹ALAN A. McLEAN, M.D.²

Since the last review, two monographs and one article have reported the first research findings from the industrial mental health project of the Menninger Foundation. In 1961, the research methodology and frame of reference were established in *Interdisciplinary Research on Work and Mental Health*(25). Part of its introduction says,

We believe that the point of view and the methods we advance in this report will be most useful to those concerned with social and psychological assessment of work activities. For example, the consultant to industry who is asked to assess people to fill particular work roles must necessarily assess the characteristics of both the individuals and their anticipated tasks and situations. We do not propose a viewpoint and method which gives simple answers to these problems, but we do underline factors which we believe need to be considered and some methods which enable the study of social and individual factors simultaneously.

In mid-1962 Solley and Munden(40) reported their five behavioral characteristics which served as an operational concept of mental health in the research, to wit, the mentally healthy person: "1) Treats others as individuals, by identifying himself with, accepting and understanding them. 2) Is flexible under both internal and external stress. 3) Obtains pleasure from many sources. 4) Sees and accepts self-limitations. 5) Uses capacities to fulfill needs in carrying out productive tasks."

Finally, describing their study of "The Midland Utility Co." many new, though properly tentative, hypotheses were proposed which will merit considerable attention in future years(26). The concern is for factors in the industrial environment which both foster and impede employee mental

health. Concepts of reciprocation between an employee and his boss, of the psychological contract between a man and his employer, and of the "balanced distance" which obtains at work are introduced. Dependency needs are discussed and documented in a chapter on "interdependence" which neatly refutes some current industrial sociological thought—particularly propounded by Argyris.

Health and Work Satisfaction. The July 1962, *Journal of Social Issues* was devoted in its entirety to "Work, Health and Satisfaction." A new research program on industrial mental health representing a joint effort of the Survey Research Center and the Research Center for Group Dynamics of the University of Michigan is described. It is essentially a study by behavioral scientists and an epidemiologist—not by psychiatrists. The environmental approach is taken. It is stated that "every environmental stress which we have so far investigated seems to affect mental health; such stresses include low status, management responsibility, technological change, role conflict, role ambiguity, the temporal requirements of shift work, threats to self-esteem in the appraisal system and others."

French and Kahn(9) discuss a number of theoretical considerations, including proposed criteria for mental health. Zander and Quinn(47) discuss affective states, contact with reality, self evaluation, motivation to grow and use abilities, and maintenance of stable interpersonal regulations. Kasl and French(21) present a theory of status and health and report some preliminary studies. The hypothesis is advanced that skill level is inversely related to dispensary visits.

Mann and Williams(28) discuss the results of introducing electronic data processing equipment in an office. They observe "While automation in the office has meant further rationalization of the work environment and the clerical worker has become less satisfied in general with his job and company, this dissatisfaction has not been so intense as to cause these employees to

¹ Members of the Committee on Occupational Psychiatry, APA assisted in preparation of this review. Acknowledgement is also due Dr. John Cleghorn, Dept. of Psychiatry, University of Cincinnati for his assistance.

² I.B.M. Corporation, 590 Madison Avenue, New York 22, N. Y.

be actively searching for other jobs."

Wolfe and Snoek(46) discuss measuring the sources of role conflict. Strong role pressures cause a high level of tension.

It should be noted that the frame of reference of these studies is not one with which psychiatrists in general will be familiar. These studies are illustrative of an increasing trend of "mental health" research by behavioral scientists other than psychiatrists.

Impact of Psychiatry on Management. In March the New York State School of Industrial and Labor Relations of Cornell University sponsored a conference on "The Impact of Psychiatry on American Management." The November issue of *Industrial Medicine and Surgery* was entirely devoted to papers and discussion from this meeting. The conference focused on the question of management's responsibility to provide an environment which will provide growth for the individual employee(16, 29). The focus of the conference was not on treating the emotionally ill person, but on the "self-actualization issue," i.e., that an individual's personal growth and maturation depend on ultimate realization of individual potentials.

Highlighted in these papers were a number of additional themes: 1) Psychiatrists are entering the industrial, commercial and civil service scene because it is felt that they have something to offer the individual and the organization, since 10%-20% of the work force at any given time have clinical behavioral problems of varying severity (27). 2) In such settings, the psychiatrist has his traditional role as a clinician but a more important function is the education of others in industry who deal with people (27). 3) Practical problems arise from the varying points of view represented by behavioral science on the one hand, and administrative practices on the other(39). The possibility of integrating the viewpoints of these two groups is discussed. Improvement in communication is stressed (2). 4) The current trends in the application of psychiatry to personnel policy formulation are reported. Findings from psychiatry and behavioral sciences which have contributed to an understanding of work, group behavior, patterns of relationships

to authority and motivation theory are discussed as they relate to personnel and management policies in the past and in the future(2, 16, 27, 30, 39). It was predicted that managers of the future will have broad training in the fundamentals of human behavior and will better understand the needs of the organization and the realities of their role(30).

Accidents. Engineering revision has made jobs safer so that 70,000 lives have been saved in the past 20 years. Much less has been done about the strictly human factors, and it is worthwhile investigating these because accidents still remain the second most important cause of lost working years, and the cost of this is enormous(15). Twenty percent of accidents since 1950 have been occupational(19).

Further progress is hindered by the fact that such a multiplicity of factors may contribute to accidents. A framework for considering these is suggested by Bize(1) who applies communication theory to accidents. He places emphasis on warning messages received by the injured person prior to the accident, interpretation of the messages both by the person himself and others surrounding him, external human pressures at the time, and the immediate and underlying motivations of both parties. Some prognostic signs are suggested by Hannaford(13), such as an increase in work errors, close calls, changes in behavior. The detail which must be emphasized in the study of accidents may preclude a gross statistical approach(37). For example, a statistical approach might overlook a case in which an intrapsychic conflict is pathologically solved by an accident. This type of possibility has not been exhausted, as was demonstrated in a study of patient accidents in hospital(44) where the accident-prone hypothesis applied to 9.7% of patients who had 23.3% of the accidents.

Absenteeism. A study of prolonged absenteeism(34) in 130 persons indicated that the long absences were primarily due to mental illness in 61%. Very few of these were psychotic. Many of the remaining 39% in the physical disease category might not have been absent, were they not also inadequate personalities. After interviews in the medical department, 30% returned to work

within one week, and 50% within ten days. The effectiveness of this technique was substantiated in another study(32). There was an undue preponderance of females in the absentee group.

It is obvious that the woman requires special health services. Her circumstance is also different in that her home job affects her job at work, and she is also more accepting of absences for minor illness than men (45).

Fallacies of statistics on sickness absence in industry and a method for comparing age-specific rates for populations with varying age distributions is made clear by de-Groot(4).

Automation was the concern of some. Gerstle(11) reports that automation is a generator of anxiety to which most people can adapt. There is fear of the unknown in the machine and reduction in actual laboring makes some feel inferior. Help the physician can give in this area is emphasized. Emery and Marek(6) report a case study of employees transferred from an old to a newly built power plant in Britain. The technological changes were discussed. The supervisor's role became one of broader control of the overall processes rather than hour to hour supervision. He was thus seen as less of an inspector and disciplinarian and more as the possessor of higher technical knowledge. The differences in responsibility and authority were also less than prior to change.

"Automation and Mental Health" was the topic of a well attended open committee meeting of the Committee on Occupational Psychiatry of the APA in Toronto in May. Discussion by Goldstein and Hulsart described experiences encountered in successfully meeting the problems created by automating processes at the *New York Times*. Their papers will be subsequently published.

Occupational Psychiatric Practice. The resistance in industry to the development of psychiatric programs continues in spite of superficial acceptance. Progress is hampered by the fact that the psychiatrist has few channels for communicating with the appropriate people, who in turn have no frame of reference for understanding what psychiatry can do(31). Likewise, the psychiatrist needs a frame of reference for un-

derstanding whether the company's interest will be largely a matter of improving progress and productivity as in large technical companies, or in improving the personal atmosphere as in older tradition-oriented family type companies. Executives are largely unaware of how they can use a psychiatrist as a consultant in management problems, quite apart from his more traditional role as a clinician. This broad role is in keeping with the modern objective of securing and maintaining health and productivity, now that specific occupational diseases are under better control. The concern now can be with early precursors of disease, not early signs. This requires a broad epidemiological analysis in keeping with the concept that non-specific stress diseases have multiple and non-specific etiologies. An example of a comprehensive approach is contained in the following: "That the total assets which the executive brings to his job must equal or exceed the total demands of his job, and that failure to achieve this relationship can result in stress disease"(20). The need for such an approach is in part due to a change in the man-job relationship, in which now there is less direct contact with processes and more psychophysiological stress(14). It is now obvious that attention to the whole man is required and involves a multiplicity of thoughtful alterations in the ways in which employees have traditionally been treated. The benefits to be reaped by such an approach are more prolonged employment and production continuity, and a lessening of the hostility which underlies suits for liability(7). Thus, a human approach to the patient also protects the company. With increasing competition, automation, and increased costs, maintaining the margin of profit depends upon better utilization of manpower, and this requires a better understanding of man in his environment. Serious problems in communication between psychiatry and management must be solved before further steps will be made. Probably neither group is sufficiently aware of its "implicit conceptual world" and its "criteria of credibility"(8).

It is further clear that full-time psychiatrists are most desirable, because only in prolonged daily contact can an intimate

understanding of problems of plant management and the labor force be obtained. Prevention can be furthered by education of the supervisory force towards handling people better and knowing when to make referrals to the medical department, by means of informal discussion groups led by the plant psychiatrist(12). One source of strain in the work environment has been nicely researched by Read(35). This involves the deletion from the communication of subordinates to superiors of information about difficulties they have encountered in their tasks. This occurs where the aspirations of subordinates are particularly strong, and is conditioned by his trust in his superior and his perception of his superior's degree of influence. This leaves the superior in a poor position to judge subordinates' ability to handle problems and insulates the subordinate from sharing the experience of the superior.

Awareness of the social and cultural milieu of employees is essential in view of the fact that the incidence of mental illness is highest the world over in areas of rapid acculturation and because ideas of health education are communicated to deaf ears when there is a disparity of ways of thinking about health between health personnel and employees(33).

There is mounting interest in rehabilitation, and cost considerations are made to seem minimal in view of the cost of compensation award(23). Criteria are being sought out for evaluating employability after psychiatric illness(18), and solutions to difficulties incurred through hiring workers with emotional problems are being worked out(17). The prognosis in terms of work disability for various diagnostic categories has been specified by Gayral and Stern(10).

The Committee on Mental Health in Industry of the AMA issued a *Guide for Evaluating Employability after Psychiatric Illness*(18). Single copies are available from the Department of Occupational Health of the AMA.

One brief monograph by Spriegel and Mumma described a survey to determine the extent and concerns of industrial mental health programs(41). The main findings follow: the reported effects of poor mental

health included, in order of indicated importance, sudden changes in attitudes and actions, excessive use of alcohol, excessive absenteeism, antagonistic attitudes, and accident proneness; mental health programs resulted in reduction in absenteeism, labor turnover, accidents, and grievances and in higher morale, including increased satisfaction of the individual worker.

Executive development programs were examined and psychological shortcomings are pointed out in Levinson's paper(24) and learning and emotional growth were said to be facilitated by the process of identification. But management training is usually assigned to staff personnel who cannot be adequate identification figures. To overcome this, management supplements training with coaching within the line organization. Reasons why this has not solved the problem are given and corrective steps are suggested.

Illness in Occupational Groups. Using the Cornell Medical Index, Valdiva and Caraveda(42) have found that a preponderance of union leaders over managers show abnormally high scores with respect to psychiatric symptoms. It should be noted, though, that the scoring of the Index may be made incorrect by the fact that some of the questions are judged normal on the basis of one's cultural criteria of normality (3).

Dunn and Cobb(5) report that the incidence of peptic ulcer is higher among foremen than executives or craftsmen.

Involuntary reactions occur with greater than usual frequency following occupational injuries in the middle-aged. They appear to be related to the loss of self-importance more than the loss of funds. Compensation has no palliative effect and may help crystallize the condition. Although complaints may lessen while attention is received from lawyers and compensation boards, there is no real improvement, and if the patient's pathological state is questioned the condition worsens.

Kornhauser(22) seeks sound evidence to answer the question "Does job strain contribute to mental illness?" Markedly poorer health was found in less skilled workers, and this could not be related to educational level or other factors which were looked at.

Tentatively it can be concluded that the job itself has a potent influence on mental health.

SOCIAL PSYCHIATRY

F. C. REDLICH, M.D., AND MAX PEPPER, M.D.¹

A discernible trend in the literature during the past year has been the increasingly important concern with planning activities. There are no doubt many factors contrib-

uting to this. Among them we would mention a growing conviction that no major research break-through in specific preventive or curative activity looms large before the horizon, and that knowledge already

¹Yale Univ. School of Medicine.

gained has not been consolidated and utilized in the most effective manner in possible prevention and treatment programs. Also in an era of rising costs for medical care services generally, there is a natural desire to maximize efficiency of administrative and organizational machinery. Thus there are signs of major efforts by many workers in psychiatry and related disciplines to break through administrative and other social barriers to the optimal use of what we have. Ruesch(79) points up this problem from the standpoint of medical education. He states that the "care of the patient" as the primary aim of medicine became submerged as a result of the somewhat disorganizing effect of increasing support for the medical sciences (as opposed to clinical medicine). This effect may be mitigated now by increasing support also for clinical medicine and education of physicians. Furthermore, it has become abundantly evident that the *kind* of further knowledge we *need* can best (or perhaps solely) be achieved from careful attention in design of research, programs and facilities to social factors and the hard facts of community life. Thus, *research* to get at "hard" epidemiological data will probably increasingly necessitate *new* kinds of *clinical* facilities to permit gathering of such data; and also *teaching* will have to relate to the interaction of the two. One logical development would clearly be closer connections between academic and teaching centers on the one hand, and community facilities and institutions such as state mental hospitals, on the other. Another factor is the report of the Joint Commission, which continues to stir lively commentary and criticism(8, 25, 72, 90).

An account of changes of emphasis in mental health work in various nations, based on WHO statistics, from 1948 to 1960 is given by Krapf and Moser(46). Brady's review(13) of publication trends in American psychiatry from 1844 to 1960 also helps to provide some perspective on the current output. Certainly to be borne in mind is that the current increased interest and emphasis on the family and the community does not reflect a totally new perspective but in large measure represents a return to former conceptions, and thus in part is

a phase in historic cycles. Many would agree with Opler(69) that important next steps in psychiatric development will be along organizational levels.

Pertinent to this are the methods for financing care, as an important consideration in determining the social setting in which psychiatric service exists. The economics of psychiatric care is obviously linked with any further developments in the field. The summary report of the Group Health Insurance research project on financing short-term ambulatory treatment indicates that such care is feasible under a prepaid health insurance plan(5). Another publication gives a comprehensive study of insurance coverage in the U. S. for mental illness(42).

Preventive Psychiatry and Public Health. Querido(76) emphasizes that the development of modern medicine renders it imperative to bring preventive and curative activities together and recognize mental health care as an aspect of general health care. An estimate of our currently available tools for modifying the amount of mental disorder produced in a population is provided in the form of a "guide"(1). This volume is a veritable primer in the field and should become a classic in social psychiatry. The chapter on prevention and treatment of the "social breakdown syndrome" is a particularly useful statement of the problem. Together with the separately published subcommittee report(2) this guide helps provide a frame of reference for all workers in program planning, evaluation, and research, and represents the kind of consolidation needed which we referred to above. Caplan(17) also gives an overview of the prospects for preventive psychiatry in the community. Especially when concerned with the problems of chronic illness, the principle of continuity of care emerges as a preventive philosophy(58).

Basic to any attempt at prevention is research in *epidemiology*. And the backbone of any epidemiological endeavor is the case identification procedure. The problem of case identification in psychiatry is discussed by Blum(11), who suggests needed research in this area. One underpinning of the whole field of epidemiologic investigations is the accuracy of definitions and

descriptions of cases and of "normals" or the "healthy." Several studies approach the problem by attempting to describe the characteristics of a group of persons labelled as "healthy" (34, 37, 88). The reliability of psychiatric diagnoses is critically examined in other reports (9, 10, 98). Kantor and Jackson (45) point out that schizophrenia is undergoing a gradual redefining process, and discuss the lines of research nurtured by social scientists. Murphy, *et al.* (64), studied a series of young women at full term pregnancy in terms of the amount of psychiatric disorder in such a population and its relationship to stress and other illness. The "personal problems" reported by neurotics, schizophrenics, and normals are compared by Folkard (30). Finney (29) proposes criteria for cases of mental illness based on a servomechanism model. It is apparent that the use of computers in epidemiologic research in social psychiatry has become standard.

More studies have addressed themselves to the relationship of season of birth and mental illness (66) and intelligence (70). Wiener (96) critically reviews the literature on premature births in relation to psychosocial correlates and Collman, *et al.* (20), report the results of a 15-year survey of the variation in incidence of mongoloid births with time, place, and maternal age. Pasamanick presents an approach to total prevalence in a survey of mental disease in an urban population (73-75). Malzberg (52) continues to publish data on distribution of disease by treatment statistics. The Cumming and Henry study (21) of the process of aging has implications for epidemiological research in its identification of factors in a longitudinally studied population. A study of the prevalence of psychiatric disorder in metropolitan old age and nursing homes is reported by Goldfarb (36). The results of a study made to determine what changes occur when low income families are moved from slums to a better housing environment have been published by Wilner, *et al.* (97). Bowlby (12) summarizes and discusses the evidence for childhood mourning as an etiological agent in mental illness.

The most significant research publication during the past year is the first volume of

the Midtown Manhattan report by Srole, *et al.* (89). A model of conceptual elegance and intellectual honesty is provided in this pioneering endeavor. This book stands as a beacon to all future researchers in the epidemiology of mental disorder.

A number of *follow-up studies* over varying lengths of time continue to appear and enrich our understanding of the life history of disorders and the role of social forces in outcome (3, 26, 40, 78, 91, 100).

The studies of Bahn, *et al.* (6, 7), illustrate the life table method of analysis on standardized clinic data and the use of such data for evaluation of treatment of various diagnostic groups and identification of those patients most likely to be helped by clinic treatment. Evidence of assumption by clinics of increasing responsibility for the psychotic patient was observed, reflecting the development of comprehensive community mental health programs. Brill (14) describes the population changes in New York State mental hospitals since the introduction of the psychotropic drugs.

The crux of epidemiological research, the measurement of incidence, remains the knotty problem it has always been in mental disorder. The answer to the question of who are the susceptibles in a population, and the problem of casefinding methods would seem to be strongly related to the community emphasis needed, which was referred to earlier. Useful bibliographies in epidemiology are given in the report of the Milbank Conference (57) which unites in a volume papers separately published earlier, and the review from Harvard (39).

Institutions. Research in the social structure, communications, and role functions of patients and staff within psychiatric hospitals continues to be reported (22, 81). Rapaport (77) brings to bear the perspectives of a social anthropologist on Maxwell Jones' therapeutic community. Artiss (4) reports on a therapeutic community of acutely psychotic schizophrenics. Fleck describes a treatment program in which the impact of the entire hospital environment is utilized to modify the behavior of young schizophrenics and their families (28). Goffman's essays (35) on the "total institution" are an original approach to the social situation of mental patients. Wing (99) also discusses

the phenomenon of institutionalism in mental hospitals. Gruenberg, *et al.*(38), report further on the attempt to evaluate administrative changes within a hospital by the appraisal of deterioration in a group of long-stay patients.

A discussion of the implications for American services of the English open mental hospitals appears in Milbank Memorial Fund publications(55, 59). The removal of barriers between the hospital and the community must take place from both directions, and the point is made that it will be necessary to examine and change legal and administrative machinery of hospital systems as well as working within current legislative frameworks. Two other articles discuss and summarize recent mental health legislation affecting patient care(71, 82). An example of an advanced community-oriented program of service and research interwoven in the functioning of an institution is given in the model by Lewis and Kraft(50).

Cross-Cultural Studies. Lambo(47) describes a syndrome ("malignant anxiety") which may be related to specific social stresses and therefore only known in specific places at specific times. Another valuable illustration of the value of the cross-cultural approach is Weinstein's book of Virgin Islanders(95) on cultural aspects of delusion. Sanua(85) reviews the literature on socio-cultural factors in families of schizophrenics, and a cultural influence is demonstrated in differential reactions by persons from different cultures to sensory deprivation.(86). From the methodological viewpoint, Chance(18) questions the cross-cultural applicability of survey questionnaires.

The Family. The past year witnessed the welcome appearance of a new journal devoted to the family. (*Family Process*, published jointly by the Mental Health Research Institute of the Palo Alto Medical Research Foundation and the Family Institute of New York.)

A number of studies illuminate the importance of the family in relationship to mental patients(16, 23, 28, 31, 32, 48, 53, 56, 68, 84) and the need for a family orientation in planning for patients.

Public Attitudes, Social Values, Social

Class. Nunnally(67) documents the popular conceptions of mental health. Another study which explored the orientation of leaders in an urban area towards problems of mental illness showed variation with an individual's order of leadership activity. Least congruent with psychiatric views are the orientations of economic leaders in the community (who are high in their influence) and religious leaders (who are most frequently called upon for help)(24). Mechanic(54) explored factors of perception of mental illness in a person by others. Lemkau, *et al.*(49), in a survey of opinions and knowledge about mental illness in an urban population produce interesting findings at variance with former reports by others, and these findings indicate that people are less ignorant about mental health matters than has been popularly supposed.

Jones(43) stresses the need for psychiatrists to clarify their thinking on the moral issues involved in sociopathy and to advocate strongly treatment of these disorders.

The importance of the different social values existing in different social classes is amply documented. Gans(33) provides a comprehensive study of an American working class group. Miller and Riessman(60, 61) critically re-examine the subculture of the working class and some commonly held stereotypes and explanations of working class culture among middle class psychiatrists and social scientists. Suggested approaches to the problems of social class-related differences in the educational system are given by Riessman(80). Others document social class factors related to personality development and disturbances of function (51, 83). Further publications corroborate the social class factors in the actual practice of psychiatry(15, 19, 41, 44, 92) and point out the fact that the lower class patient is less likely to seek treatment, and less likely to be accepted for treatment or to participate in treatment if accepted—but also that the lower class patient who is treated does as well as a similarly treated middle class patient. A relationship between obesity, social class, and mental illness is documented in another paper(62).

Medical Sociology and Social Theory. A good current guide to the literature and

general introduction to social psychiatry within the framework of social medicine and medical sociology is the volume by Susser and Watson (93). The role concept as a bridge between psychiatry and sociology is suggested by Moreno (63). Szasz (94) attempts to explain phenomena of mental illness in terms of social processes, and Smelser (87) gives a theoretical approach to unify the subject of collective behavior.

CLINICAL NEUROLOGY

WILLIAM H. TIMBERLAKE, M.D.¹

Cerebro-Vascular Disease. Severe atherosclerosis is apt to be widespread. At autopsy,

¹ Harvard Medical School, Boston, Mass.

patients with myocardial infarcts have more severe carotid atherosclerosis than other patients (59). When the entire vascular tree

from aorta to brain is examined in patients with cerebral infarcts, half have occlusion or significant narrowing intracranially, but 90% have serious obstruction of the internal carotid vertebral or subclavian arteries where early surgery might be effective(97). Such surgery, whether for stenosis or buckling of the carotid, must be considered preventive of further infarcts rather than curative, even when good backflow results(24, 34, 74).

Premonitory symptoms were elicited in one-sixth of patients with suspected cerebral embolism, but thrombosis was not excluded(94). Sudden or transient neurological symptoms in cancer patients are apt to be due to aseptic emboli from marantic endocarditis(4).

The frequency of carotid bruits in 1000 normal people varied from 85% before age 5 to 12% in those over 50(33). Allan and Mustain(2) have analyzed the production of bruits. They may have multiple causes. They are aggravated by exercise, fever, anemia, thyrotoxicosis, and carotid bruits may increase during a migraine attack. They cease when the vessel is narrowed to 1 to 2 millimeters. The systolic bruit of carotid stenosis is sharply localized, abolished by proximal compression and made louder or continuous by compression of the opposite carotid if that is not occluded. Increased flow in the opposite normal carotid may result in a bruit there. Vertebrobasilar stenosis may cause a murmur over one or both carotid or orbital regions. The high intensity, continuous murmur of a cavernous sinus fistula is loudest over the orbit, but is conducted widely in bone and is not obliterated by compression of one carotid. When present, the bruit of A-V malformations resembles that of fistulas but may be reduced particularly in the diastolic phase by compression of the jugular vein.

In a controlled study, the parenteral use of a hypotensive agent titrated by half hourly blood pressures was of definite benefit for intracerebral hemorrhage, but not for subarachnoid hemorrhage alone(56).

In a double-blind study of fundus photographs of hypertensive patients, treatment decreased the hemorrhages and exudates, local areas of arteriolar constriction sometimes relaxed, collaterals developed and

partially obstructed arterioles might recanalize(43). Hypoxia is suggested as the cause of retinal venous distention often segmental with internal carotid artery occlusion(36).

The sedimentation rate should be checked if there is sudden loss of vision, ocular vascular occlusion or unexplained ophthalmoplegia in patients 54 to 84 years old. If it is elevated, a temporal artery biopsy may confirm an occult temporal arteritis which should be treated with steroids(82).

In a controlled study of 121 patients, Hill and Marshall(37) found that the small but definite risk of intracranial hemorrhage among the half on anticoagulants was not counterbalanced by any adequate protection against thrombosis.

McKissock, *et al.*(54), report the first comparison of patients with ruptured middle cerebral artery aneurysms fully studied and considered operable then randomly assigned to surgical or conservative treatment. Only in the men was survival significantly ($p=0.05$) better after surgery. Perhaps the poor result in women is because their aneurysms are smaller and more sessile(19).

The specific benefits of physiotherapy and speech therapy are beginning to be critically appraised in terms of spontaneous recovery. Twelve children, aphasic because of vascular lesions, age 3 to 15, whose parents were specifically told to avoid trying to teach them to speak, all regained speech spontaneously, and four spoke normally. Prognosis was best when a child could pick out a named object soon after loss of speech(15). Retrospective comparison was made of 74 untreated children with cerebral palsy and a generally similar group who had at least once weekly treatment for 5 years. For mild hemiparesis, the results were similar, except that the treated group had a better quality of gait and fewer contractures. The same was true for tetraparesis, but here the eventual orthopedic surgery was the same for both groups. For the extrapyramidal type, gait and hand function were comparable though poor in both(63). In adults, in a controlled study of 80 patients with hemiparesis due to cerebrovascular accidents, functionally oriented medical care resulted in slightly, but not significantly, better muscle function and

mental state than formal rehabilitation. Adequacy in activities of daily living was slightly better in the rehabilitation group when initial impairment was mild to moderate. Only one patient, a member of the non-rehabilitation group, returned to work. The vast majority of hemiparetic patients recover satisfactorily on medical wards if proper attention is given to ambulation and self care(26).

Bickerstaff(9) describes a basilar artery occipital migraine in adolescent girls with family and past history of migraine who have teichopsia and visual impairment of both fields, dysarthria, vertigo, tinnitus, unsteady gait, acral paraesthesias and in one or more attacks gradually lose consciousness to the level of stupor.

UML 491 (1-methyl D-lysergic acid butanolamide) seems to reduce attacks of migraine by preventing the initial vasoconstriction(20, 31).

The delayed neurological deterioration after anoxia may perhaps be lessened if the patients are kept inactive for two weeks (70).

Infection. Based on 658 cases of acute bacterial meningitis, Quaade and Kristensen(71) recommended that meningococcus be treated with penicillin and a sulfonamide; hemiphilus, with streptomycin and a sulfonamide; pneumococcus, with penicillin and a sulfonamide; and undiagnosed bacteria, with penicillin, streptomycin and a sulfonamide. Early use of steroids may prevent membrane formation.

In animals, a type III pneumococcus bacteremia resulted in meningitis only when the meninges were punctured(67).

Toxoplasmosis may be divided into four phases: acute, during generalized infection; subacute, when there is prolonged infection in areas of decreased immunity (eye and brain); chronic, when there is hypersensitivity and tissue necrosis results from rupture of cysts; and burnt out, without infection but with scarring from previous infection. Treatment of the infection with sulfadiazine and pyrimethamine, like that of tuberculosis, depends upon an unusable vitamin to block biosynthesis, and toxicity can be relieved with leucovorin (folinic acid). In the chronic phase, corticoids are a useful adjuvant(28).

Contrary to expectations, Laird(44) finds a marked reduction in the incidence of general paresis over the last decade. A current review of syphilis by Beerman, *et al.* (10), recommends the VDRL Slide Flocculation test as a survey test. If this is positive, a Reiter Complement Fixation test should be done. If that is non-reactive, a Treponema Pallidum Immobilization (TPI) test should be done to distinguish a present or past syphilitic infection (positive TPI) from a Biologically False Positive (negative TPI). Present recommended therapy is 6 to 10 million units of penicillin, or 4 million units of bicillin.

Oral immunization against poliomyelitis is becoming more successful, but there are still problems. Most important has been the occurrence of 16 cases of polio in non-epidemic areas within 30 days of vaccination, hence possibly due to the inoculation(89). Two followed type I virus. One of type II virus occurred in a patient given only type III virus. Thirteen followed type III virus inoculation. All but three were in patients over 30 years old. There have been no deaths, but symptoms were sometimes severe. In some communities during the season of high incidence of other enteroviruses, these interfered with the take from oral polio vaccine(65). In other circumstances, oral polio virus caused disappearance of wild strains of polio, but other enteroviruses continued as intensive as before(23). In Algiers, a polyvalent vaccine against diphtheria, tetanus, typhoid, paratyphoid and polio gave good protection against polio, but interfered so much with other vaccines that such combinations are not recommended(7).

Neoplasm. Of 450 intracranial tumors, 34 were unexpectedly found at autopsy though 22 had caused symptoms. McLaurin and Helmer(55) make the following points: CSF pressure is not apt to rise with strokes. Only 12% of stroke patients have focal seizures compared with 50% with tumors. Meningiomas may cause intermittent symptoms and brain tumors can have a catatrophic onset. They found air studies 90% reliable; arteriograms, 80% to 90% reliable.

Calcification is more frequent in less malignant tumors, but chemically and physically is the same as pseudocalcium pre-

capitates found elsewhere in the nervous system and not related to tumor type or age(78).

Suprasellar tumors, such as craniopharyngioma, by damaging the hypothalamic source of vasopressin are more apt to cause diabetes insipidus than tumors of the posterior pituitary and may also simulate tumors of the anterior pituitary by interfering with its hypothalamic hormonal control via the portal veins(72). Sherwin, *et al.* (80), describe several cases of small hamartomas of the posterolateral hypothalamus causing multiple endocrine abnormalities.

There is an 8% risk of radiation myelopathy in treatment of nearby tumors if more than 10 cm. of cord are exposed to 3,300 rads in 42 days or less than 10 cm. of cord to 4,300 rads. The small penumbra of a super-voltage machine is safer(64). Acute radiation injury of the brain, as seen by the electron microscope, consists of clumping of chromatin, shrinkage of the nuclear membrane and blebbing of the nucleus, but the axons and myelin are unaffected. Glial swelling is limited to the astrocyte feet(69).

Multiple Sclerosis. In experimental allergic encephalomyelitis, several days before clinical symptoms appear, there is perivenous infiltration with mononuclear cells. These invade the parenchyma and seem to destroy the myelin in contrast to all other diseases where myelin breakdown occurs before mononuclear invasion. Plasma cell invasion follows as a secondary response(91).

Epilepsy, frequently focal, may occur as an initial symptom or as an integral part of a relapse of multiple sclerosis, but chronic, recurrent fits without such obvious relationship are probably coincidental and may be due to a brain tumor(50).

Forty consecutive multiple sclerosis patients with new symptoms within 14 days and without improvement were divided into two matched groups. The group treated with ACTH improved significantly more clinically ($p = 0.05$) than the control group given saline(57).

The final report of 30 patients treated with two intrathecal injections of tuberculin PPD compared with 30 given saline indicates no effect on the course of the

attack, and the occurrence of more exacerbations during the next 3 years. The immediate reaction was always uncomfortable and sometimes alarming with urinary retention, 6 cases of meningitis and 2 patients comatose(58).

Basal Ganglia Diseases. The most incisive analysis of current knowledge about the basal ganglia is Dr. Denny-Brown's monograph(21).

Smith(85), correlating clinical with post-mortem location of stereotactic lesions aimed in 11 instances at the globus pallidus and in 4 at the thalamus, found improvement only in severe lesions affecting variously the globus pallidus, ansa lenticularis, *systeme en peigne* of the internal capsule, the fields of Forel or the lateral ventral nucleus of the thalamus.

Onuaguluchi(62) has carefully described the crises of 20 post-encephalitic parkinson patients. Prodromally, there is slowness, less activity, quarrelsomeness, depression, an unpleasant aura and injection of the conjunctivae. The eyes usually turn up or up and laterally, rarely downward. Lateral movements are usually away from the side of greater rigidity. Unless there is photophobia, the eyes stare. In some, there is upward nystagmus and flickering of the lids before the eyes become fixed. Voluntary lateral movements are momentary or impossible. The pupils are usually dilated and the face flushed. Rigidity, tremor, salivation, pulse and blood pressure increase. Headache is usually frontal. One-third have vertigo. In a few, respirations become irregular and the most severe grunt, moan or give a "seagull cry." Eight patients had sweating crises with flushing and fever, not necessarily related to the oculogyric crises and usually coming late at night.

Martin and Hurwitz(48) find that post-encephalitic parkinson patients have difficulty walking because of loss of the postural controls to shift their center of balance forward and sideways. They can walk if these shifts are supplied. With Finlayson(49) they describe the disorders of postural fixation, equilibrium and righting, locomotion, phonation and articulation and akinesia of these patients.

Compared with a control group, the cognitive functions of 45 ambulatory park-

inson patients seemed to be impaired only as an effect of medication(87).

Electromyographically, the blink reflex is composed of a proprioceptive and a nociceptive component. In parkinsonism, normal adaptation of the second component does not occur(75).

Although the 1 to 3.5 per second component of intention tremor is probably neuromuscular, Brumlik(12) finds that the normal "tremor" at rest has the amplitude, frequency and wave form of a lateral ballistocardiograph, and it persists after complete neuromuscular block. Hofman(38, 39) feels that the muscle spindle apparatus plays a significant role in parkinson tremor and that rigidity is due to a defective bias of these sensors. Shimazu, *et al.*(81), as a result of EMG studies, think pallidectomy lessens rigidity by damping the gamma motor system.

The high concentration of 5-hydroxytryptamine in the areas of the brain damaged in parkinsonism and the occurrence of parkinsonian symptoms after drugs which release 5-hydroxytryptamine (reserpine) or clinically antagonize serotonin (phenothiazines) have led to speculation about a biochemical basis for parkinsonism. Barbeau(6) found a decrease of 5-hydroxyindolacetic acid excretion in the urine of parkinson patients and a transient increase of parkinsonian symptoms after giving Dopa. However, Resnick, *et al.*(73), found no difference in urinary excretion of indoles in parkinson patients or patients with other neurologic diseases in the baseline period or after 1.3 mg./kilo of 5-hydroxytryptophan daily and no change in symptoms. Present methods proved too insensitive to measure 5-hydroxyindole compounds in the CSF. They conclude a biochemical lesion, though not excluded, is unlikely.

Bittenbender and Quadfasel(11) describe a rigid variant of Huntington's chorea with an early onset. The rigidity may appear at any stage of the disease, but usually appears first proximally and often blocks out static and intention tremor and chorea.

Metabolic Disorders. Severe liver disease, other than Wilson's disease, can cause low ceruloplasmin levels in children or adults

(93). Radioactive Cu^{64} studies indicate that the basic defect in Wilson's disease may be an inability of the liver to conjugate copper to apoceruloplasmin rather than a lack of ceruloplasmin(52). By electronmicroscopy, copper is seen to be deposited in liver cells in the cytoplasmic lysosomes increasing their density. Histochemically, acid phosphatase activity is reduced in hepatic cells, particularly those with glycogen degeneration of their nuclei and cytoplasmic fat droplets and lipofuscin pigment(77). Half of the patients present with hepatic and half with neurologic symptoms, one had a metabolic bone disease(92). D1-penicillamine is reported to be more satisfactory than BAL in treatment(30), despite its slight nephrotoxicity(61). Copper clearance is thought to be the best indication of response to penicillamine(94).

Hepatic encephalopathy is probably not due to ammonia intoxication alone. In a double-blind study of the psychological functioning of cirrhotic patients, changes did not correlate with elevation of arterial blood ammonia by infusion, and it appeared that several factors may be interacting over a period of time(18). McDermott *et al.*(53), find that 18% of surgical shunt patients develop mild, intermittent encephalopathy and 6%, chronic encephalopathy. Surgical by-passing of the colon in 3 of the latter patients resulted in improvement of even severe intellectual impairment, choreoathetosis and ataxia.

Sanders(76) has reviewed the neurological complication of myxedema. Coma with convulsions and subnormal temperature occurs mostly in the winter. Treatment consists of thyroid, artificial respiration and possibly warming and steroids. Patients with myxedema psychosis may be suicidal. Paresthesias and myalgia occurred in 79 of 80 patients, and ataxia in 8 of 9 patients. Both the vestibular and acoustic division of the eighth nerve are affected in 15% to 30% of patients. The chronic, diffuse headache is helped by thyroid, but not by aspirin. Dysarthria, hoarseness and prolonged deep reflexes are due to myxedema of the muscle. The CSF protein is often increased to over 100 mg. percent. Astrom, *et al.*(5), found primary changes of skeletal muscle in biopsies. Havard(35) suggests that weakness in

thyrotoxicosis also is due to myopathy, not aesthenia.

Among 490 diabetics, Fry, *et al.*(29), found neuropathy in 66. Symmetrical peripheral neuropathy developed acutely in 4 uncontrolled diabetics who recovered rapidly when treated. Insidiously developing polyneuropathy, mononeuropathy (including ocular and facial) and asymmetrical, proximal amyotrophy occur about one-fifth of the time in diabetics while under good control. Some of each type improved. Compared with normal controls, motor nerve conduction time is impaired in ulnar median and peroneal nerves of symptomatic and asymptomatic diabetics independent of age (45).

The blood brain barrier was abnormal in 18 of 19 patients with uremia. Muscular twitching was correlated only with the rising of the CSF phosphorus level above 3.9 mg. percent(27).

Vegans, strict vegetarians with practically no vitamin B₁₂ intake, are comparatively free of clinical signs, but have diffusely abnormal EEG's(83).

Spinal Disease. A Horner's sign and pain give a bad prognosis in traumatic intradural avulsion of the brachial plexus. The use of intradermal histamine to produce a flare and so indicate an intact peripheral axon reflex is helpful diagnostically(88). Using it and myelography, surgical exploration can be avoided.

Gurdjian, *et al.*(32), tabulate the result of 1176 operations for protruded lumbar disc as: 21%, excellent; 42%, good; 12%, fair; 4%, poor; 21%, lost. They advise against operation if the myelogram is negative.

Phenylmyelography for relief of pain helped 66 cancer patients, but not 20 patients with neuralgia and pain of other causes. At autopsy, changes were not limited to C fibers(47).

Muscle Diseases. Evidence is accumulating that myasthenia gravis is an autoimmune disease. In 1960 by immunofluorescent (IF) methods, Strauss, *et al.*(86), demonstrated in myasthenic, but not in normal sera, a complement fixing globulin fraction which would bind with skeletal muscle. Beutner, *et al.*(8), directly, using labelled patient's globulin, and indirectly, using labelled anti-human gamma globulin

serum, demonstrated the IF reaction with skeletal and cardiac muscle. In a "complement staining" reaction, using labelled antiserum against guinea pig globulin to stain fixed guinea pig complement, they obtained a reaction from skeletal muscle only so that there are two antigen-antibody systems, S (skeletal), and SH (skeletal-heart). Using the S system, they have fixed antibody using the patient's own muscle, proving that this is an auto-antibody reaction. Moreover, the thymus in myasthenia histologically resembles a lymph node draining an area where a homograft is being rejected (13) and an autoimmune response can be demonstrated in its germinal centers(96). This mechanism makes understandable the lymphorrhages in the muscles and the transient myasthenia of infants born of myasthenic mothers. (The process of auto-immunization is reviewed thoroughly by Waksman(90). The technique of IF is described by Smith, *et al.*(84).)

Engel(25) describes an elegant cytochemical differentiation of muscles in a variety of neuromuscular diseases. In all forms of muscular dystrophy, except the myotonic, Pierce and Walton(68) found the same fiber necrosis, phagocytosis and even some regeneration as in polymyositis. They could not distinguish the subtypes on histological grounds alone.

Pearson(66) has found gradually increasing serum aldolase and glutamic oxalacetic transaminase in muscular dystrophy before the first hyalinization is visible in biopsies. Fifty percent of the muscle fibers are lost before weakness is perceptible. In the advanced stage of weakness when most of the muscle fibers are gone, the serum enzyme levels fall again to normal. Hughes (41) found increased serum aldolase and phosphocreatinase in carriers of muscular dystrophy, particularly sisters of patients.

Cardiac muscle is affected as early as skeletal muscle in progressive muscular dystrophy, as can be shown by ballistocardiography long before EKG changes occur(46).

Halogenation of steroids seems to increase their propensity to cause a myopathy which subsides when they are stopped(14).

Cerebrospinal Fluid. Cerebrospinal fluid glucose follows blood glucose changes with

a latency of 4 to 30 minutes and so for comparison, the blood sugar should be drawn half an hour before the CSF(51). In metachromatic leukodystrophy, the CSF reflects the rise of neutral lipids and cholesterol, but the metachromatic materials being in the areas of demyelination are not apt to reach the CSF(3). For cytologic examination of CSF using a millipore filter, saline should be added to the CSF to avoid excessive adsorption of the surfactants on the few cells(60).

Diagnosis. Shapiro has written an excellent monograph on myelography(79). Di Chiro has used laminography to prepare a superb atlas of normal fractional pneumoencephalography(22).

Humphry and Shy(42) have reviewed their experience with diagnostic EMG's in 159 patients. Intensity-duration curves fall by the third day if the facial nerve has degenerated in Bell's palsy, whereas fibrillations are rare before the tenth day(16).

Transillumination of the infant skull will demonstrate subdural hematomas after 4 to 7 days when the blood has hemolyzed(40).

Positional nystagmus of central type (persistent vertigo and nystagmus as long as the head is in the posterior dependent position) may signify a subtentorial metastasis(17).

A classification of headaches has been drawn up by the ad hoc committee(1).

ALCOHOLISM

KARL M. BOWMAN, M.D.¹

Lester(1) gives a lengthy review of the literature regarding the presence of ethyl

alcohol in the human body and its serving as an important source of energy. He speculates as to its occurrence as a result of

¹ 3831 Market St., San Francisco, Calif.

exogenous and endogenous factors. He concludes

that (1) ethanol as such, and not another volatile reducing material, occurs in human beings and other mammals; (2) ethanol is formed endogenously and not as a result of bacterial fermentation in the intestinal tract; (3) the endogenous ethanol concentration varies from individual to individual; and (4) the concentration of ethanol may be increased in a number of ways, notably by hypoxia.

The rate of formation of ethanol at the low concentrations probably obtaining in the human requires the formation of 0.79 g. of ethyl alcohol per hour in the 70-kg. adult for each increment of 10 mg. of ethanol per liter of serum. As a normal level in human beings of between 20 and 30 mg. per liter seems not unlikely, 1.6 to 2.4 g. of ethanol may be produced per hour, accounting for some 14 to 20 per cent of the basal energy requirement.

Because of the bearing this may have on the addictive process, on the genesis of alcoholism and on the treatment of the alcoholic, some suggestions are made for a thorough investigation of this question to resolve all matters at issue with regard to the endogenous nature of the ethanol and its identification and concentration.

In a second paper Lester describes in detail experiments conducted to clarify the question of endogenous ethanol. The last paragraph of his summary is quoted: "It is concluded that ethyl alcohol may be present in humans in concentrations up to 1.5 mg. per liter of blood but whether this alcohol is of endogenous origin is unresolved; even if such formation were endogenous, its fraction of the basal metabolic rate would not exceed 1 per cent. A possible role of endogenous ethanol in a theory of the etiology of alcoholism appears excluded."

Several articles have appeared dealing with the toxicity of the congeners. A study of the lethal dosage in rats of the congeners in whisky showed that furfural was the most toxic and that other congeners such as aldehydes, esters and acids were all more toxic than was ethyl alcohol. Another test comparing the congeners of vodka to those of whisky(2) showed almost no effect when vodka congeners were followed by 4 oz. of vodka. Whisky congeners had a salty, sour, pickle taste and produced a

feeling of revulsion. When 4 oz. of whisky was taken a feeling of elation was produced followed by confusion. The authors conclude that whisky allergies can occur and recommend vodka over whisky for therapeutic use.

A very large number of articles have appeared during the year discussing the merits of various drugs for the treatment of acute alcoholism and delirium tremens. Many of these articles contradict the claims given in other articles and there does not appear to be any conclusive proof of any new drug treatments of especial value.

Walsh(4) calls attention to the occasional appearance of Korsakow's psychosis following immediately a convulsive seizure. He feels that the dementia in some chronic alcoholics is due to this. He advocates the use of anticonvulsants and vitamin B during the withdrawal period. He claims that during a convulsion brain metabolism and consequently the expenditure of B vitamins may be increased fifty-fold. He considers permanent brain damage may occur if the metabolic processes in cerebral neurones are stopped for more than about 5 minutes.

The argument still continues as to the magnesium levels in the serum in acute alcoholism and in delirium tremens.

In an interesting discussion of the new Rutgers Center of Alcohol Studies, Selden D. Bacon(5) points out that there are questions and needs—from the needs which the academic disciplines have to other questions and needs which those confronted with the practical solving of problems have connected with alcoholism. All of this can perhaps be best summed up by quoting the last paragraph of his paper.

The Center of Alcohol Studies, then, is primarily a research organization. Its purpose involves biochemical studies of alcohol in relation to brain, to liver, to total organic functioning; it involves study of the processes of thought, perception, and emotion; it is concerned with analysis of custom, of innovation, of sanction, of group, of the taking-on of cultural patterns, of attitudes and moral convictions, and of their interplay and growth. It studies both the usual or "normal" and also the unusual or deviant or "pathological." Hence it is interested in ordinary drinking as well as in alcoholism. It takes questions from academic

and also from "practical problem" sources. It tests emerging answers and hypotheses in artificial and in natural settings; thus its researches are conducted in the library as well as in the laboratory, in the field and in the clinic. By focusing on one set of human and social phenomena it attempts to bring a wide scope of arts and sciences into a meaningful and useful integration. It makes its findings and interpretations useful not only by contributions to the world of research disciplines but also to the wide diversity of social-action groups concerned with problems related to alcohol and its use, perhaps above all to those concerned with health. Of special importance to the Center is the matter of collecting, editing, storing for systematic retrieval and selectively communicating both its academic and action-group findings, using all modes of communication and attempting to analyze and assess the communication process itself.

Marvin A. Block(6), Chairman of the Committee on Alcoholism of the AMA, details the program of the Committee. The final paragraph is quoted to indicate the conclusions and attitude of this committee.

The etiology of alcoholism is still a mystery. We do know that many sociological, legal, economic and cultural factors contribute to the possibility of individuals becoming alcoholics. In the field of prevention, knowledge about these factors can be brought to bear most advantageously. Rehabilitation, however, can be accomplished only by dealing with individuals who suffer from the illness. Until we understand the individual and his problems, both physical and mental, we cannot help him. It is important, therefore, that in any educational program, whether for professional or laymen, the medical and psychiatric aspects of the disease be taught in detail, and the participation of the physician in every type of program is essential.

The House of Delegates of the AMA adopted the following policy statement (7): "Blood alcohol of 0.10 per cent be accepted as *prima facie* evidence of alcoholic intoxication, recognizing that many individuals are under the influence in the 0.05 to 0.10 per cent range." This followed recommendations by the AMA Committee on Medical Aspects of Automobile Injuries and Deaths and by the AMA Committee on Medicolegal Problems approving such a statement.

In a paper entitled "Some Recent Physiological and Biochemical Investigations on Alcohol and Alcoholism," Kalant(8) gives a careful appraisal of the subject with some 133 references.

Davies(9) presents an interesting article which points out that most authorities agree that no alcoholic will ever be able to drink normally again and that successful treatment requires abstinence to be total and lifelong. He then describes "seven men who were treated for alcohol addiction and who have subsequently been able to drink normally for periods of 7 to 11 years after discharge from hospital . . . It is suggested that such cases are more common than has hitherto been recognized, and that the generally accepted view that no alcohol addict can ever again drink normally should be modified, although all patients should be advised to aim at total abstinence."

Two articles discussing this same problem(10, 11) bring out further interesting material, followed by a summary of the general discussion of these two papers presented at the Michigan Institute of Alcohol Programs, Apr. 1960. Moore feels that most therapists insist on abstinence as a part of the treatment. He concludes "Differences of opinion as to the need for abstinence in the treatment of alcoholism may partly reflect uncertainty concerning its etiology. A major reason for the controversy, however, rests in the viewing of alcoholism as a neurotic disorder. When it is seen as a manifestation of a deeply ingrained, hedonistically oriented, ego-syntonic disturbance, protected from detection through the defense mechanism of denial, the controversy seems more academic. Abstinence as the first step in the treatment of alcoholism is desired, though more often difficult to obtain, and is based on the psychological understanding of alcoholism." Krystal agrees that abstinence is desirable not only as an end but also as a condition of treatment. However, he feels that it is not always possible to secure this and that this has to be worked out by rather intensive psychotherapy particularly dealing with the patient's fantasies in relation to alcohol. In the two-page summary of the general discussion the many problems that arise in the treatment of the alcoholic are brought up. There was a considerable

disagreement as to the length of time a patient required hospital treatment. The difficulties of the therapist avoiding the role of disciplinarian was emphasized as well as various other problems of treatment.

GERIATRICS

KARL M. BOWMAN, M.D., AND BERNICE ENGLE, M.A.¹

Signs of aging noted by H. Himwich(8) in well, elderly persons include decreased basal metabolism and oxygen consumption of the body at rest; diminished plasma flow through the kidney; altered cellular function; and loss of neurons in the brain, with lessened brain weight. The fewer neurons primarily cause the impaired volume of oxygen used by the brain; their continued loss leads to senile dementia, with decreased intellectual ability, forgetfulness of recent events and emotional blunting. By age 140, it is estimated, the brain would be half its weight and mental abilities be greatly impaired.

In a comparative study(9), 20 subjects with focal loss of tissue from the cerebral hemispheres, as verified by air encephalography, had impaired highest integrative functions. The degree of impairment was "directly related to the total number of inadequately functioning neurons," no matter where or how distributed throughout the hemispheres. Komarov(11) has speculated that possibilities for altering the intracellular biochemical and biophysical processes could radically prolong life. Bjorksten (4) has suggested that the only nutritional way to control aging on a molecular level is a low caloric but adequate protein intake, "so that free amino acids can draw off some of the intermediates which would otherwise cross-link proteins or nucleic acids over their amino groups." Science can find means to break down "even heavily

cross-linked proteins and nucleic acids." This theory is considered "compatible with Shock's ten criteria."

Shock's 10 facts about aging, as summarized by Leake(12), are: 1. With age the probability of death increases logarithmically, while measurements on functional capacities decline linearly. 2. The life span is related to genetic factors; 3. Is shorter for males than for females; 4. Is influenced by diet; 5. Is shortened by increasing temperatures and lengthened by lowering temperatures; and 6. Is shortened by nonlethal radiation exposures. 7. In the same individual, the rate of change with age differs among different organ systems; and 8. A generally reduced reserve against stress goes with increasing age. 9. The age changes are greater in total organ performance than in intracellular biochemistry; and 10. With the complexity of the performance measured, the age changes increase.

Rural life, continued activity, heredity and abstinence from sexual indulgence, smoking and alcohol favored longevity in a Russian study(5) of 217 mountainous people aged 100-147. But a large scale study of aged Kentuckians gave no edge to rural over urban living(22).

Ross' review(18) of studies on centenarians pointed to factors of morale in the aged as important, particularly high motivation and group participation and achievement.

At Duke University the results of a geriatric comparative study of healthy community volunteers, residents of an old age

¹ University of California, San Francisco, Calif.

home and state hospital patients suggested that not age per se but health status critically determines the degree of relationship between EEG and intelligence test correlations. Only diffuse slow activity and slow alpha rhythm, both increasing with age, were significantly related to impairment of intellectual function in the two institutionalized groups but not in the community volunteers(15). In an Indiana study(10) of patients with verified brain damage the Halstead Index picked up both older and younger subjects with brain damage but with normal EEGs. The Birren study(3) of speed performance established a general speed factor of slower response with aging.

A British geriatrician(17) in a 2-year controlled study of 72 aged patients with paranoid illness found high dosage of phenothiazine drugs for several months very beneficial. Most of these patients (usually given a poor prognosis) materially improved or lost their symptoms.

Nialamide therapy benefited 50% of 65 depressed patients aged 60 to 80(2), but 20 chronic male geriatric patients improved only slightly(21). Ethyltryptamine was an effective energizer in a controlled study of 56 patients with parkinsonism and reactive depression(6). Electroshock therapy proved effective in very depressed schizophrenic patients who had not responded to a fair trial of antidepressant drugs. Maintenance ECT was successful in a group of depressed patients who did not improve for long with any therapy(13). A number of other reports concern improvement after use of various psychopharmacological therapies.

An attempt to increase self care and activity in aged patients in a 96-bed hospital custodial ward brought a good deal of improvement, with release of a considerable number. A British writer(19) has insisted that all long-stay geriatric wards can be developed into therapeutic communities. To reduce the numbers of long-term Welsh patients, a special type of residence for the ambulant confused aged has been proposed (1).

In a 5-state study of persons aged 65 and older, 510 highest scorers in personal adjustment were compared with 428 lowest scorers. The superficial positive factors for good adjustment included marriage, home

ownership, high school education or better, participation in social, civic or professional rather than church organizations(20).

Cumming and Henry(7) in their report of normal aging persons, a section of the Kansas City Study, have developed the disengagement theory of aging as an inevitable mutual withdrawal, with varying but decreased interaction, between the aging person and his social milieu. Ideally, old age should succeed middle age and not prolong it, and the healthy old person may properly devote some thought to death.

Three writers have outlined the advantages for both pensioner and employer of second jobs after retirement(16).

From a study of a large American Catholic religious male order, Madigan(14) has retrospectively suggested that these men because of their high role satisfactions and despite their many life stresses lived longer than did white males in the general population of the study period. Admittedly, research is needed.

EPILEPSY

WALTER J. FRIEDLANDER, M.D.¹

The parameters of electrical stimulation alter the characteristics of a seizure. The longer the duration of the stimulus to the hippocampus, the more involved the seizure and, though repeated hippocampal after-discharges do not modify the local threshold(1), the general convulsive threshold is increased by repeated (1 to 21 day) electroconvulsive seizures(2); the importance of the parameters of stimulation was emphasized by the study of a single, epileptic patient with chronically implanted electrodes in whom, depending on the parameters and sites of cortical stimulation, there were: local electrographic responses, distant potentials, contralateral homologous responses, diffuse responses, or activation of epileptiform discharges which were isolated or bilateral, diffuse, 3/sec. wave-spike complexes(3). Dow and his associates(4) found that stimulation of the cerebellum could inhibit the activity of an experimental epileptogenic lesion while ablation or cooling of the cerebellum enhanced its activity. Centrencephalic epileptics appear to have a cyclic retention of sodium with an electroclinical aggravation as the sodium increases and then a phase of improvement associated with a sodium diuresis. This is believed to be principally an intracellular sodium retention(5-8). Schneider and Rust(9) suggest that this is due to a disturbance of the diencephalic centers that govern hydroelectrolytic movements. The hydrolysis of ATP is, at least in part, coupled to a reaction with the sodium ion(10). Convulsions decrease by 50% the amount of "bound" (nondialyzable) brain sodium(11). In all these various sodium studies, potassium was usually either not affected or responded in an opposite fashion to the

sodium. Some children with "spike-wave epilepsy" may have an increase aminoaciduria(12). In 2 unrelated children with leucine-induced hypoglycemia, seizures could be induced by the administration of leucine even though the hypoglycemia was prevented by the continuous administration of glucose(13); in leucine-sensitive children, administration of galactose produces a hypergalactosemia and when leucine and galactose are given together, there is a marked decrease in insulin activity(14). Interest in gamma-aminobutyric acid (GABA) continues but its actual function remains controversial: systemically administered GABA influences the electrographic pattern in experimental epilepsy but the biochemical changes in the epileptogenic areas cannot be correlated in time with the electrical changes(15); hydroxamine or amino-oxyacetic acid can increase brain GABA, but electroconvulsive or hydrazid-induced seizures are unmodified (16, 17); and GABA or gamma-amino-beta-hydroxybutyric acid given intracisternally did not prevent toxopyrimidine or isonicotinic acid hydrazid seizures(18). On the other hand, GABA is reported to decrease hydrazide-induced running fits(19, 20), to be reduced in the brain of human epileptics (21, 22), to have an antagonistic action with strychnine, Metrazol, morphine or ammonium chloride (23) and to reduce the number of seizures and death due to oxygen toxicity(24). In experiments which differentially affect nor-epinephrine and serotonin (5HT), it is concluded that the convulsant, hexafluoro-diethyl ether decreases convulsive threshold by decreasing the nor-epinephrine rather than changing the 5HT(25); 5HT will exaggerate the EEG abnormalities in experimental epilepsy(26), will produce seizures in newly hatched chicks(27), is

¹ Dept. of Neurology, Albany Medical College, Albany, N. Y.

increased in the CSF in 4 out of 9 patients with convulsions although it was also elevated in a number of other types of CNS pathology(28), and is increased in the brain particularly in the mesencephalon and diencephalon after electroconvulsive seizures(29). Reserpine abolishes the anticonvulsant activity of a carbonic anhydrase inhibitor(30) and will increase the death rate after audiogenic convulsions(31). Extracts of brain after electric shocks are capable of facilitating the sleep effect of Evipan(32) and have a convulsant effect when given intrathecally(33). There is a lower convulsive threshold in females presumably because of the role of estrogenic substances(34-36).

Several studies reported on the relation between seizures and maturation; the type of attack experienced by the animal or human varies with age and follows the rule of the ontogeny recapitulating the phylogeny(37-40). Yakovlev discussed the histological changes of maturation and suggested that the development of a dense reticular grid of vertical and horizontal tresses of basilar dendrites and collateral axonal plexus along with other changes facilitates the development of the adult type seizures(41). Emphasis has been placed on the fact that certain types of seizures seen in infancy or young children are probably *types* of reactions rather than specific disease entities, e.g., the triad of massive spasms-mental deterioration-hypsarrhythmic EEG (42-45) or hemiseizures(46).

In the field of genetics there were reports of: the high concordance of epilepsy in monozygotic in contrast to dizygotic twins(47, 48); the positive relationship between susceptibility in mice to audiogenic seizures and "dilute coat-color" (animals who have decrease in phenylalanine hydroxylase activity)(49); and a family with photosensitivity and hyperprolinuria(50).

Obstetrical complications(51), neonatal asphyxia(52), being the first born(53) and having a very low birth weight(54, 55) all contribute to an increase incidence of epilepsy. The incidence of epilepsy in various disorders were reported; it occurs in 40-50% of patients with porencephaly(56), in only 2 of 34 patients with craniostenosis (and both of these also had mental re-

tardation)(57), in 22%(58) or 37%(59) of cases with cerebral cysticercosis, in 4% of children who have recovered from a bacterial meningitis(60) or 5% of children after tuberculous meningitis, in 5% of posterior fossa brain tumors and 37% of supratentorial brain tumors(61), in 17% of children with intracranial tumors (with an average of about 1.8 years between the onset of seizures and the diagnosis of a supratentorial tumor but only 0.3 years with an infratentorial tumor)(62), in 48% of 209 patients with a cerebral astrocytomata(63), in 13%(64) or 33%(65) of patients with cerebral angiomas, in only 3% of cases with closed head injury in whom the injury was unassociated with skull injury but in 5% who had injury to the skull, too(66), in only 6% of infants with skull fractures(67), in 42% of patients with chronic subdural hematomata(68), in 8% of patients who underwent psychosurgery(69) (with a particular predilection in patients suffering from catatonic schizophrenia(70)), in 36% of patients with phenylketonuria(71), in 14% of cases of retrolental fibroplasia(72), in 3% of patients with hyperthyroidism(73) and in 44% of patients who had neurological complications of abnormal hemoglobins(74). The general incidence of seizures in multiple sclerosis is about 4% but the characteristics and course of the seizures may differ from the usual chronic epilepsy(75-77). An unusually high incidence of at least one seizure may occur with mumps meningoencephalitis(78), with puerperal venous thrombosis(79, 80), in acute encephalopathies of obscure origin in infants and children(81), with acute uremia(82), in cerebral complications associated with open heart surgery(83), and with hypomagnesemia associated with infantile gastroenteritis(84). Among the unusual causes of seizures are reports of: a plastic explosive, C-4, taken orally(85), camphor oleogranulomata(86), late, acute poliomyelitis when there is an associated respiratory difficulty(87), touching the patient(88), the sound of church bells(89), reading(90-92), or performing simple arithmetic calculations(93). Two more cases of B6-dependent seizures were reported(94, 95). Among some of the interesting differences between groups of epileptics who have their seizures

while asleep or while awake are: the types of sleep cycles, the periods of peak performance during the day, the basic personality and the anatomical location of the brain pathology(96-98).

Twenty-four percent of the consecutive admissions to a state hospital with diagnoses of acute or chronic brain syndrome associated with alcoholism had convulsions (99). Towards elucidating the mechanisms of seizure production in alcoholics were studies demonstrating that: ethanol causes inhibition of the brain microsomal adenosinetriphosphatase by a process in which the normal stimulating effect of sodium is not lost(100); though the EEG of epileptic alcoholics are more abnormal than the nonepileptic alcoholics, the types of abnormalities do not have the usual morphological features characteristic of epilepsy(101); electroconvulsive seizure threshold in rats is decreased if they receive alcohol as their only fluid even though there are no significant pathological changes in the liver or endocrine system(102); and a post-alcoholic hypoglycemia is a not unusual cause of convulsions(103).

The one new anticonvulsant which has received the most consideration is Librium. It has usually been reported as efficacious both for seizures and for any accompanying behavior disorder(104-108); this, however, has not been the experience of everyone (109, 110). A chemically related compound, LA III, has some anticonvulsant properties, too(111). Massive doses of Librium taken in suicide attempts have not caused death (112), but the drug can cause a dermatitis (113) and seizures on sudden withdrawal (114). Also of interest in the field of pharmacology are: the very successful use of intravenous hypertonic urea for the control of status epilepticus(115), studies of the serum levels of the demethylated product of Tridione (DMO) after daily oral administration (there is a gradually increasing serum level for 3 or more weeks before it tends to level off, a serum DMO level of about 700 mgm/L is needed for good control of seizures, and excretion is increased by increasing urinary pH)(116), the paradoxical effect of morphine in facilitating electroconvulsive seizures except in rhinencephalic-damaged animals where it

will elevate the seizure threshold(117), and pretreatment with barbiturates antagonizing the hypoprothombinemic effect of coumarin anticoagulants(118).

In monkeys with experimental temporal lobe epileptic lesions there appears to be an inconsistent perceptual response or a deficiency of integration of prior experiences (119) or, more generally, experimental epileptogenic lesions seem to interfere with effective learning of a task rather than with memory, the specific type of task involved being dependent upon the particular area of cortex involved(120). In 96 psychomotor epileptics, 16 evidenced ictal emotional symptoms, particularly fear or depression (121). The 2 to 6-day episodes of withdrawn behavior that had occurred over a 30-year period in an elderly female were found to be prolonged epileptic seizures (122). In patients with petit mal, there may be a retrograde amnesia for several seconds before the seizure(123) as well as periods of "bewilderment" for 2-3 minutes unassociated with any paroxysmal EEG abnormality(124). Sixteen of 97 patients with bilateral, synchronous spike-wave EEG activity were seizure-free but all of these patients had some sort of psychiatric disorder; in the other 81 patients, there were varying degrees of behavior disorder with the highest incidence being associated with polyspike-wave and 3/sec., irregular complexes and the lowest in association with regular, 3/sec. spike-wave (125). Attention is drawn to a syndrome of "schizophrenic-like psychosis of epilepsy" in which the epilepsy usually precedes the psychosis by about 14 years without any undue schizoid traits in the prepsychotic personality; there often appears to be less involvement of affect than would usually be expected in such a group of psychotics (126). Psychomotor epileptics or epileptics divided according to the area of maximal EEG abnormality are found not to manifest a deficit in verbal I.Q. relative to performance I.Q.(127, 128). No significant differences in the MMPI are found in groups of epileptics who are divided according to the presence or absence of brain damage(129). Psychiatric studies done on convulsive children and patients with temporal lobe seizures were reported but these defy any

condensation in such a short review as this (130, 131). From a sociological standpoint, it is of interest that the main reason for hospitalization of female psychomotor epileptics in an institution is a social one, *e.g.*, death of the mother who had formerly cared for the patient, *etc.* (132).

PSYCHIATRIC SOCIAL WORK

JOHN WAX, A.C.S.W.¹

One of the most significant trends in psychiatric social work in this past year has been the increased involvement of social workers in therapeutic community programs. The therapeutic community emphasizes on social functioning and its efforts to understand and harness the social dynamics of the institution afford the social worker an excellent opportunity to make a contribution which flows directly from social work training and competence.

Since the therapeutic community is so much in vogue, the term has been appropriated by hospitals, day centers, correctional institutions and other settings, having a tremendous range of treatment philosophies and programs. For purposes of this discussion, therapeutic community will be considered to have the following characteristics.

1. Emphasis is placed on the current social behavior of the patient in interaction

with the social processes of the institution. Relatively little attention is paid to the psychopathology of the individual patient and psychodynamic insight is not a primary objective. Rather, an effort is made to help the patient see, understand, take responsibility for and ultimately alter his characteristic ways of interacting in a variety of social situations. Increased awareness of and respect for social expectations, and increased satisfaction in conforming to the demands of the social organization are primary objectives.

2. The traditional, confidential, one-to-one, patient-therapist relationship is largely supplanted by a large, complex and highly visible network of relationships with patients and staff. The intent is that all such relationships have healing properties. The patient is expected to participate actively and responsibly, not only in his own treatment, but in the treatment of his fellow patients as well. Treatment responsibility is distributed among patients and staff.

¹ Chief, Social Work Service, VA Hospital, Palo Alto, Calif.

Traditional staff roles and statuses undergo changes, *e.g.*, personnel low in the status hierarchy, who formerly had custodial functions, are encouraged to see themselves as having important treatment functions. Much of the treatment takes place in community meetings in which all of the patients and ward staff observe and comment upon current behavior. The patient is denied the secrecy of the traditional treatment relationship. His problem behavior is discussed by his peers and he is helped to face the social consequences of his behavior. Social pressure is brought to bear in an effort to produce behavior in conformity with social norms. Reality testing and reality confrontation are carried out in the same context. Distortions and projections are examined critically, while appropriate problem-solving efforts are actively supported.

3. The therapeutic community places a very high value on communication of feelings and information. In order to improve the quality and quantity of communication (and to distribute treatment responsibility) a democratic atmosphere is assiduously cultivated. Social distance between patients and staff and between echelons of staff is much reduced in order that behavior of both patients and staff may be freely discussed. All members of the community, staff and patients alike, are expected to take responsibility for the success of the enterprise by attending meetings, discussing their feelings, feeding information into discussions, participating in decision making, accepting group consensus as reality, being responsive to social pressure, being supportive and being confronting in non-punitive ways. At the staff meeting which follows the community meeting, staff behavior is commented upon, in an effort to reduce authoritarian, covert, punitive or other behaviors which are idiosyncratic or carried over from more traditional types of treatment practice.

4. Patient government and community therapy activities create a formal organization for patients. This formal organization is then placed at the service of the treatment objectives of the staff. A formal organization is a more effective instrument for transmitting and enforcing the middle class and mental health values of staff. Patient leaders

learn from staff which values, attitudes and behaviors are socially desirable and they transmit same to their fellow patients. The value system which is taught is very similar to what is taught in schools, including work, responsibility, impulse control, planning for the future, postponement of gratification, interpersonal skill and resilience under stress. One precept which is vigorously taught is unique to the mental health professions. It has to do with verbalizing rather than acting out or internalizing emotional distress.

5. In the therapeutic community most treatment takes place in a group context, reducing the opportunity to individualize the patient. There is an implicit assumption that the values and skills which are considered so serviceable for all patients in the hospital community will be equally serviceable in the community to which the patient will return. It is to this last characteristic that a major social work contribution is addressed. The assumption that the social interaction techniques learned by patients in the hospital are equally applicable in the community is highly questionable. Various economic, racial and cultural groups embrace values very different from those of the therapeutic community. For example, patients in the therapeutic community are taught to discuss their feelings with their peers. This ability in a patient is considered a sign of good response to treatment and is rewarded by staff and by other patients. However, if the patient returns to a working class neighborhood and discusses his anxieties with his peers in the hiring hall or the corner bar, he may be viewed as grossly deviant and teased, rejected or otherwise punished by a group which believes that real men act out, rather than talk out, their feelings.

The Social Work Role. The social worker, as part of his responsibility for social diagnosis and discharge planning, secures a picture of the specific social context from which the patient comes and the one to which he will return. This information is made available to the entire ward team, but the social worker carries the primary responsibility for mediating the differences between the hospital community and the patient's home community. The patient is

helped to see that certain types of emotional expressions which are actively encouraged in the therapeutic community may be socially unacceptable in his peer group, or emotionally unacceptable in his family. If such is the case, the types of expression in question should be confined to the relationship with a professional person in one of the aftercare resources which are such an important part of the discharge plan.

If the progress made by the patient in the hospital is to stand up in the community, the behaviors learned in the hospital must be adapted to the unique demands of the patient's life and bulwarked by an aftercare plan which will continue to reinforce the ego strengths and social skills necessary for survival in his subculture.

In the therapeutic community, social workers continue to carry such traditional functions as social diagnosis, casework with patients and their families and discharge planning. In addition, they take an active part in therapeutic community meetings

and in staff "re-hash" meetings. Their knowledge of social process makes them useful participants in the planning and manipulation of the social organization which is intended to be a therapeutic milieu. But their most significant contribution is in helping the patient grasp the social insight and skill learned in a group situation in the hospital and apply it in an individual situation in his own home and neighborhood.

MENTAL HEALTH IN EDUCATION

W. CARSON RYAN, Ed.D.¹

Mental health in schools is fostered by encouraging the child to have confidence in himself, Ruby H. Warner says in a recent Library of Education publication (1). In modern schools, she notes, teachers understand better the ways in which children grow and develop, and the children work in small groups because of the stimulation that comes from working together—with better mental health results.

In a recent review of the mental health possibilities in education, prepared for the National Association for Mental Health, Dr. Harry Milt begins by citing what he terms "a very useful categorical distinction that originated with Dr. Nina Ridenour"—the distinction between "education *about* mental illness" and "education *for* mental health" (2). Under this second category would be education *for prevention*, i.e., education designed to eliminate factors which contribute to mental illness, and education for

positive mental health, or "education oriented toward higher development of one's potential." The question is repeatedly raised: Does this kind of education really prevent mental illness and does it really improve mental health? There are many of us, Milt says, who would answer both of these questions in the affirmative—but how do we have any proof? He cites as an example the possible effects of the leaflet *Mental Health Is 1, 2, 3*, more than ten million copies of which have been distributed through schools, family agencies, PTA's, and many other organizations. "I very much doubt," he says, "whether there exists one single shred of positive proof that this leaflet has achieved this result for a single person." That does not mean that it has *not*, he says, "but we cannot prove that it has."

Importance of the study of early childhood situations for mental health is emphasized in a report by Dr. Beulah Parker (3). A relatively small but significant num-

¹ Mason Farm Road, Chapel Hill, N. C.

ber of problems presented by nursery school teachers, Dr. Parker finds, have their origin in the personal conflicts of individual teachers. "The teacher reacts to a child's difficulty as though it were identical with something she herself suffered as a child. Furthermore, even though the teacher herself may have a clear understanding of the reasons for emotional tensions in a child, the teacher is not trained in the techniques for making interpretations to a mother about disturbed family relationships." A consultant can help teachers determine the best level for their interventions, Dr. Parker says.

"School phobia" as one of today's school mental health problems is discussed in a recent report by Donald A. Leton, of UCLA(4). Dr. Leton describes this as simply "a condition of anxiety as related to school attendance." The term implies, he says, that the child has localized fear of school and of the experiences he may encounter there. This inference is not entirely accurate, he says, since most children who manifest school phobia have actually enjoyed school, but cannot bring themselves to participate again in this enjoyment. On the basis of referrals in school psychology over the past ten years Leton estimates that approximately 3 of every 1,000 primary-

grade pupils will show a severe school phobia in any given year, and that the incidence of milder chronic cases may approach 10 per thousand in the school grades.

At the college and university level "there is a growing appreciation of the important role mental health and emotional factors play in the academic adjustment of college students," Charles D. Spielberger reports as the result of a study prepared for the Southeastern Psychological Association(5). "Even apparently well-adjusted students have their share of emotional difficulties," he says. Perhaps the most important implication of the findings of the study, Dr. Spielberger says, is that it appears possible to identify members of the college population who, because of emotional problems, would not be likely to function at levels commensurate with their intellectual potential.

PSYCHIATRIC NURSING

MARY F. LISTON, R.N., Ed.D.¹

The field of psychiatric nursing continues to advance in the areas of clinical nursing practice, nursing education, nursing service, the mental health aspects of public health nursing and nursing research. Nursing groups have been studying the Joint Commission on Mental Illness and Health report—*Action for Mental Health*. An ad hoc committee of the ANA-NLN Coordinating Council has been appointed to identify those areas in the report which have implications for nursing and recommend appropriate allocation of responsibility for study and/or implementation between the Amer-

ican Nurses' Association and the National League for Nursing.

The past year has given substantial evidence that nurses are vitally concerned with the problem of their role definition as individual practitioners and as members of the psychiatric and nursing teams. Psychiatric nursing is viewed as a special vocation concerned with meeting the needs of the emotionally and mentally ill as well as maintaining and promoting health(1). The role of the nurse as a therapeutic agent(2) has been explored from various viewpoints, that of sociotherapist(3) and as a special psychotherapeutic nurse who is responsible directly to the physician(4).

Areas of concern in the clinical practice

¹ National League for Nursing, 10 Columbus Circle, New York, N. Y.

of psychiatric nursing include care of patients with marked regression(5), muteness(6), and chronic helpfulness(7); the need for consistency in setting limits on patients' behavior(8), the value of assessing and appraising the patients' areas of positive functioning in nursing care(9), and patients' perceptions of the nurses' uniform and its meaning in a psychiatric hospital (10). One group reported on the role of nursing personnel and patients in changing the physical environment of the hospital (11).

The nurse's role has been explored from the standpoint of the independent functioning of the nurse in maintaining and supervising the patient's environment(12), the functions of the psychiatric nursing specialist(13), and the relationship of psychotherapy and the practice of psychiatric nursing(14). Interpersonal techniques are viewed by one expert as the crux of the practice of nursing in a psychiatric setting and the counseling role as the heart of psychiatric nursing(15). Specialized aspects of the nurse's role included participation in group therapy(16, 17) and the use of work therapy in the management of disturbed patients(18). A social interaction inventory has been developed to assess the nature of verbal responses selected by nurses faced with emotion laden situations representative of those encountered in their practice with patients and families(19). The need to evaluate nursing care in a mental hospital was recognized by the nursing service in one hospital and a form was devised for this purpose(20).

Increasing interest has been given to the nurse's role in the day hospital for psychiatric patients(21). In day and night care centers the nurse is focussing her work primarily with a group rather than with individual patients(22). The nurse in the psychiatric clinic is seen as an active member of a therapy team, an active participant in intake work and workup, and as a collaborative therapist(23). One study concluded that the nurse may make a vital and hitherto neglected professional contribution to patients in an adult psychiatric clinic(24). Nursing personnel have been concerned with the nursing care of the mentally retarded in the hospital setting(25) as well

as the public health nurse's function in the community in a program for mentally retarded children(26). There is also evidence of need to determine the role of the nurse with troubled children(27).

The clinical programs at the ANA biennial convention, at meetings of NLN state and local councils on psychiatric and mental health nursing, and at the APA meeting give ample evidence of the active interest in nursing practice by all nursing groups.

Nursing educators have been concerned with the integration of mental health and psychiatric nursing content in the baccalaureate nursing program(28). This area was the focus of a working conference for instructors in baccalaureate nursing programs sponsored by the NLN. The education and preparation of the nursing student in psychiatric nursing is considered an important factor in recruiting nurses for practice in the field(29). Measurement of the attitudes of diploma nursing students about mental illness indicated that change in attitudes is not merely a matter of increasing information or providing contacts with mental patients, but involves a number of factors not clearly delineated or understood(30).

The education of the psychiatric aide or technician is of vital concern for psychiatric nursing. Attempts have been made to make training programs more effective and useful (31). An evaluation of aide performance as perceived by nurses, aides and patients indicated that performance evaluations of aides are best made by the nurse who works directly with the aide(32). One study tested the hypothesis that there is an improvement in ward adjustment of patients resulting from a similarity of commonly held likes and dislikes between patients and their assigned aide trainees(33).

Aides, attendants, technicians and practical nurses have reported on their work with disturbed, geriatric and regressed patients, retarded children, patients in nursing homes and their role in remotivation. The use of the remotivation technique has been of special value to this group of workers (34).

The administrative aspects of nursing service in psychiatric settings have been explored. The primary task for the nursing

service administrator is described as being able to obtain sufficient leadership staff who can collaborate in the development of a philosophy and a conceptual framework for nursing service(35). The area of supervision is considered one that is fertile for research(36).

The role of the public health nurse in mental health problems and in nursing services for the discharged psychiatric patient and his family is an area of concern for public health nursing. The need for referral of patients to appropriate agencies has been stressed(37). The participation of the public health nurse in early recognition of mental health problems, the giving of supportive care and/or referral are seen as meaningful tasks for public health nursing students and practitioners(38). Programs that provide for psychiatric aftercare of patients and their families are important factors in the provision for continuity of nursing services(39, 40). Public health nurses as well as psychiatric nurses need to be adequately oriented so that they may work collaboratively and cooperatively in their task of providing continuity of care for patients(41).

The recruitment of nurses for placement in psychiatric settings, a problem of joint concern for nursing service and nursing education, needs continuing study and evaluation. While there is considerable interest in nursing research, increased efforts will have to be directed in the research area concerning such problems as role definition of the psychiatric nurse, the relationship of educational experiences to career choice in psychiatric nursing, the role of the aide or attendant as a member of the nursing team, and patterns of nursing service in psychiatric settings.

FAMILY CARE AND OUTPATIENT PSYCHIATRY

WALTER E. BARTON, M.D.¹

FAMILY CARE

Karl and Russell(1) report that in the 40 Veterans Administration Hospitals that employ family care 9% of those placed were in the hospital less than one year ; 51% one to 9 years ; and 40% had been in the hospital over 10 years. Last year, almost 4,000 improved psychiatric patients were on trial visit from VA Hospitals in homes other than their own. This is an increase of 129% in the 5-year period.

Barton(2), in a new book, *Administration in Psychiatry*, describes the assumptions governing the use of family care. The chronically ill live more normal lives in family care than on the wards of a hospital. It is less costly, avoids capital construction and saves personnel. It reduces overcrowding and over concentration of patients. It provides an opportunity for adjustment of individuals who have families that are too stressful or are unwilling to accept them. It serves as a half-way facility for selected patients. It provides a test of the capabilities of adjustment in the community for the older patient.

Mayotte(3) suggests the goals of family care have changed to include : placement of patients who are in courses of vocational training, or receiving on-the-job training in the community ; placement of patients who require a substitute home pending the determination of eligibility for financial assistance under some other welfare program ; financial assistance at family care rates to distant relatives if they will provide a suitable home, and placement of retarded

patients who may then attend special classes in schools or work in sheltered shops. Monthly payments are added to the caretaker's allowance for transportation.

Davis(4) stated that in Norway one half of all mentally disturbed patients live in the community with foster families. For example, the Dikemark Hospital has 800 inpatient beds and 950 patients in family care. Norway (in 1961) had 5,000 patients in family care, 3,000 patients in nursing homes and 8,000 patients in mental hospitals.

Dumont(5) was a member of a survey team that visited Gheel, Belgium. They sought to learn the reasons for the drop in the number of patients being placed in family care. There has been a decline in the tradition observing the religious ritual or of belief in the magical power of the relics of St. Dymphna. Psychiatrists in Belgium do not favor family care. In spite of the rising standards of living, the industrialization of the country, and the static remuneration paid to caretakers, citizens still maintain a "know-how" to manage mental patients well, and would accept more patients than are presently referred.

Abrams(6) believes there is less need for family care because there are fewer suitable patients now remaining in the hospital ; that its use is limited in those who remain ; that the few staff members available are unable to prepare patients for placement, or to supervise them afterward. He believes that the energy available might be better expended on increasing the efficiency of the acute intensive treatment programs in the hospitals rather than work with the chronically ill. He concludes that few people seem willing to

¹ Superintendent, Boston State Hospital, and Assoc. Prof. of Psychiatry, Boston University Medical School.

accept former patients into their homes.

Bowen and Fischer(7) sampled 5% of the total population of Marion, Indiana. Of the respondents 54% were willing to take mental patients into their home if the patient was a relative or friend; 28% would accept someone who was not related. Persons who were 35 to 54 years old were most willing and those over 55 less favorably disposed to accept ex-patients into their homes.

Family care provides a setting in which to learn normal social responsibility, according to McNeel(8). It serves as a stepping stone to church attendance, to participation in community life and to employment.

Davidson(9) suggested that psychotherapy, particularly group therapy, deserved a wider trial using the new environment of family care as a testing ground for new patterns in living.

Schutzer and Baldwin(10) warn that younger patients may become too dependent in family care. Those in the age group 17 to 28 with group sessions increased in self confidence, ventilated their fears and feelings, and were instructed in work opportunities.

Patients in family care in the United States and Canada as of June 30, 1962:

United States: Veterans Administration² 2,697; New York 2,880; California 2,412; Illinois 1,573; Michigan 1,154; Ohio 810; Maryland 468; New Jersey 439; Kansas 412; Rhode Island 274; Pennsylvania 245; Maine 210; Indiana 207; Massachusetts 206; North Carolina 200; Connecticut 81; Kentucky 37; Idaho 30; Virginia 17; Vermont 4. Total 14,356; 1960 total 12,507.

Canada: Ontario 1,300; Saskatchewan 98; Quebec (Verdun) 43; Prince Edward Island (Riverside) 23; British Columbia 2. Total 1,466.

This demonstrates the continued growth in the family care program. California placed 55% more patients in 1961 as compared to 1959. The greatest expansion was in placement of the retarded. One hundred dollars a year is allowed to each patient to buy clothes in the community where he lives; \$115 a month is the average payment made to caretakers. The program

provides orientation and group discussions as well as counselling for foster home mothers. Volunteers transport patients to family care and help develop recreational activities in the family care home.

New York, one of the heaviest users of family care, showed a slight decrease in the number of patients in residence. A new policy reduced the number of patients in each family care home. Social and recreational activities were instituted for all family care patients. Enforced rules for safety insured no patients sleeping above the second floor, good housekeeping practices, good smoking habits, available fire extinguishers, hand rails on stairways, proper wiring and lighting, and an accessible first aid kit.

Maryland has been experimenting with the use of foster homes as an alternate to hospitalization.

Rhode Island reports about one third of the patients in family care are in supervised work placements in the community.

Michigan increased its appropriation for 1962 and 1963 to permit growth of the family care program as additional staff are employed.

North Carolina provides homemaker services for the elderly.

In Massachusetts placements declined by about 50% in a two-year period.

In Connecticut the numbers reported would be larger if all patients living in extramural homes other than their own were counted. Patients are placed in convalescent and boarding homes in a cooperative plan with the Welfare Department.

Idaho has had a study project that provides motivation of patients into family care and into community work. Patients are employed in the principal industries of that state: mechanized farming, mining and lumbering. Of the patients placed 52% remained out, 48% returned, but half of those who returned were later replaced.

For the first time figures were obtained from Canada which show the use of approved homes for family care is increasing rapidly. Ontario has 13 hospitals in the program. Three hospitals with an aggregated 3,500 beds have 800 patients in family care. One hospital alone has 330, equal to 25% of its patients in residence.

² Calendar year 1961.

The Province of Ontario hopes to see an increase in the provision of hostels and half-way houses and the operation of these facilities by the community rather than by the hospital system. Nurses are preferred to social workers to supervise patients in family care by some hospitals. Medical service to patients in family care is provided by local practitioners.

In Saskatchewan the program has been developing slowly since its start 7 years ago. The availability of homes greatly exceeds the number of patients placed. Only the number of social workers and money available limits the program expansion.

In Prince Edward Island patients over 65 provide the bulk of those in family care. Mental defectives and chronically ill schizophrenics predominate as the most common diagnostic disorders in patients placed. The average length of residence in family care was 15½ months. Patients are placed in a family with the same religious affiliation. Family care is less expensive than hospital care and patient functioning is markedly improved over that observed in the hospital. There has been no difficulty in their own homes.

In Verdun, Quebec a 5-year study was completed on 113 patients placed in 90 family care homes. Schizophrenia was the most frequent diagnosis. The average stay in the hospital of those placed was 6½ years. Nearly one third of the group studied had been discharged from family care. Their survey showed that a majority of the caretakers manifest a high degree of interest in their patients.

OUTPATIENT PSYCHIATRY

Brown(1) indicates that 60 of 128 patients on a waiting list at the Massachusetts Mental Health Center received a home visit by a team of psychiatrist and social worker. They also interviewed the referring psychiatrist and found that 27% of psychiatrists had never made a home visit; 38% made one to five such visits a year and 20% made 6 to 25 home visits in a year. Only 15% of psychiatrists had extensive experience in visiting patients in their own homes.

Lemkau(2) studied 10,000 adults in

Maryland (population of 3 million) who were admitted to 50 outpatient clinics. Most persons seen were in the age group 25 to 54. Of every 100 adults in the outpatient clinic, 44 are in treatment at the end of 4 months, 21 at 6 months, and 10 at 18 months. Patients in the age group 15 to 24 and over 65, as a rule, have very short periods of treatment, so do those who live in rural communities or those who suffer from alcoholism. Patients from the higher social and economic levels tend to spend a longer time in treatment. Veteran patients are in treatment the longest. Those lowest in economic scale have the shortest treatment time. Patients in aftercare, following release from a mental hospital, have long periods of treatment. About 2/5 of all the patients seen withdrew without notice. Fifteen percent of the patients seen in outpatient clinics were mentally retarded.

Perkins(3) surveyed the number of clinics in New York City to discover whether the recommended ratio of outpatient clinics to population, set down by the Joint Commission on Mental Illness and Health, had been achieved. He found that if part-time clinics were included, New York City now had one psychiatric clinic to every 60,797 people. Manhattan borough had reached the recommended ratio of 1 to 50,000.

Hankoff(4) studied the outpatient use of drugs in a double blind experiment: 169 chronic schizophrenic patients were treated. Twenty-two and a half percent showed denial of illness. Those who deny their illness are prone to rehospitalization and are often immobile in treatment. Patients given phenothiazine drugs tended to be more accepting of their illness, avoided hospitalization and showed improvement.

Ungerleider(5) described an emergency consultation service established at the Cleveland University Hospital. In a 6 month's period, 375 emergency calls were received. Some interesting statistics concerning those who used the service were obtained.

Stone(6) studied 65 adult psychiatric patients treated in an outpatient setting who were followed for five years. Most were diagnosed as character disorders and psychoneuroses. Most patients had 6 months of psychotherapy; 30 patients in the group

returned for evaluation. Anxiety and depression, when present, were reported to have been immediately relieved following therapy. Patients who were least improved were the ones who had had somatic symptoms. Most patients improved socially and had gained spontaneity in close relationships. The ability to respond to treatment, they felt, may be a function of the patient's success in communicating his difficulties, and of the acceptance of his therapist.

Nilsson and Kurland(7) surveyed a group of ex-patients who were capable of using their changed attitudes toward the mental hospital in a constructive manner. Their potential value in public education was suggested.

Englehardt(8) studied 275 schizophrenic patients in an outpatient clinic; all had been on weekly psychotherapeutic interviews. Patients came from the lower social and economic level in the community. They were unable to pay fees. Most were in the age range between 19 and 44. One third of the 275 patients had previous hospitalization for mental illness. All patients were divided into 3 groups: one received chlorpromazine, another promazine, and a third placebo. The need for hospitalization, change in thought disorder, and change in social behavior were noted. The results indicated a reduction in thought disorder that was greater in those who had been severely disturbed; drugs improved social behavior and reduced the need for hospitalization.

Ross(9) found that $\frac{1}{4}$ of the psychiatric clinics gave no time, or less than 10% of their time, to community services either in liaison, educational, or in consultation services. The author quotes Norman, who stated that 6% of staff time, in the clinics he surveyed, was used for promotion of mental health in the community.

Norman(10) noted a 32% increase of the number of patients receiving outpatient services in the 5-year period 1954 to 1959. Professional man hours available for outpatient services also increased by 41%. The 5-year growth in the clinic population exceeded the general population growth in the same period in the order of 32% as compared to 8%. New services for adults accounted for most of the expansion. There

are still limited clinic services for the pre-school child and for the adult over 60. A large number of patients surveyed withdrew from treatment without notice. Persons who had psychogenic disorders received more interviews and more attention than those with organic disorders.

Coleman(11) found that one-half of the patients who came to the psychiatric clinic turned away after one encounter. Lack of interest, lack of understanding, and discouragement were given as reasons. When the clinic assigned a psychiatric nurse, who made house visits, to work with patients, it appeared patients ventilated resentful feelings and returned more frequently for treatment.

MacLeod(12) reported that many seriously disturbed patients are unable to tolerate the one to one relationship in treatment in a clinic. He advocated greater use of brief supportive psychotherapy and of group treatment.

The Canadian Mental Health Association(13) states that there are 140 mental health treatment clinics, public and private, offering services in Canada. Continuity of care is a basic principle of medical treatment in a new long range program that would provide services for patients, without loss of job, in communities where they live.

Bahn(14), in a methodological study, comments that first admissions to mental hospitals have been used as an index of services to the mentally disturbed. Outpatient department figures have been used as a new measure in Maryland since 1954. The rates of admission to outpatient services are high for children of school age and low for adults in non-metropolitan areas and the reverse is true in Baltimore. Many more boys are seen than girls. The sex differential disappears at age 30. Pre-school children and the aged have the lowest rates of psychiatric clinic admissions. Outpatient services tend to be brief. Of all patients seen 56% had their final interview at the end of the first month and 83% had their final interview at the end of the eighth month, with a median number of interviews, only 4. There was a higher retention rate in clinic treatment for those who had been released from the

mental hospital and for those who lived in metropolitan areas.

FORENSIC PSYCHIATRY

LAWRENCE Z. FREEDMAN, M.D.¹

Psychiatrists who recognize that the legal as well as social matrix of our society is inextricably related not only to a shared sense of justice but to the psychic health of the entire community will welcome the Model Penal Code(1) completed last year. Sponsored by the American Law Institute it follows a decade of dedicated effort by eminent legal scholars (including "our wisest judge," the late Judge Learned Hand) with the advice of psychiatrists and behavioral scientists under the brilliant

direction of Wechsler of Columbia. The American Medical Association sponsored its first National Conference on Mental Illness and Health(2) and developed a progressive program which, in many ways, complemented and reinforced the report of the Joint Commission on Mental Illness and Health(3). It included recommendations for the legal implementation of community mental health programs as well as the treatment of the drug addict, the delinquent, and the sociopath. All these reports are simply models for action lacking as yet the energy of official power; their worth de-

¹ Foundations' Fund Research Professor of Psychiatry, University of Chicago School of Medicine.

pend on their implementation. If they do become effective, the level of care of the mentally ill, of the disturbed offender, the morale and effectiveness of our healing profession and the moral stature of our society will be elevated.

There were discussions of the sources as well as the forms of law. Hart(4) argued that natural law theory reflects basic truths about human nature and need not rest on metaphysical assumptions. Given the qualities of vulnerability, of approximate equality, and the human limitation of altruism, of understanding, of strength of will, and of resources, all societies must control violence, theft, and deception if they are to survive. K. Erikson(5) theorized that deviants express a community-wide need and that a specific fraction, usually young adults from lower economic classes, fulfill these relatively stable deviant roles.

Many were concerned about the right of the mentally ill to privacy, to just hospitalization and discharge procedures as well as to a clarification of limits of their responsibility for harmful social acts. Connecticut enacted a statute ensuring and defining the privilege of privacy of the patient's communication to his psychiatrist(6). The American Bar Foundation is studying the hospitalization of the mentally ill(7) in order to write a model act which will facilitate voluntary hospitalizations without jettisoning legal rights. As in England(8) the goal is to eliminate unnecessary distinctions between the treatment of the mentally ill and other sick persons. Several states including Ohio(9) have recently enacted codes for the care of the mentally ill which do tend to increase such hospital admissions. New York State requires petition and medical certification but may spare the patient himself participation in the legal procedures. This was upheld by a New York court as being consistent with due process since subsequent statutory hearings are available. A *Harvard Law Review* note(10) challenges this decision and favors serving personal notice to each patient. Curran(11) also upholds personal notice pointing out that friends and relatives may seek the patient's confinement. He doubts that serving legal notice "by a constable, too" causes "serious harm" to the mentally ill. (The re-

viewer's experience is not consistent with this judgment.)

Hess and Thomas(12) found that courts, psychiatrists, and hospitals misinterpreted and misapplied their roles in the proceedings leading to incompetency to stand trial in Michigan. Both the cause of justice and the welfare of the mentally ill suffer by this confusion. Szasz(13) raised the question of the psychiatric examination of the defendant for mental competency against his will. Glueck in his 1962 Isaac Ray Award Lectures offered a comprehensive legal formula for determining relief from responsibility for socially harmful acts. One of its novel features, on the American scene, is its provision for a mid-verdict of partial responsibility. Last year Judge Biggs, in the Currens case(14), wrote a decision freeing from responsibility defendants who "lacked substantial capacity to conform."² Goldstein and Fine(15), citing their finding that the indigent defendant had inadequate psychiatric assistance, observed that the language concerning responsibility is not meaningful unless it can be implemented with competent psychiatric testimony. Kuh(17) proposed that the issue of responsibility be tried by a judge without a jury.

Widespread preoccupation with narcotic abuse was reflected in the White House Conference on Narcotic Addiction(18). The report of the Ad Hoc Committee for the participants is an excellent precis and deserves national distribution. Narcotic abuse is, in fact, decreasing while excessive intake of such psychotropic but nonnarcotic drugs as the barbituates and dexidrene is increasing. There are marginal but significant subcultures whose members seek to breach their alienation and to achieve that sense of social cohesiveness and personal euphoria which the dominant community pursues through alcohol (the most widely used addictive drug). Holding that drug-abusers are treatable, the Conference re-

² In most U. S. jurisdictions the "right and wrong" and "knowledge" criteria of M'Naghten prevails. In some states this is combined with the "irresistible impulse" rule. There is also the "product" test of the Durham decision(16) and the Model Penal Code(1) which exculpates when there is "substantial impairment . . . to appreciate . . . or to conform."

jected long imprisonment³ or indefinite ambulatory maintenance dosages as proper social responses. Like the American Medical Association and the National Research Council of the National Academy of Sciences, the Conference seemed to favor institutional treatment where drug consumption could be controlled. In one study, Hirsch(19), who treated parents of adolescent drug addicts in groups, found a common pattern of the reluctantly and unhappily married mother whose son, sexually conflicted and passively related to women, turned to drugs. Israeli investigators(21), observing that in the Orient drug addiction is more frequent than alcoholism, partly because of the religious prohibition against alcohol, concluded that environment and culture determine the form which the addiction takes. Their subjects, mainly Middle and Near Eastern Jews were negativistic and hostile, and were considered untreatable outside a hospital setting. Bell(22) studying amphetamine addiction found no specific pattern of psychiatric disturbance although alcoholism and mental illness in the home and unhappy childhood were common. He found amphetamine addicts to be recalcitrant and tending toward deterioration. He therefore urged measures for prevention rather than post hoc treatment. Glue sniffing is a form of intoxication now available to even small children(23). Its effects range from mild euphoria to coma, and it may be habit forming as well as physically harmful.

Several papers emphasized somatic determinants of socially deviant behavior. Stott(24) reported a high correlation between certain physical disorders and behavioral difficulties. This, with Wilkin's finding that boys born during the traumatic early years of World War II had a higher proneness to adolescent delinquency, led to an hypothesis that congenital impairment of the nervous system may so reduce resistance to environmental stress as to predispose to delinquency. Anderson and Plymate(25) as well as Laufer(26) described adolescents with behavior disorders which seemed related to

cerebral dysfunction or brain damage. Woods(27) described a syndrome of adolescent violence associated with a 6- to 14-per second positive spiking dysrhythmia in the EEG. The dysrhythmia is, in his view, a biologically determined stress which in an impoverished ego permits the expression of non-neutralized aggression. Michaels(28) urged a holistic model in the study of delinquency. His earlier finding of the high correlation between delinquency and enuresis reinforced the hypothesis of Glover and others that some delinquency may be psychosomatic equivalents arising from imbalance of psychic excitation and discharge mechanisms. Klintworth(29) describing a monozygotic twin pair who were discordant for homosexuality reviewed also Kallman's series of monozygotic twins with concordant male homosexuality as well as other genetic evidence in support of the assumption that sub-threshold predisposing elements such as mutant genes and congenital factors may within the matrix of certain life experiences result in deviant sexuality. Petrie, *et al.*(30), studied the perceptual characteristics of juvenile delinquents who were more likely to be either "stimulus-governed" (characteristic in her experience of brain-damaged subjects) or, by the definition of the research, "reducers." Since "reducers" suffer from "monotony, isolation, and enforced inactivity," education of delinquents and pre-delinquents should, Petrie advises, be appropriately adapted.

Rothstein(31) differentiated the value perceptions of delinquents compared to non-delinquents as to which factors contributed to high social status (*e.g.*, toughness and notoriety versus loyalty and trustworthiness). The Gluecks(32) published another report from their bio-social study of the determinants of juvenile delinquency. In previous books, they proposed a predictive device based on intrafamilial relationships; later they described the somatotypic characteristics of the delinquent. Now they have analyzed particular individual and factor-trait interpenetrations within the family. They suggest that "differential contamination" is probably a more appropriate phrase than "differential association," in the sense that "contamination depends not merely on exposure but also on susceptibility as

³ In any event, the United States Supreme Court last year invalidated a California law which made drug addiction a crime punishable by imprisonment(20).

opposed to immunity." Michael and Colthorp(33), using the Glueck Social Prediction Scale, achieved poor over-all accuracy as individual judges but excellent(92%) group prediction of delinquency. However, they were only 23% correct in their expectation of non-delinquency. Lively, Dinitz, and Reckless(34) suggested the use of several scaling techniques to predict future delinquent patterns in 12 year olds.

The social structure of the adolescent gang was characterized(35) as based on a status hierarchy related to physical dominance but bound together by such relatively simple, common motivating tasks as anti-social destruction and direct instinctual gratification. It is thus at an intermediate stage of social organization between individual aggressive dominance and the complex social role definition based on division of labor. It provides an area for functioning in what to the youngsters is an alien culture. An impressionistic look at modern Parisian gangs(36) indicated that the social milieu from which they arise, poverty, overcrowding, poor recreational facilities, disrupted family life and community organization in the new low rent housing projects "banlieues," resemble those with which we are familiar.

The juvenile courts as old as this century, before whom 20% of youths between the ages of 10 and 17 now appear, are increasingly and variously criticized for being ineffective, for violating the child's constitutional rights, and both for coddling and being too harsh. The thrust of such criticisms as well as proper corrections are contained in an excellent published symposium(37) held at the University of Chicago last year. Vinter and Janowitz(38) have systematically studied juvenile correctional institutions ranging from those with custodial to those with treatment goals. Zald(39) reported from this study that the treatment institutions were in a continuous problem solving process and consequently were more obviously conflict ridden. However, a high level of conflict did not necessarily impede therapeutic goals but could, indeed, reinforce them.

An historical review of substantive and semantic differences within psychiatry and the law during the 19th century concerning

Pritchard's "moral insanity," the diagnostic ancestor of the sociopath, has a fascinating—and discouragingly—modern ring(40). In the personal development of the sociopath, O'Neal, *et al.*(41), found a high incidence of parental desertion, lack of supervision, divorce and non-support in the background of sociopathic personalities. Their fathers had often themselves been alcoholic, anti-social personalities. These paternal characteristics predisposed the son to sociopathy even when the father had not lived at home. Jones(8) appealed for more concerted and effective treatment of the sociopath, as the confluence of psychopathological, ethical, and legal questions, with community-wide resources. He cited his English experience and the pioneering experiments going on in California.

Suicide became a subject of much speculation and some research last year, perhaps reflecting the continuing menace of self-destruction facing mankind. The suicide of an American celebrity evoked intense and world-wide response. Meerloo(42) discussed mass as well as individual suicide. Stengel(43) estimated that in urban areas there were 7 to 8 attempted suicides for each of the reported 16,000 self-destructive acts per year. By this estimate there are about 100,000 suicidal attempts each year and one million living persons in this country who have tried to take their own lives. As an alarm, an appeal or an aggressive act it usually stirs at least one other person to reassure the victim that it matters whether he lives or dies. Bakan(44) tried to absorb the mood, the feeling tone of the suicidal personality through introspection and other means. Suicide, he saw as a symbolic or real defection of the social obligation to live, as a blocking of the durational or time sense where there is no expectation of future excitement or gratification. The suicide paradoxically attains independence and alienation through an act which expresses his interdependence with others. Outwardly conforming, in his exodus, he expresses antisocial impulses while eliciting pity. Toolan(45) found a few attempted suicides among very young children who were likely to be schizophrenic, but in the adolescent group where it is an important cause of death, character disorder and depressive re-

actions predominated. Boys outnumbered girls in "completed" suicides, but girls predominate in suicidal attempts. Precipitated often by real or feared loss of love object, the depressions of the young are often overlooked since they are expressed frequently in behavioral and somatic symptoms. Neither age nor diagnosis should obscure underlying depression. Satterfield(46) reported the death by suicide of an hysteric; psychiatrists too frequently dismiss self-destructive efforts of this group as histrionic gestures. Selzer and Payne(47) found some evidence that certain automobile accidents may be unconscious suicidal equivalents. There was a significantly high accident rate for men who had seriously considered suicide even though they were, at the time, unaware of any conscious effort toward self-destruction.

In many centers imaginative, inventive, and vigorous efforts were made to devise therapeutic techniques appropriate to social and behavioral problems. This is a wholesome reaction to prevailing practice of applying truncated conventional psychotherapy to inappropriate and unwilling subjects. Kitchener, *et al.*(48), conducted a 5-year treatment program for aggressive, acting-out boys 8 to 10 years old by channeling aggressive behavior into a game relationship in which the therapist could play a figure of control. The level of therapeutic response was geared to the level of perceived patient ego-integration. Interpretation progressed from concrete behavioral responses to symbolic communication and gestures and finally to direct discussion of problems. Gladstone(49) working with youthful offenders expressed his own personality viewpoints, preferences, and idiosyncrasies in a deliberate effort to arouse and maintain interest and to establish some human and personal relationship with the patient. He took on the active challenging parental role as well as the accepting one. Bromberg(50) suggested that psychodrama, particularly the technique of role-reversal, might be effective preventative therapy against the precipitation of violent crime.

The Wisconsin Sex Crimes Law which provides for outpatient or in-residence treatment for sexual offenders has now been in force for 10 years. Pacht, Halleck, and

Ehrmann(51) present a 9-year report of its practical implementation as well as the therapeutic and medical ethical problems it raised for the participating psychiatrists. They believe the program has improved the treatment opportunities of the disturbed sexual deviant. Uehling(52), conducting group therapy in this program, underlines the paradox of the therapist who permissively elicits information and attempts to make an objective presentation to a review board. Since the sex deviate must respond to some form of treatment as a condition for his release, assessment of progress is complex. Kopp(53) as well as Cabeen and Coleman(54) had some success with the treatment of sex offenders by group therapy. The prognosis was better for sex deviates with a diagnosis of psychoneurosis than for the psychopathic personalities.

Margolis, Krystal, and Siegel(55) report "modest but steady" success with poorly motivated alcoholics with an active treatment program which includes deliberate confrontation and anxiety arousal as well as participant involvement in legal, social, medical and familial relationships when indicated. Similarly, Chafetz, *et al.*(56), were able to improve the initial visit and sustain treatment rate for alcoholics by such techniques as participant involvement in their social care. Behavioral adaptation is by no means synonymous with mental health. Gerard, Aeanger and Wile(57) found that formerly confirmed alcoholics could maintain abstinence in spite of serious mental disturbance. That these therapeutic innovations may be relevant to a wider range of behavioral problems is demonstrated by a report by Guze, *et al.*(58), that in a representative group of over 200 criminals almost half were alcoholics.

O'Reilly and Reich(59) and Jensen(60) found LSD increased the improvement rate of alcoholics significantly. Kraft reported favorable results with mephenozone in the treatment of childhood behavioral problems, including hyperactivity and school truancy when associated with an EEG pattern of 14 and 6 spikes per second(61).

A new case book on criminal law by Donnelly, Goldstein, and Schwartz(62) incorporated psychiatric and sociologic views, and a compendium on legal and criminal

psychology was published (64). The *Annals of the American Academy of Political and Social Science* devoted an excellent issue to "Crime and the American Penal System" (63).

ADMINISTRATIVE PSYCHIATRY

J. MARTIN MYERS, M.D., AND LAUREN H. SMITH, M.D.¹

The administrative psychiatrist is increasingly interested in integrated programs with flexibility to meet the present and future needs of the mentally ill and their therapy. Inpatient care is but one element in the continuum of facilities; it should be personalized, utilizing small local facilities if possible(1).

With more intensive treatment and diversification of psychiatric facilities, a declining hospital population is predicted by Barton (2). Studies from New York reveal that the number of hospitalized mentally ill continues to fall, particularly for the younger schizophrenic age groups. Brill and Patton expect that by 1970 from 6%-19% fewer beds will be needed than in 1960(3). The present need for beds in England using integrated psychiatric services is 1.8 per 1000 for the mentally ill, according to Maclay(4). Approximately half these beds would be for prolonged treatment (more than 2 years), one quarter for median stay (3 months to 2 years), and one quarter for short term treatment (less than 3 months). His prediction that in 1974 less than half the beds in use in 1959 will be needed has been questioned. Barr and Parnell(5) found that in the Oxford area admissions and readmissions rose as the resident population decreased; they feel that the two main factors, drugs and vigorous outpatient treatment policy, may be temporary. A cohort study of three London hospitals showed that first admissions for affective disorders, but not for schizophrenics, increased markedly from 1951 to 1956; readmissions increased in both categories.

Each readmission tended to be longer. Indeed 25% more beds were needed to serve the 1956 cohort, 1 to 3 years after admission (6).

Jones and Sidebottom(7) point out that the reduction in long stay patients over the past few years may not be easy to replicate with hard core patients and increasing psychogeriatric cases. They note that for 60 hospitals with day care centers no more than 1,500 patients are cared for and that the actual cost of running such centers is greater than estimated. They also argue that from an economic point of view dispersal of personnel in a variety of community settings may be more expensive and less efficient than concentrating them in one physical plant such as a mental hospital.

Very little relationship between length of hospital stay and symptoms of illness was demonstrated in a study of male schizophrenics under 60, hospitalized more than 2 years, but there was a positive relationship between length of stay and apathy about life outside the hospital. The authors concluded that "institutionalism" is an important factor in long stay patients but that "deterioration" (increasing clinical deficit) cannot be demonstrated after 2 years. They argue thus that multiple admissions of short duration "have a beneficial effect in preventing the secondary handicaps of institutionalism"(8).

The number of reports supporting open door policy and therapeutic community are too numerous to catalogue. Littlemore Hospital describes an open door policy on a disturbed ward for both sexes(9) and Fairhill Hospital, a female ward where patients take responsibility for their own medications, offers free access to the ward

¹ Respectively, Medical Director, Consultant for Medical Development, Institute of the Pennsylvania Hospital, Philadelphia, Pa.

nursing office and telephone(10). One study which determined the patients' viewpoint about therapeutic factors offered by closed wards reported that 45% of the patients felt that the protection and control afforded were the two most significant factors in their recovery. Because of these positive aspects of the closed doors, caution is recommended before they be abandoned (11).

There has been a substantial rise in voluntary first admissions in the United States, both absolute and percentagewise. However, it is still far below that in Europe and particularly in England. Unfortunately, though court commitments in 1961 had declined from those in 1956, they still accounted for the largest percentage of first admissions(12).

Large psychiatric hospitals are being broken up into units. The advantages and disadvantages of the autonomous unit system at the Ontario Hospital are described after a year of experience(13). At the Towers Hospital 300 bed units are under the full clinical responsibility of a consultant psychiatrist which the new Mental Health Act of England permits because it relieves the medical superintendent of responsibility for the clinical treatment of any patient other than those personally under his care. Kidd states that ideally these 300 bed units should be staffed by two consultant-level psychiatrists and four other physicians(14). A Moscow mental hospital adheres to the unit system(15). The organization of Fort Logan State Hospital with continuity-of-care teams serving patients from a geographical area regardless of treatment locus (inpatient, day and family care, etc.) is described by Lewis and Kraft(16).

Opening psychiatric units to other psychiatrists and physicians is increasing. At least two state hospital systems have done this in the last year (Delaware and Washington). The administrator of a private psychiatric hospital feels it contributes to better care, community education, and greater effectiveness(17). A general practitioner and psychiatrist described how the former treated his own patients using two beds on a psychiatric ward of a teaching general hospital(18).

The importance of general hospital psychiatric units is well accepted. The Veterans Administration has admitted to 5500 beds in its general hospitals as many patients as to 55,000 beds in neuropsychiatric hospitals and feels that its new hospitals should be full service hospitals with about 500 medical and surgical beds and about half as many neuropsychiatric ones(19). Studying 100 consecutive admissions to a psychiatric hospital, Cahn concluded that in a large city such as Montreal, with excellent facilities in several general hospitals, there is a need for the services of a mental hospital, not only for those never considered for treatment in a general hospital but also for those who had already been treated in that type of unit but whose physicians considered a psychiatric hospital preferable(20).

An excellent review of the history and current status of day hospitals states: "The experience of this hospital [Massachusetts Mental Health Center] and that of other psychiatric institutions tempts us to conclude that the Day Hospital is potentially the major primary psychiatric facility of the future"(21). McNichol of Louisiana(22), Ryan, *et al.*, of Newfoundland(23), Bierer of England(24), Cowen of Chicago(25), report favorably on this type of unit, as do Shaw and MacMillan for the geriatric patient(26) and Pfaitz for the adolescent(27).

Halfway houses were found by Harbert and Taylor to be good testing ground for certain types of patients, though somewhat overvalued therapeutically(28). Quiet chronics respond better in this facility than do schizoid paranoids(29).

The Nova Scotia Mental Health Plan successfully gets psychiatrists out into the rural communities where they work in general hospitals(30).

The book *Frontiers in General Hospital Psychiatry* will interest most administrative psychiatrists because it covers many areas of interest to them other than what its title might imply, *e.g.*, Mental Health Service in Denmark, The Impact of the General Hospital on the Private Psychiatric Hospital (31).

MILITARY PSYCHIATRY

JOSEPH S. SKOBBA, M.D.¹

The publications on military psychiatry this year reflect no special trend but cover the range from selection through treatment to post-service observations.

The least well-understood variables in selecting Army officer candidates were those of personality and motivation, according to Garrett and Tierney(1). To determine if the MMPI would give any value in clarifying such personality and motivation variables and in predicting success of candidates at OCS, the following study was conducted. For a 3-year period candidates already accepted for OCS by the existing methods were given a routine MMPI during their first week of training. Answer sheets were then used for later comparison with the performance of the tested candidates. In the process of training, certain candidates were dropped from OCS as being unsuitable because of lack of motivation. This

was referred to as "Motivation-Loss Group." Certain other candidates were dropped temporarily from their original class but allowed to start with a succeeding class and eventually did graduate. This was referred to as the "Turn-Back Graduate Group." Other candidates completed their course in the minimum possible time. This group was referred to as the "First-Time Graduate Group." Initially samples of 33 Motivation-Losses and of 45 First-Time-Graduates were studied. The MMPI's of these candidates were subjected to item analysis. A scale of 36 items was derived. The items were scored so that high scores were indicative of high motivation for completion of training. The motivation scale was then cross-validated. The data were analyzed by constructing composite profiles for each of the three types of candidates studied. Further, profiles of all of the candidates were analyzed in terms of elevation and code type to determine general characteristics of offi-

¹ 490 Peachtree St., N.E., Atlanta 8, Ga.

cer candidates and whether or not there was any relationship between these data and subsequent performances in training. Findings were as follows: 1. Specific Motivation scale derived for the MMPI did not specifically discriminate on cross-validation between people who had completed training and those who were dropped because of lack of motivation. 2. Composite profiles were not significantly different for the three samples. 3. Profiles when individually examined tended to show more similarity than differences in the three samples. 4. When elevation of particular scales, especially subtle and obvious scales, was studied, it was found that there were significant differences on certain MMPI scales indicating that graduates tended to be somewhat healthier psychologically than those who were dropped because of lack of motivation.

Nardini and Herrmann(2) discuss the Navy psychiatric assessment program in the Antarctic. During the establishment of initial Antarctic bases immediately preceding the International Geophysical Year, the Navy expedition had one man who developed a psychosis and because it was impossible to evacuate him, the management problems were very great. As a result of this incident, a psychiatric assessment program was begun and included all personnel, military and civilian, who were scheduled to winter over during the IGY. The bulk of the data accumulated was analyzed by the staff of the U. S. Navy Medical Neuropsychiatric Research Unit, San Diego, Calif.

All personnel assigned to duty in the Antarctic program were volunteers selected on the basis of military or civilian specialty training. More than half were over 25 years of age and almost half had more than 6 years of service. Each man was given an unstructured psychiatric interview, a Rorschach test, and four primary areas were used to determine the psychiatric suitability for the Antarctic program. These areas were: 1) motivation, 2) history of past personal effectiveness, 3) present ego strength and adequacy of defense mechanisms, and 4) adequacy of interpersonal relationships. Those who showed no obvious defects or weaknesses in these four areas were considered sufficiently stable to adjust in the Antarctic—or for almost any program

of this nature. Four sources of criterion data were built into the research design: peer nominations, supervisor performance ratings, medical symptoms check lists, and debriefing interviews with personnel at the completion of the wintering-over experience.

During the 5-year history of the assessment program there were no documented cases of psychotic illness. It is felt that the program was effective in identifying and eliminating individuals who would develop emotional illness under the stress of isolation.

The most important variable in adjustment to Antarctic isolation now is considered to be vocational effectiveness. Structure and composition of the small isolated group is next in importance.

In a one-year study of the diagnoses of referrals to Mental Hygiene Consultation Services, Ryan(3) found that only about 6% were diagnosed as psychotic or neurotic. The remainder consisted of individuals who were referred because of inadequate or inappropriate performance of duty. Three types described were escapist, the reluctant soldier, and the bewildered soldier. For these the problem is most appropriately classified as a social problem. Constructive utilization of the forces within the soldier's environment is made. Brief contacts were fully utilized with the patient and with those important to him—the primary means by which an adjustment is effected. An atmosphere is created and maintained in which the soldier can see only successful adaptation to his environment as a solution to his problem. The soldier must discover an attitude of unconditioned expectancy that he will adjust to the situation. In such an atmosphere, if a psychiatric diagnosis is ruled out, the soldier is told that he is not regarded as sick. The brief contact consists of recognizing with the soldier that he does have a problem, that someone from the MHCS will help him to understand it and solve it, and that the whole procedure will not take long. The process may involve listening, explaining or interpreting, both with the serviceman and others in his command. Upon occasion it may require request to command to reassign or otherwise to alter a situation which seems to be

creating undue stress. In certain instances it may require enlisting the assistance of parents or other authority figures to reinforce the soldier's motivation. The brief contact may require a conference with the immediate commander, first to understand his point of view in relation to the problem and, second, to offer guidance to the commander in his effort to find a constructive solution to it. Another approach with command is by conference with groups of Unit Commanders to discuss ways of dealing with the various kinds of problems. Focus is not on the individual soldier but on the social situation in which difficulties with individuals may arise. The MHCS may initiate recommendations to command in relation to policy considerations. The emphasis is on constructive solutions to the problems in terms of utilization of personnel rather than discharge.

Ginsburg(4) writes of the treatment of the problem drinker in an overseas theater by the general medical officer. He notes that the general medical officer can successfully treat the problem drinker on an outpatient basis when the therapy is based on a medical regimen and special attention is given to the doctor-patient relationship. The medical regimen is centered on the treatment of co-existing physical disorders so often found associated with chronic alcoholism. The use of vitamins, dietary measures, and tranquilizers can be considered. Antabuse is a significant advance in the clinical treatment of the problem drinker provided that it is used only after the physician has become thoroughly familiar with its indications and contraindications. Acceptance of the drinker as a man with a problem deserving medical attention instead of condemnation serves as a boost to his self-esteem. The physician must respect the patient's sensitivity and exaggerated pride permitting him to use devices he finds necessary to make seeking treatment acceptable. At the same time, the drinker is expected to assume a large degree of responsibility for his participation in the treatment program with absolute abstinence as his goal. He stresses the follow-up as an important aspect in the program.

Grold and Hill(5), in order to ascertain the true reasons for failure to keep appoint-

ments, reviewed the records of a division psychiatric section for the first six months of 1961. The study indicated that the reluctance to take advantage of psychiatric assistance is related to the individual and group images of the psychiatric section and psychiatric patient. They found that misconceptions about psychiatric patients and psychiatry are derived from a variety of fears, attitudes, and unrealistic expectations of the individual patient, the referral sources, and the patient's unit, which can and do conflict with one another. Through an increased exchange of information between the psychiatric section, the units, and referral sources, misconceptions and distortions were reduced. Mutual problems were identified and possibilities for cooperation explored. As a result of the study a more intensive educational program was developed with an increase of primary contacts with sources of referrals and units within the division. The authors conclude that consideration must be given to the forces outside of the psychotherapeutic process which impede the use of available psychiatric assistance. After the program was instituted, in spite of a doubling of the case load, the missed appointments were reduced to one-half of the original number.

Anderson and Lauterbach(6) attempted to gather information which would clarify common impressions among psychiatric staffs of military hospitals concerning the frequency of expectancy of psychiatric breakdown: 248 consecutive male enlisted psychiatric admissions to Walter Reed General Hospital were compared with the current population as to age, rank, and length of service, first by total number of cases, then according to the main diagnostic subgroups, psychotic reactions, and character and behavior disorders. It was found that there was a disproportionate number of patients in the grade of private, suggesting less than average success of this group as soldiers prior to hospitalizations. Differences from parent population in terms of age and length of service were found to be of less magnitude and in the case of the psychoses, not statistically significant.

Mack(7) lists principles to guide the selection of psychiatric patients for return to the United States from overseas areas

based on his experience as a psychiatrist at the USAF Hospital at Tachikawah, Japan. He stresses the importance of establishing sound criteria for returning patients because of the great significance of air evacuation for the psychiatric patient, his family, and the military community. The indications he lists are as follows: 1. Unrelenting anxiety or other emotional pain beyond the capacity of the individual to manage even with appropriate therapy. 2. Inability to perform the military duties or handle household responsibilities. 3. Continuing taxation or draining of local medical facilities beyond their resources. 4. In the case of dependents, interference with the sponsors' discharge of his military duties as a result of the neurosis.

He points out the fact that as the number of psychiatrists available to treat patients increases, the number of patients evacuated from overseas is decreased. While recognizing the necessity for the "medical-administrative split" which makes patients in the character-behavior disorder group ineligible for air evacuation, he believes that the practical necessity of such a split from the military standpoint should not be allowed to obscure its artificiality but to spur research aimed at understanding and helping these patients.

Nardini(8) served 3½ years as a prisoner of war of the Japanese in World War II in the Philippine Islands and in Japan from 1942 to 1945. Having worked as a psychiatrist on active duty in the U. S. Navy for the subsequent 15 years, the author has undisputed knowledge of the problems of the prisoner of war. He explains that most POW's are unable to explain their emotional reactions. The POW feels that he has lost prestige, he is confused, bewildered, and has a sense of unreality; he feels helpless, defenseless, shame, guilt, belittlement and failure—even though he has not given up as an individual but has surrendered as part of a unit. All the conditions that man would prefer not to have happen to him can and do happen when he becomes a prisoner of war—cold, heat, starvation, insects, monotony, inadequate clothing, foul odors, physical and moral abuse. Ability to withstand such punishment is not universal.

The death rate is high in the first six weeks of imprisonment. The young and

weak of spirit are first to die. To survive, the individual must "develop a philosophic, fatalistic but non-defeatist attitude and intense application of life's energies to the present." He needs a sense of humor, tact, moral courage, ability to manage hostility and fight depression . . . he needs "enough inner resources to last out a long drought of outer stimuli."

Physicians as prisoners of war in the majority possessed those better integrated and adjusted qualities. The physician must care for mortally ill patients with no effective medicine and no supportive care. He recognizes deficiency and other diseases which lead to death in a prescribed period of time and finds the same symptoms developing in himself. Emotional disorders are related to apathy, withdrawal and depression. Schizophrenic reactions and suicides are less than average. Dr. Nardini tells of his attempts to care for 100 seriously ill men housed in a bamboo shack, and the amazingly surprising effects of placebo remedies which he describes as just short of miraculous.

Brain-washing is much misunderstood and there is unnecessary concern over this method of influencing men's minds. He suggests that we should "train and lecture loyalty to our forces" and inform them that the best is expected of them, but we must realize that many will fail under the pressure no matter what we demand. There is lack of realism in regulations that require a POW to give no information other than name, rank, and serial number. "Universal heroism cannot come to pass," Dr. Nardini says, and concludes by saying ". . . in the future we might gauge the index of man's humanitarian growth and gain by the manner in which he is able to rise above his more basic cruel animalistic impulses as reflected in his treatment of prisoners of war."

Schneck(9) reported on four patients who, while under psychiatric treatment, revealed that during military service or on induction they had deliberately feigned psychological symptoms. In the course of treatment they found that they had, in fact, without being conscious or aware of it at the time, suffered the very distress they had believed they were falsifying. The author

concludes that this appears to reflect curiously a self-exclusion component of ego-functioning. He considered the behavior to lie in the border between malingering in its general acceptance as a manifestation of a personality disorder and hysteria. In his opinion, psychodynamically, the elements in pseudo-malingering are essentially hysterical. The maneuver is an emergency device to maintain the integrity of the ego. It is an attempt to deny the illness by the expedient of claiming illness. The circumstances involving avoidance of military service were sufficiently dramatic to highlight the reactions and to prompt special focus of attention on them. He concludes that pseudo-malingering is probably far more widespread and its characteristics more subtle than indicated by his patients. He recommends additional attention and investigation.

The *Index Medicus* for 1962 lists a number of articles dealing with military psychiatry from countries other than the United States (10-16).

PSYCHIATRIC EDUCATION

FRANKLIN G. EBAUGH, M.D.,¹ AND ROBERT H. BARNES, M.D.²

Frequently, in past years, we have called attention to the pessimistic picture of a future where medicine will be less and less able to meet human needs because of manpower shortages. It is gratifying this year to take a more optimistic view and note the impressive progress being made in facing the needs for increasing numbers of doctors. New schools of medicine have been opened recently at Yeshiva University, the University of Florida, and the University of Kentucky. A two-year school has been developed at the University of New Mexico, and two- or four-year schools are authorized, or about to be authorized as follows: the University of California (San Diego), the University of Texas (San Antonio), the University of Connecticut, Michigan State University, the University of Arizona, Rutgers University, and Brown University. The

possibility of other new schools is being seriously considered in New York, Ohio, Maryland, Delaware, and Hawaii. The feasibility of a regional school of medicine sponsored by Nevada, Idaho, Montana, and Wyoming is being explored. Thus, we are moving closer to the creation of 20 new schools that was advocated by a number of surveys 5 to 10 years ago (1).

Faculties have also expanded markedly in medical schools during the last decade. Despite the great increase in medical students during the last 10 years, the total medical school faculty available for teaching has increased proportionately at an even greater rate. Total faculty (full and part time) has increased more than 100% between 1951 and 1960 (2). Full time teachers constituted 25% of faculties in 1951 and 31% in 1960. The percentage increase of students and trainees in American medical schools during this 1951-1960 period is also interesting: medical students—17%, graduate

¹ 1801 High St., Denver, Colorado.

² Kansas City, Mo.

students—9%, interns and residents—168%, and others (dental, nursing, technicians)—19%. The percentage increase in full time faculty during this period was 176% and was interestingly greater in the clinical fields than in the basic science fields (214% vs. 124% increase). Another significant growth was in Ph.D.'s in the clinical departments—an increase of 498%.

A survey of the literature in medical education during the year, however, indicates sources of serious concern. One area receiving particular attention is the increasing emphasis in medical schools and teaching hospitals on research activities to the detriment of teaching and patient care. Ruesch(3) points out that the tremendous increase in research funds has drawn clinicians over into research and attracted non-clinicians into medicine to the extent that we have fewer people taking care of patients or learning how. He calls attention to the twenty-fold increase in research funds in the last 15 years and suggests "mediocre research and the concomitant neglect of clinical training have put the population in double jeopardy."

Cummins in his presidential address to the American Ass. of Anatomists, entitled "The Golden Age of Research and the Price We Pay For It"(4), views with real concern the "trend toward subordination of teaching" and indicates that unless this is arrested, "the operation of our schools will become a travesty on medical education, and this in the face of compelling reasons for the training of more and better physicians." In terms of correcting this situation, Ruesch(3) makes the following suggestion: "Clinicians with teaching ability and medical skills should be at the head of clinical departments in hospital divisions. Only when students and residents are provided with models of clinical excellence in responsible positions does effective learning take place." Cummins places the corrective responsibility on administration and faculty in the following manner: "University presidents, deans, and faculty should unite to re-establish the honored and essential role of teaching in the university scene."

De Takats(5) underlines the same problems of research-teaching imbalance in the university-affiliated hospital. "What needs

to be examined is whether or not the running of clinical departments by research professors or medical educators can be kept in sufficient balance for optimum care by the medical staff."

It has frequently been suggested to these reviewers that more emphasis be put on reported advances in medical education abroad. Unfortunately, the increased volume of reports in the American literature with marked improvement in their quality makes this increasingly difficult. For those particularly interested in a comprehensive review of medical education around the world, we call attention to a 200-page survey of medical education abroad in the *Journal of Medical Education*(6).

Undergraduate Medical Education. The Associate Dean of the Johns Hopkins School of Medicine has looked searchingly at the basic medical sciences in relation to what he calls "The Revolution in Biology"(7). He points out the tremendous progress that has been made in molecular and sub-molecular biology, calling attention particularly to new knowledge about DNA and its relation to cellular processes and genetics in particular. He raises serious questions as to whether medicine is sufficiently flexible to accept and utilize this new knowledge. He believes major revisions in medical thinking and educational structure will be necessary if this new knowledge is properly incorporated in the basic sciences and communicated to the medical student. "To my mind, medicine has little choice but to remain a progressive branch of biology. The alternative is a biological society divided into two cultures: science and medicine. The next fifty years could see our once proud profession degenerated to a second rate technology, fostered by a second rate educational system and practicing second rate medicine"(7).

While biology has made more dramatic advances in the last two decades than psychology and psychiatry, advances in our field have been substantial. The applications of basic molecular biology to our field will soon be upon us to properly integrate and utilize. Much careful thinking must be done to incorporate dynamic psychiatry and psychology within the basic medical sciences curriculum for medical students. All too

often, our efforts have consisted of rather anemic and disjointed lectures on personality development, interspersed at weekly intervals in the freshman and sophomore curriculum.

Largely in response to the final report of the Joint Commission on Mental Health and Illness (*Action For Mental Health*), the AMA convened an extensive 3-day Congress on Mental Illness and Health. In preparation for this a Preliminary Program Conference on Mental Illness and Health with 175 distinguished professional leaders in attendance was held in late 1961. From this evolved the program of the AMA Council on Mental Health. Vital to this program were certain recommendations in terms of psychiatric training of medical students. The document strongly recommended more extensive and specific curriculum development around practical aspects of the doctor-patient relationship, as well as special emphasis on alcoholism, drug addiction, juvenile delinquency, mental retardation, family dynamics, and special emotional problems of children and the aging.

The Training Branch of the NIMH reported on an effort to improve and extend the training of medical students in psychiatry through the offering of stipends for extra curricular training(8). This program has been set up to enable selected students to obtain additional clinical and research training as part of their general medical preparation. It is hoped that this will interest more medical students in psychiatric specialization. During the period from 1957 to 1960, 2216 medical and osteopathic students received these stipends. The next few years should tell whether this program has had a significant influence on these students' professional specialization and orientation toward psychiatry.

As in past years, many reports appeared dealing with new techniques and programs for presenting both basic and clinical psychiatry to medical students. Only two representative items will be noted. The University of Missouri reported on a field trip program in psychiatry for senior medical students as one of the unique developments in this new department of psychiatry (9). As a way of introducing the senior student to his psychiatric patient's home

milieu, he accompanies the psychiatric social worker and/or psychiatric nurse on visits to the referring local doctor, the community agencies involved with the patient, and to the patient's family itself. The results of these trips are tied together on return to the medical center in conferences with supervising ward staff.

Ward(10) reviewed an interesting technique by which the instructor may directly supervise and coach the medical student in diagnostic and therapeutic interviews with patients. The teacher views the patient and student through a one-way mirror or closed circuit TV and can communicate directly with the student during the interview through an unobtrusive earphone device. The patient is informed of this initially, but the prompting is done without obvious interference. It has resulted in effective supervision in beginning psychotherapy and is well received by students and patients.

House Officers' Education (Interns, Residents, Fellows). The latest *Health Manpower Source Book*(11) indicates that from 1950 to 1960 approved residency programs increased by 70% (for all specialties). For psychiatry the increase was 109%; surgery residencies increased 41% and internal medicine 47%; 82% of all residency positions were filled in 1960 in psychiatry, as compared with 93% in surgery, and 89% in internal medicine. The foreign medical graduate continues to be a significant participant in residency training in the United States with 24% of all residency openings in all specialties filled by foreign medical graduates. Psychiatric residencies were 19% filled by foreign medical graduates as compared with 26% of surgical residencies and 23% of internal medicine residencies filled by such graduates. For those interested in results of the first four years of activity of the Educational Council for Foreign Medical Graduates, may we refer you to the *Annual Report* for 1961(12). On this basis of the eight examinations given so far, approximately 62.5% of foreign graduate candidates have qualified on their ECFMG examinations. It was feared when the ECFMG system went into effect that this would drastically cut down on the number of foreign graduates training in the United States. Interestingly, this has not been the case. In 1961 there

were over 3500 foreign medical graduates who took the examination in foreign centers and obtained certificates. If all these certified candidates come immediately to internships or residencies in U. S. hospitals the inflow of *certified* foreign graduates will be greater in 1962 than the inflow of *uncertified* foreign medical graduates in 1957 (approximately 3300) (12).

In line with the conclusions of the Joint Commission that the main unfinished business of psychiatry is treatment of psychotic individuals, a number of critical looks have been taken at much of current psychiatric residency training in the United States.

Felix (13) has written concerning the implications of goals of therapy. He suggests that we stop looking at deep, long term psychotherapy as the ideal or only real goal for psychiatric treatment and that "without feeling guilty, we state our primary goal to be to return as many of our patients as possible to social usefulness." He underlines the lack of emphasis in many programs on training residents to care adequately for psychotics and to be able to function effectively in a hospital setting.

Eisenberg (14) in a major address at this year's American Orthopsychiatric Ass. meeting says that no residency program should be considered adequate that does not provide substantial experience in community and public hospital psychiatry. He is also critical of training in child psychiatry which does not give the resident or fellow adequate experience in dealing with chronic brain syndrome and mentally defective children. He calls for more emphasis in training programs on the physiological, biochemical, and sociological determinants of behavior.

Two reports from Oregon present specific programs relevant to the teaching of social psychiatry. Saslow (15) indicates that the individual, intra-psychic approach is so often inadequate and that many senior staff psychiatrists have not yet learned how to deal with people in groups, continuing "their over-emphasis on feelings, thinking, and behavior on an individual basis." Of particular interest is his report on the joint training of psychiatrists and psychologists. They share many ward functions, both as individual therapists, group therapists,

teachers of nurses aides, and as team leaders. High mutual regard appears to exist between psychiatrists and psychologists trained in this joint manner. He emphasizes the importance of ward meetings as a teaching experience. Jones (16) also outlines some of the techniques in training for social psychiatry at the ward level.

One of the very exciting training programs in community psychiatry is that carried on by the State of Maryland in conjunction with the two medical schools, private and state hospitals, and local health departments. Local mental health programs in 13 of Maryland's counties are staffed by 16 psychiatric residents representing six training institutions. These residents each spend one day a week as consultants to the local health officers of the county and serve as psychiatric staff members of the local mental health program. The program is well supervised and theoretical aspects of public health psychiatry are discussed in weekly seminars, conducted by Dr. Paul Lemkau at the Johns Hopkins School of Hygiene and Public Health. The emphasis is on the operating and supervising of a program in community psychiatry rather than a direct outpatient treatment service (17).

A pioneer endeavor in introducing psychiatric residents to community mental health and the public health aspects of psychiatry was organized by Dr. Lucy Ozarin and the Region VI staff of the USPHS Regional Office in Kansas City, Mo. in Mar. 1962. Twenty-seven residents from various training programs in the 7-state area were brought together at PHS expense, for a week long workshop. Many of the residents noted that this opened up entirely new areas that they had not encountered in their years of residency (18).

A Cincinnati group reported on the training value of the "Wednesday Afternoon Clinic: A Supportive Care Program" (19). The clinical program is set up to care for the so-called "poor" therapy cases, generally psychotic or severe psychoneurotics, through brief, not too frequent contacts for supportive interviews and medication. The residents have learned techniques of dealing effectively and helpfully with patients that cannot appropriately be treated by more

intensive psychotherapeutic relationships. While this is not particularly unique, it is rare in the literature to find a description of a systematic training and treatment program to equip the psychiatrist for this important aspect of his work.

Gitelson(20) gives an excellent historical review of the importance of psychoanalytic knowledge in the psychiatrist's training and indicates that the analyst can participate in such training basically in his capacity as an "enlightened psychiatrist."

Continuing Medical Education. As a result of the Joint Commission's report and other developments, more interest was generated in this area than in any comparable period in the past. An editorial in the *J.A.M.A.*(21) spoke of this as the "undeveloped frontier" of medical education and notes that this field is in a much more primitive state than undergraduate and resident training. The Council on Medical Education and Hospitals has announced an intention to appraise and accredit continuing education courses in the future much as it does intern and residency programs. We refer those interested to a summary report of the Joint Study Committee on Continuing Medical Education(22). This outlines the organization of an ambitious program for the continuing education of all physicians on a voluntary basis. The AMA this year lists 118 post-graduate courses in psychiatry, ranging from relatively prosaic titles such as "Psychiatry and General Practice" to more intriguing captions, "Psychiatric Aspects of Feminine Sexual Function," and "Body Involvement in Emotional Conflict"(23).

The AMA Council on Mental Health strongly recommended the expansion of post-graduate education on three levels: 1) relatively short courses for physicians without specialized psychiatric training, 2) more intensive training for non-psychiatrists in the management of well defined emotional problems, and 3) advanced courses for psychiatric specialists stressing improvement of the psychiatrist as a teacher in the foregoing programs and the strengthening of the psychiatrist's capabilities as a consultant to other physicians(24). The Council noted further that psychiatrists "should also be prepared to teach courses to candi-

dates in non-medical health professions"(24).

The NIMH in 1959 initiated a grant program for the support of psychiatric training of physicians engaged in the practice of medicine other than psychiatry. In 1960, \$385,000 was designated for the post-graduate education aspects of the program; 1,732 physicians participated in these programs, usually institutes, all day conferences, workshops, etc.(25).

Forman, *et al.* (26), reported on one such program, supported by the NIMH, where particular emphasis was placed on evaluating the effectiveness of teaching in a 12-week seminar type course in brief psychotherapy. More extensive studies of this sort are needed to ascertain whether these courses actually accomplish what we wish them to and whether they are worthwhile doing. An interesting description of another project of this sort in Brooklyn has been presented. Here, as in the above study, an informal round table approach seemed best. Interestingly, little response was attained from younger physicians with 85% of those present graduated from medical school before 1940(27). The recommendations of the sub-section of the AMA Congress on Mental Health concerned with post-graduate education strongly underlined the need for conducting this type of teaching around clinical material, having it patient and problem orientated rather than didactic or theoretical in nature. Small group seminars with continuity of instructors was strongly recommended. This group also recommended the post-graduate training of psychiatrists to make them more effective in this type of instruction and consulting work(28).

The shortage of capable and well trained full time teachers in psychiatry has been repeatedly emphasized. In 1956 the NIMH inaugurated the Career Teacher Program in an effort to provide more and better qualified teachers. Grants were made on an annual basis to those interested in pursuing psychiatric teaching as a career. Between 1956 and 1959, 43 appointments were made in psychiatry. It is believed that this program has kept a significant number of capable people in the teaching area(29).

Two rather extensive reports on psycho-

analytic education came out in 1962. One was a publication of a selection of papers presented at the annual meeting of the American Psychoanalytic Ass. on its 50th anniversary. An historical review by Bertram Lewin is presented, as well as a review of the development of the Association's program with establishment of C.O.P.E.—a standing committee of the Association on psychiatric education(30). Masserman edited a larger monograph on psychoanalytic education at the behest of the American Academy of Psychoanalysis with contributions from many of the current leaders in this field(32).

For those interested in setting up or participating in training programs in hypnosis, the report of the Committee on Training in Medical Hypnosis of the Council on Mental Health of the AMA was published (32). An extensive outline of recommended courses with notes as to content, technique in teaching, size of classes, *etc.*, is presented. The Committee notes the great need for such training courses, properly conducted, and the almost complete dearth of systematic training currently in medical hypnosis.

REHABILITATION AND OCCUPATIONAL THERAPY

WARREN A. MANN, M.D., AND WILLIAM B. TERHUNE, M.D.¹

In reading articles currently in the literature, in talking to psychiatrists from various sections of the country, and in talking to

patients, one gathers now that the biggest problem facing psychiatry is that of the patient returning to the community from the mental hospital. In years gone by the idea of rehabilitation was more confined

¹ The Silver Hill Foundation, New Canaan, Conn.

in scope, but at present it seems to cover anything that happens from the moment the patient enters the purview of psychiatry until he becomes an independent citizen outside the concern of psychiatric facilities. This widening of the scope of concern is apparently related to better medication, more open hospitals, and a more rapid turnover rate in all psychiatric hospitals, pouring more and more people back into the community. Since this step from hospitalization to resumption of community living is what rehabilitation comprises, we find ourselves reviewing more articles this year which have as their focus the individual mental patient vis-à-vis his community. Therefore, we have chosen as our focus the area of community mental health as it pertains to the field of rehabilitation. This is highlighted by Braceland's comment(1), "There is little use in giving the patient the advantage of the best in rehabilitation procedures if the family or the community will not receive him when he recovers." That this has become a very real problem is substantiated by Harrison's report(2) that "The extent of the readmission problem is apparent from just one set of figures for the state mental hospitals in 1959. In that year there were 175,727 patients discharged, but there were 80,344 readmissions to these same hospitals."

We have divided our reporting on publications which have come to our attention this year into several sections. The first of these covers the responsibilities of the hospital to the patient and the community. Noteworthy among this group is the article by Ananian and Biddle(3) reporting further on the experience of the Prep Shop at the Philadelphia State Hospital. The authors point out that the hospital can, through this means, supply industry with people trained in good work habits, and can give an evaluation of peoples' abilities to potential employers. In book form the studies done in Vermont by Chittick, *et al.*(4), give us the detailed experience of the Vermont State System in the program of evaluation in the rehabilitation of chronic schizophrenic patients. Denber and Rajotte(5) have given a description of the work therapy program in Manhattan State Hospital indicating the need for graded responsibility

in a factory workshop pointing toward eventual emergence into the community. They find it possible to operate such a program successfully without an increase in specialized personnel. Alberts(6) has described a project at the South Florida State Hospital in which patients are released to work in the community during the day and remain in the hospital at night. In a similar type of program(7), patients at the Brooklyn State Hospital leave during the day to work as volunteers for community agencies. The hospital staff assumes responsibility for evaluation and effective placement in community agencies. Friedman(8) tells of an interesting school program conducted at the Hudson Valley State Hospital by professional teachers who are hospitalized patients. Navran(9) reports on an analysis of failures in patients returning to the community from the VA Hospital in Sepulveda. Olshansky(10) points out the need for careful screening of patients prior to their admission into programs such as those mentioned above, so that the patients are not plunged into a competitive market above their capacities, with the risk of relapse. Wayne(11) discusses the problem of integration of aftercare facilities with hospitals, indicating that in his experience the parent hospital should maintain a close professional and physical link with the rehabilitation agency in order to give greater flexibility in moving out and back according to need. Barton(12) comments that the psychiatrist will probably play an increasingly less significant role in this transition and will be replaced gradually by a skilled rehabilitation team. Wolfe(13) feels that an important part of the hospital's responsibility is a professional vocational evaluation of the abilities of the patient in order to give the employer a sound reference. In Connecticut, Donnelly(14) reports the cooperative program of a state hospital and a visiting nurse association in which the nursing service, educated by the hospital staff, helps smooth the way for the post-hospital psychiatric patient. Fargher and his group(15) describe a rehabilitation program in the State of Washington through the coordinated efforts of the state hospital, local health department and the O.V.R. This latter report gives a good outline for those interested in organ-

izing such programs. The McLean Hospital, as announced by de Marneffe and Prekup(16), is opening up a new rehabilitation center which will be close to the hospital in order to combine the continued care and rehabilitation of patients with the training of psychiatric residents and student nurses.

The second section is concerned with transitional facilities standing between the hospital and the community. Bierer(17) wants us to distinguish carefully between the true day hospital as a separate entity and the treatment units contained within various other hospitals and rehabilitation centers. Coleman and Greenblatt(18) discuss the development and challenges of the day hospital and report on a study to determine the feelings of patients participating in day care. Pfautz(19) describes the new adolescent day care program at the Butler Health Center in Providence and discusses the functions of such a facility. A progress report has been published on the rehabilitation house in St. Louis, a cooperative project of the St. Louis State Hospital, the Missouri O.V.R., and the St. Louis Mental Health Association(20). This is a transitional residential unit for male patients who average some three months in residence. Wolff and Colacino(21) comment on the Minnesota follow-up study indicating that patients who lived in a foster home or boarding home during the transitional phase were rehospitalized significantly less than those who lived with their families. It is important to note that the VA reports it has gained the equivalent of four 600-bed hospitals through placement of recovering mental patients in foster homes during the past 10 years(22). In the excellent book edited by Greenblatt, Levinson and Klerman(23), 25 papers and discussions are included. These papers were presented at a conference on the problems of transition from hospital to community held in Boston in March, 1960, and cover problems in discharge planning, facilities used in transition, community influences and supports, family influences and supports, and the role of pharmacotherapeutic agents in the transition.

Our third grouping is concerned with the responsibilities of the community to the

hospital. Adrain(24) reports on the secondary school and college level training offered to patients at the Menninger Hospital. Bingham(25) describes the hospital "open house" intended to encourage the public to see what the hospital and patients are like and to share in the rehabilitation program. Mental health education in Massachusetts, reported on by Elbaum and Maloney(26), utilizes a psychiatric social worker and the publicity agent of the Department of Mental Health who, working as a team, interpret the state program to the public. An unusual program in Florida goes into action when a patient is committed to a state mental hospital(27). The Mental Health Resource Council of Hillsborough County, including 33 agencies of the county, combines forces to bring the patient back into the community, avoids duplicating the community efforts, and streamlines the community facilities for help.

The fourth grouping of papers is related to general community level concerns. The National Association for Mental Health held a Leadership Conference in Washington in March 1962(28). Top level representatives of government and professional organizations emphasized the need for increased public understanding of mental health problems and urged increased cooperation between community and professional groups. Ozarin(29) has published a review of Community Mental Health Legislation adopted in this country from 1954-1960 which shows the trend in recent years to be toward local controls with state subsidy. In that regard it was reported that funds budgeted for community mental health services throughout the United States during 1961 totalled \$91 million(30). Muth(31) has published findings of a study of community treatment facilities based on correspondence conducted with 48 countries. A major conference is represented by the book *Mental Health Teaching in Schools of Public Health*, which elaborates on the background and current facilities for training of community mental health specialists(32). A book by Nunnally(33) describes a group of studies designed to discover what the public knows about mental health and has many suggestions for those engaged in public education regarding mental ill-

ness. Ross(34) gives some valuable advice in an article dealing with the education of the family and the community to the needs of a mental patient in the convalescent period. Salkind(35) is concerned because, in spite of the various campaigns and committees, we are not reaching employers who might hire the psychologically handicapped individual. He suggests that a staff of trained public relations specialists with knowledge in this field might be successful in influencing employer attitudes. In the recently published proceedings of an important institute held in St. Louis in 1961, much emphasis is placed on this lack of understanding on the part of employers (36).

We have again dealt separately with the publications representing other countries. Huseuth(37) describes a new type of transitional facility in England which provides holidays for hospitalized patients. Harbert and Taylor(38) mention that records from an aftercare hostel will aid in evaluation of the returning patient, should rehospitalization become necessary. Day(39) emphasizes the need to allay unreasonable fears and refute misapprehensions in patients going into rehabilitative work. A report by Krapf and Moser(40) on a survey conducted by the Mental Health Section of WHO compares mental health facilities in different countries. It is especially interesting to note that halfway houses or sheltered workshops exist in all psychiatric hospitals in the USSR. Norway apparently has an experience similar to that in the United States as reported in an article by Davis(41). He states that more patients are being treated outside the hospitals than in the institutions. This calls for a new social philosophy toward rehabilitation to which the public is being awakened.

Occupational therapy continues to play an important part in psychiatric treatment, although the literature is not abundant. The reviewer senses a need for writers to assure the personnel working in the field of the great value of occupational therapy to the psychiatric team. Therefore, it seems important to call attention to a paper by Jantzen(42) which outlines some reasons why the occupational therapist plays such

a large part in the general treatment picture. This paper is backed up by the previously mentioned survey of the Mental Health Section of WHO(37) which reveals that occupational therapy facilities have been much extended in countries all over the world, especially in the last 10 years. The relationship between occupational therapy and psychiatry was the subject of a survey sponsored by the APA and reported on this year by Conte and Shimota(43). The survey shows that all who responded considered occupational therapy an effective treatment procedure for psychiatric patients, although opinions differed on the degree of its importance. It was suggested that poor communication techniques may cause the apparent lack of interest of some psychiatrists in occupational therapists' reports. The very new book by Linn, Weinroth and Shamah(44) gives one of the best discussions of the dynamic relationship between occupational therapy and hospital psychiatry published in several years. Also of note is the report by Morehouse(45) on the ceramic project at the Brockton VA Hospital which uses wages as a means of increasing motivation. Norton and Gaster(46) describe a program of progressive levels of work complexity from the ward to the occupational therapy center at the Central Islip Hospital. A youth program in progress at the Anoka State Hospital in Minnesota is discussed by Babcock, Dellvina and Azela(47) who find that adolescents are easier to treat when they are kept separate from other age groups. A preliminary report by Lawn(48) reports on the practical use in art work of designs that are symbols of human experience. A dynamic paper by Peck(49) discusses the development and management of transference to the occupational therapist. Of note this year is a study course for occupational therapists offered in Boston on the transitional programs in psychiatric occupational therapy(50). In October of 1962 the World Federation of Occupational Therapists held its third International Congress(51). Proceedings of this important meeting will be published under the title *Cultural Patterns Affecting Rehabilitation*.

COMMENTS

QUACKERY

A recent issue of the *World Medical Journal* carries a special article on "The Problem of Quackery," containing brief reports from several European countries and from Australia and the Philippines as well.

Speaking for Denmark, Dr. Charles Jacobsen, past President of the World Medical Association, states that under a law passed in 1934, "a quack is subject to punishment only if it can be proved that his treatment endangered the patient's life or resulted in injury to his body or his health." Under these difficult conditions "quackery has flourished extensively." Nevertheless legal proceedings are taken in only one or two cases annually.

"Without doubt the most extensive field of quackery in Denmark is chiropractic . . ." It has been so established in the Danish courts. "Quackery flourishes," Dr. Jacobson states, "largely because the human being craves mystery and the supernatural and believes in it."

Although in France the law against quackery is rigid, Dr. J. R. Gosset, Associate Editor, W.M.J., states that there are probably as many quacks as physicians, one of the most valid reasons being "the great number of credulous people in the world." Quacks "practice openly and freely, with extensive newspaper advertising. They have recently organized as a 'National Group for the Defense of Free Medical Practitioners.'"

In the Netherlands Dr. A. P. N. de Groot is President of the Society Against Quackery, formed in 1881. He states, "Only about 300 out of thousands of doctors are members." This Society is apparently the only agency actively fighting quackery. It publishes a monthly paper exposing many kinds of frauds, encourages prosecution and gives public lectures.

"It is astounding—and rather humiliating," writes Walo Van Greyerz, M.D. of Stockholm, Chief Medical Officer of Civil Defence, "that in a country like Sweden, which might boast a certain degree of enlightenment, quackery still exists and even thrives."

An official 1951 report indicated that there were "about 500 persons dealing in some form of quackery . . . The number was certainly much higher . . . A new law defining permissible and forbidden practice by laymen came into effect Jan. 1, 1961, but it was considered that the time had not yet come for total prohibition of quackery.

In Australia, Dr. C. J. Ross-Smith, General Secretary, Australian Medical Association, reports that quackery is not a major problem, and that "all States excepting Victoria report that its practice is reasonably well controlled." The forms of charlatanism now more commonly practiced are "chiropraxis, osteopathy, hypnotherapy and, in Victoria particularly, the field of 'scientology.'" This latter cult, originating in America, "is regarded as a dangerous and near criminal activity . . . and the object of its technique is clearly to obtain a degree of dominance over the mind of the victim . . . [which] inevitably leads to the extraction of large sums of money."

It is thought that the restriction on advertising by any one not registered under a State Medical Practitioner's Act is largely responsible for limiting the spread of quackery in Australia, although in both Victoria and Western Australia there have been vigorous political campaigns to remove these restrictions.

Quackery is reported as a serious and continuing problem in the Philippines despite all efforts of the Philippine Medical Association to bring it under control. Drs. Romu Eldez and Ferrcol, reporting in the *World Medical Journal*, state that in addition to the "buyo-chewing midwives," herb-alists and faith healers, the most dangerous quack is the licensed practitioner who "employs fraud and deception in advertising his calling."

At a recent annual convention of the P.M.A. the subject of the meeting was "Quackery—the Scourge of the Nation's Health." It thrives for the same reasons that prevail everywhere: "(1) superstition;

(2) ignorance; (3) gullibility of the people; and (4) lax laws," with accent on the latter. However the Medical Act of 1959 has increased the powers of the Board of Medical Examiners and offers hope of reduction in the number of irregular practitioners in the islands.

The world-wide prevalence of quackery in the healing arts, the disturbing periodic

reports of the head of the F.B.I., and the other unpleasant doings of individuals in all social and political ranks that soil the pages of the daily newspaper—all this does not greatly encourage the optimists, if such there be, who dream of the perfectibility of the human species in the best of all possible worlds.

C. B. F.

It is impossible to foresee the future of science, particularly of psychology, . . . It may be that psychological causation can be freed from its present dependence on the body. But in the present state of psychology and physiology (1935), belief in immortality can, at any rate, claim no support from science, and such arguments as are possible on the subject point to the probable extinction of personality at death. We may regret the thought that we shall not survive, but it is a comfort to think that all the persecutors and Jew-baiters and humbugs will not continue to exist for all eternity. We may be told that they would improve in time, but I doubt it.

—BERTRAND RUSSELL

NEWS AND NOTES

THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following are Diplomates who successfully completed the Board examination given in October, 1962:

PSYCHIATRY

Alig, Vincent Boone, M.D., Indianapolis, Ind.
 Anderson, Paul Sanford, M.D., Mayview, Pa.
 Apolito, Arnaldo, M.D., Lyndhurst, N. J.
 Ardis, Mark Burkett, M.D., Downey, Ill.
 Baldwin, Albert E., M.D., Euclid, O.
 Barrett, William W., M.D., Salt Lake City, Utah
 Barron, Antioch R., M.D., Chicago, Ill.
 Bergmann, John Frederick, M.D., St. Louis, Mo.
 Bjornstad, Harry, M.D., Canton, O.
 Black, LaVerne Nelson, M.D., Cleveland, O.
 Blatt, Ronald William, M.D., Detroit, Mich.
 Blumenfeld, Neal M., M.D., Berkeley, Calif.
 Breakstone, Irving L., M.D., Miami, Fla.
 Burris, Boyd Lee, M.D., Washington, D. C.
 Capone, Antonio, M.D., Providence, R. I.
 Carnahan, Clarence E., Jr., M.D., Worthington, O.
 Carter, Donald Clayton, M.D., St. Cloud, Minn.
 Chamberlin, Cecil R., Jr., M.D., Topeka, Kan.
 Chang, Emilie V. C., M.D., Elizabeth, N. J.
 Ching, Alfred, M.D., Northville, Mich.
 Clancy, Jonathan Holt, M.D., Bala Cynwyd, Pa.
 Clark, Paul C., M.D., Bay Pines, Fla.
 Cohen, Sheldon B., M.D., Atlanta, Ga.
 Cook, Elwyn Curtis, M.D., Topeka, Kan.
 Coopersmith, Richard Connell, M.D., Reno, Nev.
 Coulter, Lawrence William, M.D., Rochester, N. Y.
 Dunlap, James R., M.D., Omaha, Neb.
 D'Zmura, Thomas Leo, M.D., Philadelphia, Pa.
 Eason, William M., M.D., Topeka, Kan.
 Egan, Merritt H., M.D., Salt Lake City, Utah
 Fieve, Ronald R., M.D., New York, N. Y.
 Firestone, Melvin P., M.D., West Palm Beach, Fla.

 *Certified in Supplementary Psychiatry

AMERICAN PSYCHOPATHOLOGICAL ASSOCIATION.—The annual meeting of the Association will take place Feb. 22-23, 1963 at the Park Sheraton Hotel in New York City. The topic of the symposium is "The Psychopathology of Perception." Inquiries should be directed to Dr. Fritz A. Freyhan, Secretary, c/o Saint Elizabeths Hospital, Washington 20, D. C.

TRAINING IN CHILD PSYCHIATRY, HARVARD MEDICAL SCHOOL.—The Department of Psychiatry has been given a grant for a two-year training program at the combined facilities of the Children's Unit at the Metropolitan State Hospital in Waltham, Mass., and Beaver Brook Guidance Center in Belmont, Mass. The course has been approved by the Council on Medical Education of

the A.M.A. The program will be under the joint direction of Donald S. Gair, M.D., as Director of Training, Gertrude A. Rogers, M.D., Clinical Director, Children's Unit, and Carlos L. Hudson, M.D., Director, Beaver Brook Guidance Center.

VIIIth INTERAMERICAN CONGRESS OF PSYCHOLOGY.—This Congress will be held in Mar Del Plata, Argentina, April 2-6, 1963 under the auspices of the Dept. of Psychology, La Plata University. Central theme: The Professional Training and the Functions of the Psychologist. Active participants in the Congress must be members of the Interamerican Society of Psychology. For information write to: Dr. Samuel Pearlman, Brooklyn College, Brooklyn 10, N. Y.

APPLICATIONS FOR HOFHEIMER AWARD.—The American Psychiatric Association invites application for its annual Hofheimer Prize Award (\$1500) for outstanding research in its field. Applicant must be a United States or Canadian citizen not older than 40, and can be any professional person who has done creative research relevant to behavior. (In a research group the majority must meet the citizenship requirement and their median age must be not more than 40.) The Award applies to work published within the past 3 years. To apply: Submit eight copies of published work and data concerning age and citizenship by March 1, 1963, to Eugene Bliss, M.D., Chairman, Hofheimer Prize Board, 156 Westminster Ave., Salt Lake City 15, Utah.

THE MISSOURI INSTITUTE OF PSYCHIATRY.—The Institute of Psychiatry at St. Louis State Hospital was formally dedicated by Governor John M. Dalton and opened for service Oct. 22, 1962. It is housed in a new \$6,000,000 building named in honor of Louis H. Kohler, M.D., the hospital's superintendent. It has the unique distinction of following the recommendation found in *Action for Mental Health*, the final report of the Joint Commission on Mental Illness and Health relating to the need for research and training institutions located on the

grounds of a public hospital and affiliated with a university.

Dr. George A. Ulett, Acting Director, Division of Mental Diseases, appointed Dr. Max Fink as director of the teaching and research program.

Jack R. Ewalt, Jr., M.D., Harvard University Professor of Psychiatry, delivered the dedication address.

CHILDREN AND THE THREAT OF NUCLEAR WAR.—This 22-page pamphlet is a publication of the Child Study Association of America, founded in 1888 with a "program of preventive mental health education" for parents and community groups. It was prepared in response to requests from parents and educators. For single copies write to the Child Study Association of America, Inc., 9 E. 89th St., New York 28, N. Y. Quantity rates available upon request.

CONFERENCE ON STUDENT MENTAL HEALTH.—In response to the need for an examination of student mental health problems in Canada, the Canadian Mental Health Association, the National Federation of Canadian University Students and World University Service of Canada have agreed to convene a Conference on Student Mental Health to take place at Queen's University, Kingston, Ontario, May 10-13, 1963. Participants in the Conference will come from the fields of university counselling and health services, university administrative staffs concerned with student mental health problems, and from appropriate national organizations. One of the principal purposes of the Conference will be to stimulate the gathering of data on student mental health problems in Canada.

University presidents and national participating organizations will be asked to name Conference participants in January 1963, at which time the details of the Conference programme will be announced.

CLARKE HORACE BARNACLE, F.A.C.P.—Born in St. Paul, Minn., January 15, 1906; died in Denver, Colorado, October 4, 1962. B.S. from University of Minnesota, 1928.

M.B. in 1929, M.D., 1930, from the University of Minnesota Medical School. Dr. Barnacle had a brilliant past and teaching career, especially teaching at University of Colorado Medical School. He is survived by his wife, Martha, a son, John, pre-med student at Northwestern, two daughters, Nancy and Mary.

CHANGE-OVER AT SAINT ELIZABETHS.—

With the retirement of Dr. Winfred Overholser ends a quarter century during which he conducted that great institution with enviable credit and distinction. He came to Washington from Massachusetts where after many years in the state hospital service he became Commissioner of Mental Diseases. He was appointed Professor of Psychiatry at the George Washington University School of Medicine at the same time that he became superintendent of Saint Elizabeths Hospital.

Dr. Overholser was President of the American Psychiatric Association for the year 1947-1948. He has received numerous honors both at home and abroad, including appointment as the first Isaac Ray Lecturer in 1952 with publication of the volume *The Psychiatrist and the Law* in the following year.

The George Washington University bestowed upon him the honorary degree of Doctor of Laws.

The new superintendent, Dr. Dale C. Cameron, appointed by Secretary Celebrezze of the Department of Health, Education and Welfare, is no stranger to Saint Elizabeths Hospital. He has had the advantage of a long career in the Public Health Service entailing a wide variety of work in various parts of the country; and for a period was Commissioner of Mental Health in Minnesota. During the last two years of Dr. Overholser's superintendency Dr. Cameron served as Assistant Superintendent of Saint Elizabeths Hospital.

INTERNATIONAL CONFERENCE ON THE BIOLOGICAL TREATMENT OF MENTAL ILLNESS.—

The Conference was sponsored by the Manfred Sakel Foundation, and held at the New York Academy of Medicine from Oct. 31 to Nov. 3, 1962. Max Rinkel, Boston,

Mass., arranged the conference and was its Chairman; Harold E. Himwich, Galesburg, Ill., the Co-Chairman. Jack R. Ewalt, as President Elect of the American Psychiatric Association, and D. Ewen Cameron, as President of the World Psychiatric Association, extended greetings. Outstanding scientists from 22 nations participated, including a delegation from the USSR. Fifty-two papers were read; they covered a wide range of methodological and theoretical problems, and gave a comprehensive review of the exciting biological research now going on at an accelerated pace. Space does not permit the discussion of all individual papers, important and interesting as they are. Only some selected papers will be reported here.

K. Bowman stressed the dangers to psychiatry brought about by the current biological progress. He observed: "When clear-cut organic factors are found to be the cause of a particular mental disease . . . a large percentage of psychiatrists lose all interest in the disorder and often wish to turn it over to a specialist in some other field of medicine." "It seems, therefore, basic to the future of psychiatry that we do not lose the fundamental idea that *a psychiatrist is a doctor of medicine* (italics, the reporter) who specializes in the particular field of mental disorders. . ." H. Hoff (Vienna) more optimistically stated: Because the great masters of psychiatry were convinced of that fact, "they were able to change the course of psychiatry: Wagner-Jauregg by the discovery of the malaria treatment, Sakel by the discovery of the insulin shock treatment." M. Roth (Newcastle upon Tyne, England), in a theoretically important paper, considered the differential effects of biological treatments in their bearing on developing the classification of mental disease.

H. W. Magoun reviewed recent results of research on "neural plasticity" and "memory." He reported that the hippocampus and entorhinal cortex of the temporal lobe play an exceedingly important role in processing novel information into storage, as well as in mechanisms underlying early consolidation and recall. Furthermore, current advances in genetic biochemistry point to the importance of DNA (deoxyribonu-

cleic acid) and RNA (ribonucleic acid) for information-coding, specification and replication. Magoun predicted that further developments which relate memory function to the nucleic acid metabolism of nerve cells will lead to a better understanding of the normal function of the brain, and to a more effective therapy when it is impaired. A. S. Marrazzi discussed essentially cerebral homeostasis as a basis of biological treatment of mental illness. Normal interrelation of normal equilibria at the various levels constitutes homeostasis or successful adaptation which is reflected in mental health. Heterostasis is the failure of adaptation. The object of therapy is the restoration of homeostasis. D. G. Friend indicated the important role of catecholamines in the activity of the CNS. He reported that carefully controlled studies in man have shown that the administration of catecholamine precursors, before and after monoamine oxidase inhibition, is not capable of arousing patients from a depressed state. He theorized that either the catecholamines in man do not have a specific arousing effect or that the catecholamine precursor does not cross the blood-brain barrier in adequate amounts. These findings differ from those that have been observed in animal experimentation. E. Costa reported on the storage depots of norepinephrine and serotonin as neurochemical transducers. H. E. Himwich established statistically a correlation between degrees of psychotic behavior in schizophrenics and their urinary excretion of tryptamine, indole-3-acetic acid and 5-hydroxytryptamine. Williamina Himwich, in excellent motion pictures, demonstrated the behavior of dogs resulting from the administration of 5-hydroxytryptophan and of serotonin antagonists. M. Altschule reported a definite increase of aminochromes in the blood of most schizophrenic patients and a probable causal relationship between the urinary excretion of aminochromes and clinical symptoms. He observed that pineal extracts caused amelioration of hyperaminochromia. G. N. Thompson proposed the theory that irritative lesions in the frontal and thalamic tracts play a very important part in the causation of sociopathic behavior. The determining factor, however, is the location of the lesion. For therapy, specific

frontohypothalamic suppressing agents are needed.

Papers, presented by independent groups in the USA (J. Bergen, H. Hoagland of the Worcester group and R. Pennell of the Protein Foundation; J. S. Gottlieb, Wayne University; R. G. Heath, Tulane University) and Sweden (G. Ehrensward, S. Martens), seemed to strengthen the view that a biochemical abnormality exists in the blood of schizophrenics. The groups used different assay methods, yet the results of each showed that the abnormal substance is associated with either the α_2 or β -globulins. It was suggested that the active moiety is a small molecule attached to a carrier protein which has not yet been identified but is described as an extremely unstable substance. None of the tests for the possible psychotoxic substance were claimed to be specific for schizophrenia, nor was it established that this substance is causally related to the disease or resulting from it. S. Bogoch reported on glycoproteins in the cerebrospinal fluid of schizophrenics. Linus Pauling entered the discussion and pointed out that in his opinion "most mental diseases are molecular diseases, the result of a biochemical abnormality in the human body, a genetic damage."

F. A. Freyhan analyzed the clinical and theoretical basis for establishing a rationale for the biological treatment of psychiatric disorders. Criticizing nosologic sterility, he stressed the need for a psychopathological orientation to provide a valid, therapeutic frame of reference. J. Elkes considered "nodal areas" in psychopharmacology, with special emphasis on the study of symbolic processes in man. H. Ehrhardt (Marburg) contrasted "hospital psychiatry" with "university psychiatry" and explained why, in Germany, drug treatment prevails over all other somatic treatments in state-supported mental hospitals. Public criticism and fear of a malpractice suit have led to the virtual abandonment of insulin coma and ECT; only university hospitals, enjoying greater prestige, are able to base treatment on psychiatric considerations alone. M. Greenblatt reported that in depressions EST produced a two-thirds improvement in contrast to 50% or less achieved by antidepressant drugs. These findings are based

on a carefully designed control study in three psychiatric hospitals. Lauretta Bender reported that daily doses of LSD-25 and UML-491 proved effective in making schizophrenic children less anxious, less autistic and more spontaneous in social relations. A. Weissman delivered a cogent critical analysis of operant conditioning techniques as investigative instruments in behavioral pharmacology. H. Hippus (West Berlin), discussing permanent pharmacotherapy of schizophrenia, stated that the prognosis of schizophrenic patients can be improved by long-term treatment with phenothiazines on an ambulatory basis, and J. O. Cole examined the problem of whether there are real clinical differences between active phenothiazines. H. Akimoto (Tokyo) challenged the designation of imipramine as an antidepressant. He found that it has specific effects on affective disorders regardless of the prevailing clinical manifestations.

Biological therapies and critical evaluations of hospital and village community care, open hospital care, and cultural and social variables were discussed by leading psychiatrists from Nigeria, Brazil, Peru, India, Ceylon, Thailand, and Russia. I. Senanayake reported that of 100,000 patients with mental illness in Ceylon, only 5,000, in government hospitals, receive modern treatment; the remaining 95,000 patients are treated by invocation, charms and rituals. In Thailand (P. Ratanakorn reported), the biological treatment is about the same as in the USA and some European countries.

From a paper presented by the Russian delegate, G. Y. Avrutski (Moscow), it clearly emerged that the treatment of mental illness in the USSR follows the concept of Pavlov's theories on conditioned reflexes, and L. Cammer reported that low-dose insulin treatment seems to modify the psychophysiological conditioning of anxiety according to Pavlovian laws.

Opinions as to ICT ranged from its acceptance (M. Remy, Switzerland: "Insulin treatment has kept its entire value") to its rejection (A. Parkash, Punjab, and N. S. Vahia, Bombay, India: "Insulin treatment was discontinued"). I. F. Bennett conducted a survey of ICT and found that in the USA only 63 clinics still use it today, while about 214 hospitals had active insulin clinics in the late 1950's. Modern techniques of ICT were demonstrated by H. P. Laqueur and K. Dussik at the insulin unit of the Creedmoor State Hospital, in New York.

A banquet marked the closing of this most successful conference. It was held in honor of the participating scientists and attended by members of the Diplomatic Corps of the various nations. The main speaker was Nobel Prize Laureate, Linus Pauling, who gave an enthusiastically received scholarly lecture on mental illness as a molecular disease. He stressed particularly the importance of more extended biological research in psychiatry.

Heinrich Klüver,
University of Chicago.

WIT

Wit consists in knowing the resemblance of things which differ, and the difference of things which are alike.

—MADAME DE STAEL

BOOK REVIEWS

MENTAL PATIENTS IN TRANSITION. Ed. by *Milton Greenblatt, M.D., Daniel J. Levinson, Ph.D., and Gerald L. Klerman, M.D.* (Springfield, Ill.: Charles C Thomas, 1961, pp. 378.)

There is a welcome increase in the emphasis on 1. Intensive treatment and early return to the community of recently hospitalized mental patients, and 2. The rehabilitation and discharge of patients who have been hospitalized for many months or years. The problems of the chronically ill still present the greatest challenges to mental hospitals and the communities they serve.

Two major factors determine the feasibility of each patient's discharge from the hospital, i.e., the degree to which he has recovered from his illness, and the nature of the family, community, and economic situation to which he will return. The hospital staff is thus concerned not alone with its patient, but the patient-community interaction, in short, "the mental patient in transition."

To survey current activities and trends in this field, the editors, in March 1960, organized an interdisciplinary meeting of professional persons working on problems of patient transition. This book contains the edited proceedings of that meeting, and consists of twenty-five articles, two special presentations, and sixteen introductory comments and discussions by fifty-nine authors.

The material is, in general, of high quality, but as in most multiple-author books, the reader will note some unevenness in clarity of presentation and content of papers. It is well organized in five sections dealing with 1. Problems of discharge planning, 2. Facilities used in transition, 3. Community influences, 4. Family influences, and 5. The role of pharmacotherapeutic agents. Warren S. McCulloch's presentation is delightfully written.

This book should be of interest to all professional workers involved in service to mental patients.

DALE C. CAMERON, M.D.,
Washington, D. C.

PSYCHOPATHEN. Daseinsanalytische Untersuchungen zur Struktur und Verlaufsgestalt von Psychopathien. By *Heinz Häfner.* (Berlin-Göttingen-Heidelberg: Springer-Verlag, 1961, pp. 230.)

On the background of Heidegger's ontology,

the author is using Binswanger's Daseinsanalyse and Husserl's phenomenology with mild modifications to forge for himself a tool of Daseinshermeneutik (interpretation of human existence). With this tool he undertakes to examine, to describe, and to interpret the structure and the course of psychopathies. He presents *in extenso* the life histories of a psychopathic swindler, of a psychopathic hypochondriac and of a poikilothymic psychopath. He then constructs an outline of "psychopathic existential constitution" (psychopathische Daseinsverfassung) which he is eager to illuminate from several viewpoints.

The earnestness, the endeavor, and the achievement of the author cannot but be commended. He offers a variety of points which are likely to be useful in future work on the "psychopaths."

Emphasizing the relevance of "facticity" (Factizität) he reports a number of observations and interpretations which were not unknown heretofore. The author, a promising psychiatrist of the younger generation, has adapted his style to wordage à la Binswanger who, incidentally, wrote a preface to this monograph. This means with all due respect to both of them that much of what is being discussed could have been expressed more simply.

It is expected that in years to come existential concepts will be integrated into psychiatry and psychopathology. The attempt to make existential analysis the cover-all for our discipline appears theoretically unsound and practically unfeasible.

EUGEN KAHN, M.D.,
Houston, Texas.

WESTERN PSYCHOTHERAPY AND HINDU SADHANA. By *Hans Jacobs.* (New York: International University Press, 1961, pp. 231. \$6.75.)

This is a carefully written and thoughtful book. It expresses the findings in India of an experienced western psychiatrist as he interprets them, together with his personal philosophies. This book will be of interest to every one in psychiatry and allied fields who has an interest in the Indian doctrines and schools of thought, especially Yoga. Dr. Jacobs has lived and worked in a number of countries. This volume represents a distillate of his accumulated wisdom. The author describes his work as a "contribution to comparative studies

in psychology and metaphysics."

This is not a light nor lightly read exposition. One must attend carefully to grasp the subtleties of Hindu views of life as the author seeks to make them clear to us in English. Following a short preface, the data are presented in three major sections: part I concerns the background of contemporary thought as interpreted briefly by Dr. Jacobs; part II, with four chapters, is a general exposition of Freudian and Jungian principles and the pathways taken in India; the final part is a general estimation with six chapters, including ones on Yoga and the West, Modern Psychiatry, and The Religious Problem with Jung. There are frequent footnotes with references to a wide selection of Western and Indian sources. Illustrations of interest are included from the author's clinical experiences with the treatment of patients. Some of their art work is reproduced. This book will help widen our acquaintance with Indian philosophy and aid in undertaking comparisons and contrasts with certain of our western dynamic schools of thought.

HENRY P. LAUGHLIN, M.D.,
Chevy Chase, Md.

CONTEMPORARY EUROPEAN PSYCHIATRY. Edited by *Leopold Bellak, M.D.* (New York: Grove Press; London: Evergreen Books, 1962, pp. 372, incl. index. \$7.50. Evergreen paperback, 1961. \$3.95.)

Dr. Bellak tells us in his Introduction that to date he has spent about half of his life in Europe and half in the United States. On the basis of his "double life" therefore he is in a position to offer some personal views on the differences and resemblances of European and American psychiatry. This he does in a discriminating and useful fashion in his Introduction. Here too he gives brief sketches of those invited to represent the several countries: France, Pierre Pichot; Germany and Austria, Hans Hoff and O. H. Arnold; Great Britain, Sir Aubrey Lewis; Italy, Ugo Cerletti; Scandinavia, Gabriel Langfeldt; The Soviet Union, V. A. Gilyarovsky; Switzerland, Gaetano Bernedetti and Christian Müller.

In European psychiatry as a whole, as compared with American, Bellak states, "There is undoubtedly more of a descriptive, genetically-organically oriented trend . . . Further, except for a few psychoanalysts, the practice of psychiatry is more related to institutions than to private practice; it is more concerned with psychoses than neuroses; its clinical descriptions are richer and its classifications more complex . . . Psychiatric considerations enter

less into the general field of activities, into other branches of medicine, and, in particular, into public concern with raising children . . ."

Special attention may profitably be given to developments in Scandinavia where, as Bellak remarks, "Meticulous research along genetic lines runs parallel to a predominantly 'organic' psychiatric orientation which stems mostly from classical German psychiatry. Yet here one sees some of the most advanced concepts of social psychiatry." It must be remembered that Langfeldt who speaks for Scandinavia is an enlightened humanist who fights superstition and popular delusions of all kinds.

In Britain, generally speaking, "psychiatric life appears to move in steadfast, sober paths." Sir Aubrey Lewis, reporting for England, remarks that the National Health Act "which turned Great Britain into a welfare state, brought psychiatry firmly into the general household of medicine." That's one thing to credit the N.H.S. with.

Bellak seems to be of two minds about European psychiatry. "At its worst," he says, it "reminds one of American psychiatry of some decades ago," and he adds disparagingly, "or of some of its non-dynamic psychiatry today." But overleaf he softens the slight. "At its best, European psychiatry has a vitality, a creativity, and a progressiveness unmatched in the United States."

There is considerable preoccupation in continental Europe, *i.e.*, in Germany and Switzerland especially, with the tendentious negativism of existentialism. Indeed the report from Switzerland, after taking account of the great debt to Forel, Bleuler and Jung, proceeds to "the principal trends" of the contemporary scene and opens with two pages of existentialist doctrine. This reminds us of something Aubrey Lewis said in his chapter on Great Britain (p. 146): "The countrymen of Locke and Hume are reluctant to embrace the latest certainties of the enthusiast or the cloudy abstractions of the metaphysician. Existential analysis, as described by some European psychopathologists and therapists, has found no home here." And Sir Aubrey adds that "this empirical and skeptical attitude . . . may have hindered the acceptance of psychoanalysis as a system, and fostered a slight bias toward the study of somatic rather than mental dynamics as a gateway to the knowledge of human behaviour." In England, however, psychoanalysis is strongly represented, although divided "by the contest between those who accept Melanie Klein's views and those, like Edward Glover and Anna Freud, who maintain a more conservative or orthodox stand-

point." Aubrey Lewis outlines briefly these differences and neatly concludes, "It is not for the outsider to attempt to judge this controversy."

The reporter for Russia pays constant tribute to the great Pavlov. "Today, in general, Soviet psychiatry is being reorganized on the basis of Pavlov's teachings." Also he credits Pavlov with correcting some of the "erroneous views" of pre-revolutionary psychiatrists who "overestimated the role of heredity and constitution." An important contribution of Soviet psychiatry, he states, is "a consistent materialist theory of the pathogenesis of mental illness." As is well known psychoanalysis is not popular in Russia; and leucotomies "were banned by special order of the Minister of Public Health."

Swiss psychiatry, apparently contrasting somewhat with practice in Britain, finds "that the psychotherapists' contribution greatly exceeds the resources of a rationally mastered somatic treatment technique." It is interesting to find that "in Switzerland the term 'clinical psychologist,' as it is used in the United States, does not exist." And "the subject of psychology is classified under philosophy in Swiss universities."

In current French psychiatry Pichot speaks of increased interest in the neuroses rather than in the psychoses, in the affective and unconscious rather than in the intellectual and conscious aspects, in the dynamic rather than in the static features. These trends, however, Pichot adds, "have been established only gradually. The main currents of the preceding period . . . still constitute the basis of modern psychiatry."

In France as in Britain the psychoanalytic movement underwent a schism. There are two societies, each conducting its own training courses, unassociated with the university curriculum.

The most important psychiatric center in France is the Sainte-Anne Hospital, presided over by Professor Jean Delay of the University of Paris. Delay's work has had a paramount influence in French psychopathology and "achieves a harmonious synthesis of the diverse influences."

Cerletti, reporting for Italy that gave us electroshock therapy (Cerletti 1938), speaks of the traditional organic trend in Italian psychiatry. "Such an orientation could not favor the development in Italy of the dynamic psychopathology formulated by Freud and his pupils . . ." However to keep an open door Cerletti, against opposition, included lectures on psychoanalytic theory in his teaching. He found that "the Italian public did not respond

to the new concepts with the strong interest manifested by the Anglo-Saxons." A psychoanalytic society of some 20 members has been formed.

Cerletti considers that research in the biochemistry of the nervous system "will ultimately prove most fruitful."

Hoff and Arnold writing of German psychiatry state that "one can find only a few points of contact among the various schools of thought. Yet, the degree of difference between these theoretical trends is not nearly as great as that which exists in American psychiatry."

In a long chapter the authors try to take account of the diverse trends in psychiatric thought, and not only in Germany. They conclude "that psychiatry is in a state of crisis," although they are hopeful that it is only transitory. They look more to Freud for help than some of the other reporters do. "The theories of Freud, with all the inconsistencies which adhere to them, have accomplished more to acquaint man with his brother than any other event of the last century."

Langfeldt (Scandinavia) has a good word to say for descriptive psychiatry (an expression that an occasional American writer unfortunately uses as a term of derogation, apparently unmindful of the fact that all science begins with observation and description of what is observed, and that if only observation and description could be *complete*—as of course they never are—full understanding would follow). Speaking of schizophrenia studies in Norway, Langfeldt says, "As in other disorders, the purely descriptive method has been retained with regard to the diagnosis of schizophrenia. Thus, no one has attempted to conduct a psychological investigation of the psychogenetic factors of this disease, or of its psychotherapy. Here too, the main contributions to research have been in the pathophysiological field." Langfeldt is most outspoken in criticism of psychoanalytic methods, and especially of their prevalence in the United States; and he adds, "one cannot help but be discouraged by the ignorance of many American psychiatrists with regard to the results of research in heredity, constitution, and biology, and in particular, with their almost complete disregard of ordinary descriptive diagnosis and prognosis." There has been a consistent historical development of psychiatry in the Scandinavian countries, "with its firm attachment to hereditary, constitutional, and biological factors . . ."

The author comments that "psychoanalysts are never appointed to permanent positions at

any of the Scandinavian university clinics or mental hospitals."

One wonders if in any other field of medicine or other science so many divisive trends develop as in psychiatry. Such division is of course in inverse proportion to the amount of solid knowledge on which the discipline is based. It is comforting to read the words of Sir Aubrey Lewis about the atmosphere in which for the most part British psychiatrists pursue their labors: "Although psychiatry in Great Britain is not homogeneous, either in theory or in practice, it is not sharply divided into recognizable schools, centered on prominent men with distinctive views. The climate of opinion is temperate; the intellectual winds are seldom sharp and nipping. As in other branches of medicine, assertive therapeutic claims are met with tacit distrust and, on rare occasions, public puncture. Theorizing is expected to take forms that can be tested experimentally (unless it follows well-trodden paths, such as those of psychoanalysis). Polemics are rare; but criticism is nonetheless steady and palpable."

C.B.F.

DIE EIGENART DER KINDLICHEN HIRNTÄTIGKEIT
By *Albrecht Peiper*. (Leipzig: Georg Thieme, 1961, pp. 749. D.M.71.70.)

This admirable book, devoted to the specific nature of cerebral activity in the human infant, covers the field fairly exhaustively. Professor Peiper takes the view that consciousness and higher intellectual activities have their origins in sensory perception. If sensations are the elementary and uninterpreted items of experience, perceptions are the meanings with which those items are invested. Professor Peiper is concerned, in this volume, to trace the development of human activity as a consequence of the growth of the child's ability to perceive. He, therefore, considers the development of sensory activity, of facial expression, posture and motion, locomotion, movements, clinically important reflexes, the neurology of respiration, the neurology of food intake, sleep and sleep-like conditions, conditioned reflexes, neurological characteristics of certain developmental stages, evolution and breakdown of cerebral activity, and finally, the child and its environment.

Professor Peiper has many wise things to say in this well-illustrated and well-documented volume. It should be found of the greatest value by all students of human behavioral development.

ASHLEY MONTAGU, PH.D.,
Cherry Hill, N. J.

DISTURBIOS PSIQUIÁTRICOS DA CRIANÇA. By *Haim Grünsun*. (São Paulo: Fundo Editorial Prociens, 1961, pp. 576.)

This textbook by a Brazilian professor of child psychiatry is the first in a series of 3 volumes (the second will be devoted to behaviour disturbances, the third to psychosomatic disturbances in children). The present volume is a guide to the practical examination, diagnosis and treatment in child psychiatry. The first chapter teaches how to extract the life history of the child. The second describes the function of each member of a child psychiatric team. Then comes a detailed outline of the clinical and psychological examination. We note an emphasis on the neurological examination and on the developmental and motor tests. Four main clinical pictures are discussed in detail: oligophrenia, epilepsy, child psychoses (schizophrenic and manic-depressive) and delinquency. In the concluding chapters the author distinguishes the medication, therapeutic education and institutional treatment. In the therapeutic education the emphasis is put on habit formation: teaching the child to sleep, eat, dress himself properly, etc., and on graduated exercises for the development of concentration and other mental functions.

Grünsun's textbook has eminent didactic qualities. It gives precise definitions, lucid explanations, instructive case histories and clear-cut classifications which follow the Kraepelinian nosology. The medical philosophy is based on neurophysiology and classical pedagogics; no mention is made of psychoanalysis. Curiously enough, although the outlook is decidedly European, the bibliography draws heavily on English and American authors. The publishers should be complimented for the beautiful paper and printing of both text and illustrations.

H. ELLENBERGER, M.D.,
Montreal, Canada.

PSYCHOPATHOLOGY OF AGING. Edited by *Paul H. Hoch, M.D.*, and *Joseph Zubin, Ph.D.* (New York and London: Grune & Stratton, 1961, pp. 306. \$9.75.)

This book contains papers presented at the 1960 meeting of the American Psychopathological Association. It deals with mental illness in the aged, and is divided into four parts.

Part I deals with Epidemiology. There is a fascinating historical review. A statistical review of cerebrovascular disease reveals mainly that reporting is inconsistent. The most solid epidemiological contribution deals with trends in hospitalization and patterns of care

in the mentally ill aged. This exhaustive survey contrasts the recent plateau in first hospital admissions for mental illness in the aged with the steadily increasing expectation of such illness in our population. Interesting speculations are made to account for this variance.

Part II, Psychology, has three reviews of quantitative experimental studies of certain factors in aging. For example, one study attempts to measure adaptability in the aged. In Chapter 8, Dr. Arnhoff decries traditional negativism in psychological studies of the aged. Dr. Wechsler discusses the "G" factor in intelligence. The "G" factor is defined as the capacity to perceive relevant relationships. He suggests that the "G" factor declines more than memory with aging, leaving memory, poor though it may be, the relative mainstay of the aged.

Part III deals with Psychophysiology and Genetics. Three psychophysiological papers are interesting, but inconclusive. The genetic contribution by Dr. Kallmann is aimed largely at demonstrating the genetic basis for longevity in the comparison of one egg and two egg twins.

Part IV deals with Management Problems. The current trends in the State of New York are described. There is a survey of the various agencies and institutions in the State serving the psychiatrically ill aged, and an optimistic report, also from New York State, of an intensive treatment geriatric ward in a State hospital. A study of the technique of outpatient treatment of the depressed elderly patient is reported. The last chapter relates pre-admission isolation to poor adjustment in homes for the aged.

In summary, this published collection of papers gives a creditable review of the problem of mental illness in the aged. It is strongest in its global approach and should be of special interest to administrators or others concerned with long range planning in this area.

Louisville, Ky.

CONDITIONED REFLEX THERAPY. By Andrew Salter. (New York: Capricorn Books, 1961, pp. x, 359. \$1.75.)

This is a reprint in paper back of Salter's cloth bound book which appeared in 1949. It is written by a practicing psychologist on Park Avenue, the author of an excellent book on hypnosis, to expound his methods of treatment of psychoneuroses, anxieties, stuttering, drug addiction, smoking, etc. The methods he uses are briefly common sense and the sub-

stitution of activity for indecision and the various forms of inhibition which beset the midcentury civilized man. The author attributes his successes in alleviating his patients' ills to Pavlov's conditional reflex principles. The book is replete with case histories. On the authority of the author he has been remarkably successful in curing his patients in contrast to prolonged analytical theory.

At the present time there are two main schools of thought which underlie psychopathology—those of Freud and of Pavlov. American psychiatry has been eclectic, Freudian, or to a very limited degree, physiological and Pavlovian. The proponents of the theories emanating from the two chief leaders have in general been violently opposed. The present volume is an espousal of Pavlovian principles and a renunciation of Freudian. Although this book makes no pretence of a scientific evaluation of Pavlovian theories, it nevertheless adduces examples of a simplified psychotherapy which the writer believes is based on Pavlovian concepts of excitation and inhibition. One successful internist who treats psychiatric patients (Parmalee) tells me that he recommends this book to patients, many of whom definitely benefit by following its rules. The book is a practical rather than a theoretical discussion of Pavlovian principles.

The historical importance of the book is that it was a pioneer in the USA of the application of Pavlovian theory in psychotherapy at a time when it was dangerous—or at least unpopular—to accredit the 1903 Russian Nobel Prize winner. Until Wolpe's recent book on the use of the conditional reflex in psychiatry, Salter's *Conditional Reflex Theory* has been almost the only book in English on the subject.

W. HORSLEY GANTT, M.D.,
Baltimore, Md.

PREVENTION OF MENTAL DISORDERS IN CHILDREN—INITIAL EXPLORATIONS. Ed. by Gerald Caplan, M.D. (New York: Basic Books, 1961, pp. 425. \$8.50.)

This book contains 16 original papers on the main theme: the prevention of mental disorders of childhood. They represent the preparatory material for the conference of the International Association of Child Psychiatry and allied disciplines held in August 1962, in Holland.

Dr. Caplan, who has brought this material together, has arbitrarily divided these 16 papers into four groupings: four papers deal with the organic factors that have a noxious effect on the child's mental health; the next four

papers deal with "psychosocial implications of interpersonal relationships within the family"; the next group of five papers are on the "psychosocial implications of situational and maturational crises in the development of personality in children"; and finally, three papers deal with the "socio-psychologic implications of the school setting for promoting of mental health."

While each of the papers focus on one of the above areas, it is clear that all of them touch on all the areas: the organic, the psychological, and the socio-economic.

The book has a great deal of rich material and will be most useful in the various fields in which child psychiatrists and allied disciplines function. The clear theme of the material deals with the broader life of children and does not focus on the therapeutic work on the individual child and his family. Dr. Caplan has written an introductory chapter giving a condensed summary of each of the papers.

FREDERICK H. ALLEN, M.D.,
Philadelphia, Pa.

HANDBUCH DER NEUROSENLEHRE UND PSYCHOTHERAPIE. VOL. V. Ed. by Victor E. Frankl, Victor E. Freiherr v. Gebattel, and J. H. Schultz. (Munich, Germany: Urban & Schwarzenberg, 1961-1962, parts (*Lieferungen*) 21 (pp. 135. DM 17,50); 22 (pp. 228. DM 28,75); 23 (pp. 259. DM 32,50); and 24 (pp. 243. DM 32,50).

The last volume of the *Handbuch* is now completed. The previous ones have already been reviewed in this Journal. As with the previous parts, each new section seems to be devoted to specific topics, except for *Lieferung* 21, which deals partly with "intrapsychiatric *Grenzgebiete* (allied fields)," such as shock therapy, psycho-surgery, pathology of the hypothalamus, and problems of child neuroses originating from or associated with encephalopathy, psychopathy, waywardness and delinquency, and "constitutional" problems. The last three *Lieferungen* each have their own theme. No. 22 deals with medical "specialties" in relation to psychosomatic illnesses (although this reviewer did not encounter the term "psychosomatic" in any of the authors). An excellent contribution by Guenther Clauser on internal medicine gives the reader an insight into German methods of classifying etiologies and treating emotional components of organic illness by means of case histories. Clauser bases many of his practises on Kretschmer, as probably do most of his colleagues in Germany, i.e., on the adynamic method without psychotherapy, as

we understand it. J. Lassner writes about anesthesiology, theorizing on "preoperative" and "postoperative" psychotherapy. Many of his theses are well taken, and well-known in this country. L. Kreuz and O. Boos add to Lassner's contribution by writing about psychotherapy in surgery "including orthopedics." Hans-Joachim Prill presents two articles on gynecology and obstetrics, partly raising similar questions as Lassner, Kreuz and Boos, with respect to surgical problems; in addition, frigidity, sterility, impotence, climacteric and adnexal disorders are discussed. Hellmuth Kleinsorge discusses urology, Otto-Suël Hinz ophthalmology, Siegfried Borelli dermatology, G. Joppich pediatrics, and Heinrich Hanselmann *Heilpaedagogik* (psychological and sociological concepts of the personality the development of which is distorted or arrested). *Heilpaedagogik* has become rather "popular" in Germany, and is often taught and practised by non-medical, although well-trained, practitioners, who base their theories on Freudian concepts. All this is found in *Lieferung* 22.

Lieferung 23 and 24 are, strictly speaking, devoted to non-medical *Grenzgebiete* (allied disciplines), such as forensics, criminology, education, anthropology, and the "evaluation" of various theories of the neuroses. No. 24 is devoted only to theology: one Catholic, two Protestant, and one Jewish point of view are represented. The editors had intended to complement these with a "discussion," but cancelled their intention when the Jewish representative, Norman Salit (New York), died before finishing his contribution. The editors felt, however, that if they had taken a "stand," they would have disagreed with Salit, as would the reviewer. (While Rabbi Salit undoubtedly represents his religious point of view well and is ably competent speaking about Judaism, the fact that he seems to consider Freud an "enemy of religion" may show him to be in error, particularly when he believes that Frankl and his "logotherapy" are now the reincarnation of "traditional Jewish concepts.")

The subjects and author indexes, attached to No. 24, number over 70 pages, and will make it easy for the reader to refer to all five volumes quickly. Briefly to evaluate the individual contributions is difficult, since the contributions are different in conception, content, and scholarship. The publisher can be congratulated for a minimum of printing errors particularly since much of the source material is multi-lingual. Some contributions contain some of the finest writing this reviewer has ever seen; other contributions are so marked with aggression against certain individuals or

schools of thought that they could just as well have been omitted; often the writings overlap, which reflects the divided editorship of the *Handbuch* (in making inquiries of all three editors, this reviewer learned that one editor did not know of the others' functions and even disclaimed knowledge of the editorship of the others). Still, with all their striving for *Gründlichkeit* (thoroughness) and universality, the editors have achieved a monumental enterprise, probably comparable with its noble American counterpart, *The American Handbook of Psychiatry*.

Los Angeles, Calif.

THE ANNUAL OF CZECHOSLOVAK MEDICAL LITERATURE 1959. *National Medical Library.* (Prague: State Health Publishing House, 1961, pp. 732.)

This 732-page compilation, under the direction of Dr. Joseph Navrátil of the National Library in Prague, includes author and subject index (80 pages), and covers the whole range of medicine, including reports on books and periodicals in brief form, and notices of contributions of each author published abroad. All specialties are covered, including neurology, psychiatry, sciences basic to medicine, also public health, veterinary medicine, and medical history.

F. V.

ADOLESCENTS: PSYCHOANALYTIC APPROACH TO PROBLEMS AND THERAPY. Edited by *Sandor Lorand, M.D., and Henry I. Schneer, M.D.* (New York: Paul B. Hoeber, 1961, pp. 368. \$8.50.)

This volume contains the contributions of 19 authors who report on their clinical experience with a wide variety of behavior problems developing in adolescence. The material was drawn largely from lectures given by the authors at the State University of New York and sponsored by the Division of Child Psychiatry.

The title accurately reveals the emphasis in all the articles. Each author is a practicing psychoanalyst. A partial list of the titles reveals the wide scope and covers most of the deviant behavior problems arising in both boy and girl as each seeks to solve the dilemmas of this period.

Each article contains a detailed case study

from which principles are discussed with particular emphasis on the therapeutic method employed. These case studies provide the practical application of the tenets of psychoanalysis and all adhere closely to classical theories of this school. Most of the articles contain references to the literature and an adequate index is provided.

This book will prove valuable to those who view this period from the psychoanalytic point of view. For those who view and deal with the adolescent from a different point of view, the book provides much provocative material.

FREDERICK H. ALLEN, M.D.,
Philadelphia, Pa.

HOW TO BE AN ADOLESCENT—AND SURVIVE. By *John L. Schimel, M.D.* (New York: Richards Rosen Press, 1961, pp. 158. \$2.95.)

When a Juvenile Court judge recently asked an adolescent why he had gotten into trouble the boy replied: "There will probably be a thermonuclear war in the near future and I don't expect to survive." The author of this book has no answer for this most important problem of survival for our youth, but he gives in this serious and readable book advice about how to cope with the world in which they find themselves. He may be right when he seems to imply that it will be a pretty regimented one. Consequently he instructs his adolescent readers in areas he considers most important: how to be a good interviewee—that is how to handle oneself best in an interview so as to get admitted to a college, a graduate school or a job; how to acquire "learnable skills" for the mastery of encounters with teachers, employers, *et al.*; how to face the various forms of taking examinations and tests; how to "improve communications."

In the epilogue the author addresses his young readers: "You will be expected to have mastered certain skills in dealing with your fellow man. Your career, from first to last, will reflect the extent to which you have acquired these skills." I am afraid the bright adolescent will gather from this presentation that personal relations are more important than competence, communication more important than content, and that success depends not on what you know but on handling those whom you know.

THE CRITICS OF PSYCHIATRY: A REVIEW OF CONTEMPORARY CRITICAL ATTITUDES¹

MILTON H. MILLER, M.D., AND SEYMOUR L. HALLECK, M.D.²

The psychiatrist has probably both the most prestige and is at the same time the most highly criticized person on the American professional scene. Before entering the field, he may have heard psychiatry spoken of as a quasi-medical subject, and his knowledge is often derived in the beginning from novels, films, newspapers or other sources. During medical training and residency, he learns to tolerate the ambivalence of other medical colleagues towards his work and learns as well how to express his own ideas in such a way as to protect himself from the onslaughts of more vigorous critics. As he begins his practice of psychiatry, he can perhaps rightfully say, "Who knows more of criticism than I? I even invite and encourage my patients to express their resentments and disagreements to me directly."

Thus in a way, the individual trainee and young psychiatrist recapitulates personally the exposure to criticism which has been characteristic in the history of psychiatry from its earliest days. Many of the complaints which the student hears prove fatuous in the light of his own growing clinical experience, and he is likely to see many critics as being crankish, overdetermined in their ideas, and generally motivated by other than scientific values. He may early develop a preoccupation with the motivation of his critics rather than with the contents of their criticisms and this attitude is reinforced by his daily contact with patients in which intellectual attacks upon him often have roots in disturbing personal conflicts. This knowledge is helpful to him in his work with patients, but at the same time it may make him somewhat less than fully

open to examination of his basic postulates and ideas.

It has seemed to the authors that individually and as a profession, we develop at times the habit of lumping all criticisms and all critics together, the better to disregard them all. It is certainly comforting to find apparently the same motivations behind the devastating critique of a scholar examining our basic assumptions as we may find in the over-ideational attacks of an obsessive or angry patient. Such apparent discovery, by preserving our comfort for the moment, cannot provide a favorable atmosphere for the continued growth and development of our profession.

A review of the critical literature of contemporary scientists, fellow physicians, fellow psychiatrists will leave the uncommitted reader with the strong feeling that these works are not to be taken lightly. Contemporary criticism focuses upon all aspects of psychiatry and none of our postulates, conceptions, or empirically derived practices are immune to attack. Neither for that matter, is any subdivision of psychiatry immune; neither the psychoanalysts nor the biological psychiatrists, nor those in social psychiatric fields can claim freedom from lengthy critique. Many psychiatrists assume that psychiatric practice as we know it is here to stay, that it is essentially solidly based, that its various hypotheses are either clearly proved or "are the best we have," that our diagnostic therapeutic and theoretical ideas are widely accepted by fellow scientists as valid. The authors will attempt to show that this is far from true. For example, proof of the existence and significance of out-of-awareness motivation has been described as "on the same scientific level as the miracles" of the Bible(1). Similarly, our pride in the humanistic orientation of our profession is contested by one reputable scholar as "perhaps the last one of the medieval absolutist controls over the

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Respectively, Chairman, Assoc. Prof., Dept. of Psychiatry, University of Wisconsin, Madison, Wis.

destiny of the individual"(2). One entrenched conviction that we help is contested by reputable scholars who say that psychiatric therapy is a great impediment to recovery from emotional illness.

Contemporary critics of psychiatry run the gamut. They range from distinguished scholars in a variety of specialty areas including psychiatry and extend down to haranguing zealots whose professional careers seem almost exclusively devoted to "exposing" psychiatry in order to facilitate the professional extinction of this breed. As authors embarking upon review of a touchy, difficult, emotionally-laden area, we try to be guided by two fundamental hypotheses; first, the "facts are friendly"; secondly, we feel that the honest search for truth characterizes not only ourselves and our immediate professional colleagues but characterized the intention of our critics as well. We will focus upon the intellectual content of the critique and will devote particular attention to evaluations of leading scientific writings during the last ten years, in the English and American literature. Contemporary critical attitudes will be considered under five headings: 1. Is "mental illness" as conceived of by psychiatrists a valid concept? Do medical analogies apply to the complicated issues of human behavior? 2. Are there scientific bases for any of the fundamental hypotheses which underlie any of the psychiatric therapies? 3. Do psychiatric therapies work; are they useful? Are there significant demonstrations of the effectiveness of any form of psychiatric therapy? 4. Is there a basis for psychiatric contribution to delinquency, law, philosophy, theology? Do psychiatrists leave the treatment room and go to other areas, promising more than they deliver? 5. Can the needs of our society which are currently met by psychiatrists be fulfilled more economically, more adequately and more equitably in some other fashion?

In his book, *The Myth of Mental Illness*, Thomas Szasz(3, 4), practicing psychoanalyst, questions the entire conception of "mental illness" as a medical problem. For Szasz, disorders of behavior are not adequately understood by us, due to an unwillingness to give up our medical frame of reference. He questions the motivation

of psychiatry in wishing to adhere to the prestige and status of medicine in areas which do not belong in the province of medicine. He states,

There is no such thing as mental illness. The concept of mental illness is being put to work to obscure certain difficulties which are inherent in the social intercourse of persons. If this is true, the concept functions as a disguise; for instead of calling attention to conflicting human needs, aspirations and values, the notion of mental illness provides an amoral and impersonal thing as an explanation for problems in living.

He suggests that many of the concepts currently listed under the title of illness should be classified instead as examples of man's struggle with the problems of how he should live. Similarly, Hollingshead and Redlich(5) have thoroughly reconsidered our time-honored conception of neurosis as a relatively well-defined entity. They observe, "We take the position that a neurosis is a state of mind, not only of the sufferer, but also of the therapist and it appears likewise to be connected to the class positions of the therapist and the patient." A diagnosis arises from a number of conditioning factors; the experiences of the patient, the training and techniques of the doctor, as well as the social values of the community. Is the schizophrenic patient the iconoclast of our time? Jules Masserman(6) suggests that the psychotic may be the individual who refuses to believe the delusions which allow other people to live in comfort. Rogers (7-9) has questioned the entire concept of diagnosis and serious critiques of the whole concept of mental illness, neurosis, psychosis, and diagnosis have been presented by others(10-12).

The second area of contention in the eyes of many of the critics of psychiatry pertains to the question as to whether there is a scientific basis for any of the fundamental hypotheses which underlie psychiatric therapies. Such variant concepts of the hypotheses concerning out-of-awareness (unconscious) motivation and the various rationale behind somatic treatments have been comprehensively questioned. Do psychiatric underpinnings and foundations rest upon the clouds? H. J. Eysenck, noted

English psychologist, in a series of writings (13-17), has criticized the concept of unconscious motivation which he finds unnecessary to explain human behavior or success in psychotherapy. Similarly, he raises questions as to the value of any procedure based upon the concept of unconscious motivation, including psychological projective tests. Regarding projective tests, Eysenck indicates that "results are not superior to the results that would be secured by writing different diagnoses on the faces of a dye and then casting the dye to determine the personality of the subject." The concept of the unconscious has been questioned by other psychologists(33), by a number of philosophers, including Nagel (18), Van Den Haag(19), and Hook(1). A different perspective of human behavior which need not be dependent upon unconscious motivations is presented by existential theorists including Rogers(8, 9), May(20), Sonneman(21), Boss(22), and Farber(23). The concept of psychic determinism is seriously questioned by Angel(24), who points out that new findings in modern physics tend to make our ideas of determinism appear naive and untenable.

The concept of psychodynamics is vigorously criticized by psychiatrists Cleckley and Thigpen(25) who feel that psychiatry has made something of a Holy Grail of this term. They ask the question, "How do men of learning and high intelligence come to accept and hold with such stout faith beliefs for which there is so little demonstrable evidence?" In answering their own question, some of the points which they find relevant are

(a) the tendency of psychiatrists to mix truisms with unproved assumptions and to offer this mixture under a single term, (b) the tendency to use verbal constructs in overexpanding exercises of reason or rationalization that progressively lose relation to observable realities, (c) the tendency to use of assumptions which are accepted without evidence but on faith by the therapist and are discovered again and again through some symbolism and other unreliable means of inference in the unconscious of patients, (d) the tendency to use of jargon to blur implausible concepts and to convey the impression that something real is being disclosed and (e) the gradual and pervasive influence of sincerely committed devo-

tees of metapsychological creeds and students and disciples who are led to feel, "It is only because of resistance that I cannot see evidence for what teachers affirm with such true faith."

On this line, perhaps the most devastating criticism of our preoccupation with "dynamics" was made by Jules Masserman(26) in his jocular description of the dynamics of *unguis incarnatus*. Astonishingly, this satirical discussion was taken literally by a number of colleagues.

Central in the writings of many critics (1, 10, 11, 18, 27-33) who question the fundamental hypotheses of psychiatry are the assertions of weaknesses, inadequacy, and secular orientation of much psychiatric research. Bailey(10) traces this deficit to the beginnings of the psychological movement and to Freud, stating, "Freud's psychological writings are reveries . . . Freud failed at all experimentation, thus his theories today are badly backed." No less seriously criticized are the psychiatrists with an organic, heavy biological orientation. Hakeem notes that eclectic and biologically oriented psychiatric theories are not scientifically based(12).

Another large group of contemporary critics are to be found among those who use an existential, theological or sociological approach. The existential movement in psychiatry includes some who seriously question the ultimate knowability of motivation of human beings. May(20) and Rogers(8) have both expressed doubts about the kind of world in which we would live if there were ever to be an ultimate knowability as regards behavior. Other existentialists feel that a biological psychiatry which considers man as a bundle of drives and repressions fails to understand the nature of man's being. These critics(33, 34) are perplexed at the rigidities of modern psychoanalysis and psychiatry which they see as moving towards an all-inclusive theory of behavior which fails to recognize human potentialities and which deprives the patient of alternative approaches to improvement because of our own rigid inflexibilities. Allers(35) and Pongratz(36), whose orientations may be described as "existential-theological," feel that in ignoring religious motivations, psychiatry is incomplete and can never

come to understand the true nature of man. Other theologians such as Fulton Sheen (37) are critical of a tendency of psychiatry to imply knowledge of "a first cause," when according to Sheen such knowledge is the province only of religion. Fromm(38) and Percy(39) are concerned with the development of a type of psychiatry which can help man to adjust and to satisfy biological needs and which yet leaves him desperately alienated from himself.

While many of the basic assumptions underlying psychiatric practice have psychoanalytic derivation, it would be misleading to assume that these attacks exempt other forms of psychiatric practice. While the non-analytic psychiatrist may nod approvingly at some of the harder criticisms of psychoanalysis and the dynamic psychiatrist, he is misled if he believes that he is himself in some way exempt from attack. Insofar as he uses diagnostic, evaluative, psychological concepts in his work, he is susceptible to the same charges levied against the psychoanalyst.

By this time, the defensive psychiatrist may be acknowledging, "perhaps there is no such thing as mental illness, and perhaps our theories are fatuous, but we do help people!" This latter assumption has been bitterly criticized by a number of scientific students. Eysenck(13-17) has made detailed statistical studies of various forms of psychotherapy and concludes, "There is absolutely no data available suggesting that human beings change as the result of psychotherapeutic contact." He feels that where psychotherapeutic methods produce a cure, the practitioners are actually using methods derived from learning theory and that results of conventional therapies are really inferior to those obtained with conditioning and learning theory approaches. Eysenck believes that insight and recovery of past memories is not at all essential to a development of cure. Further, he deplors the tendency to minimize the values of symptomatic cure which he feels is possible without insight. In these observations, he is warmly supported by Stevenson(40) and Wolpe(41).

In the field of preventive psychiatry, Carstairs(42) notes that we have been unable to produce positive evidence that preventive

measures materially cut down on the symptoms of psychiatric attacks of children or their parents. Wortis(43) notes that approximately one-third of patients get well with treatment, one-third may be minimally influenced by treatment, and one-third do poorly. Bailey(10) observes that Esquirol reported identical results 120 years ago. Denker(44) reports that "most psychoneurotics recover within 2 years with no other assistance than episodic counsel from a general practitioner." In this instance there was no evidence that the contacts with the general practitioner were of much therapeutic value. Similar studies have been reported from Great Britain(45). Schlein(46) reports no demonstrable differences in patients seen transiently in contrast with those patients who were seen for long periods of psychotherapy. This observer, however, contrary to Eysenck's view did feel that certain changes were demonstrable in patients who were seen in client-centered therapy. Bailey with characteristic vigor has questioned the efficacy of all areas of psychiatric treatment including psychosurgery, ECT and tranquilizing medications. Regarding the rather glowing reports in our literature concerning tranquilizer therapy, a popular play of speakers has been to read a very favorable paragraph ostensibly about the impact of new medications, and then reveal to the audience that this article was written one hundred years ago and concerns the bromides. In a more scholarly vein(10, 47), all of the organic therapies have been vigorously criticized as either lacking in effectiveness or as creating problems for patients which are perhaps worse than the illness(48, 49). The problem of research which naively leads us to unrealistic expectations of drug therapy has also been carefully examined(50-53).

The psychiatrist who leaves his treatment room and goes to other areas of science or the humanities faces a broad battery of critics. Is there a basis for psychiatric contribution to delinquency, the law, philosophy, theology, literature, and world government? A loud cacaphony of yes-no is heard in reply. The phenomenon of the psychiatrist in the courtroom, the battle of the experts, has received sharp attention from critics both within and outside the pro-

fession. Many feel that psychiatry contributes little to the issue of man's capacity to be responsible for a crime. Wiseman(54) along with other critics(12, 55-58) feels that psychiatry has only confused the issue of criminal responsibility and some go so far as to suggest that the profession should be barred from the courtroom(59). Szasz (60-62) is, understandably, extremely wary of psychiatric intervention in the legal system. He feels that in entering the arena of the courtroom, the psychiatrist attempts to become involved in ethical and moral issues which are not his province. He states, "Psychiatry has no special competence in matters of responsibilities and should avoid ethical and moral obligations which have been forced upon him." He is critical of "psychiatrization" of the law, believing that ultimately this procedure is not conducive to the needs of society or to the criminal offender. Hakeem(12, 57), an associate professor of sociology at the University of Wisconsin, feels that psychiatrists represent a menace to the administration of criminal justice. He states,

Psychiatrists have been engaged for a long time in a relentless and extensive campaign to extend the scope and power of their influences in the administration of justice and . . . in the policies and practices of correctional institutions and agencies. This campaign has now reached reckless and irresponsible proportions and there has been a resort to questionable tactics. Unseemly as it may appear, the profession of psychiatry has even gone so far as to bestow prices and honors and unabashed flattery upon judges who have handed down decisions that it sees favorable to its cause. And in the service of this campaign psychiatrists have produced a barrage of literature much of which is propagandistic in nature.

He questions the ability of any psychiatrist who serves as an expert on most any aspect of human behavior, and cites the work of Taft(63) whose research seemed to demonstrate laymen to be superior to psychiatrists in the judgments of peoples' motivations, emotions and personality traits. Other critics such as Hartung(2) and Sutherland(64) deplore the "need of other disciplines to genuflect before psychiatry" and are particularly concerned with the power of psychiatry to influence legislation with regard

to sexual crimes. Schuessler and Cressey (65) have been critical of psychological tests when applied to criminals and noncriminals because of the lack of distinguishability of the two groups. Such eminent psychiatrists as Glover(66), Schmideberg(67) and Bowman(68) have raised doubts as to the current status of our effectiveness in treating criminal offenders. They strongly fear that psychiatry may have oversold its capabilities.

Many thoughtful theological scholars have seen dangers in the psychiatric approach to problems of living. Some theologians are concerned with the possibility of a psychotherapist's advice being adverse to church doctrine. Walker and London (69), Kaplan(70) and Mowrer(71) are concerned lest clergymen abandon their own spiritual powers of healing and be seductively led to entrust all problems of life to the psychiatrist. Another theologian, Hutchinson(73), is concerned with the "cult of reassurance" promulgated by psychiatry which rejects any note of pessimism and fails to deal with "the realities and failures of life." Mode(74) and Allers(35) fear that psychiatry must almost by definition be an entirely humanistic concept which leaves little room for spiritual values. Leaders in the Catholic Church have had many reservations as to the implications of psychoanalysis(37, 75, 76), psychotherapy and various biologically based therapies, feeling that psychiatry may play a role in providing reassurance, thereby reducing guilt-feelings and encouraging permissiveness. Other theological scholars have raised similar issues(77-79). Fellow psychiatrist Cleckley is extremely concerned with the tendency of psychiatry to justify abnormal forms of sex behavior as being within the realm of normal, feeling that we often imply that such behavior is permissible and right. Alfred Kinsey(81) on the other hand views psychiatrists and psychiatry as being too moralistic.

The ventures of psychiatrists into areas such as political science, international relationships and the meaning of philosophy and history has also brought forth a chorus of critical voices. Cussan(82) feels that psychiatrists are attempting to accept too much social responsibility for all health

problems and that it is premature for psychiatrists to "look for fresh worlds to conquer." Fishman(77) and Williams(83) have vigorously protested the tendency on the part of the psychiatrists to interpret the beliefs of philosophers, the personalities of historical characters, and the personality traits of Biblical characters in the light of psychological and psychoanalytic ideas. Dession(84) cautions psychiatry to "look at its own value-judgments, its own viewpoints and its own terminology in the light of their implications for broader social scene." Even so ardent a protagonist as Mike Gorman(85) notes that the public tempts the psychiatrist to become an expert in too many facets outside his field and that this results in the psychiatrist exaggerating his own capacity. Indeed, communications by members of the profession (3, 12, 86, 87) have cautioned against the seductive lure of those who see the psychiatrist as a sort of super-person, and who conceive of a new world where good psychiatrists rule and Platonic perfection is achieved.

In approaching the fifth heading, we ask the question of whether the current functioning of psychiatric profession best meets the needs of our society. Critics in this area again range from the profound to the nasty and picayune. Some of the most vocal criticisms in this area come from fellow physicians. The psychiatrist's unique relationship to other physicians and to medicine in general has evoked widespread discussion. Those psychiatrists who earn the major portion of their living through practicing psychotherapy and who tend to give little or no courtesy have been sharply criticized by Jacques May(88), Dean(89), various county medical officers, and even a society here and there. Further, the tendency of the psychotherapeutic physician to avoid the traditional colleague relationship when working with some member of the doctor's family, coupled with the general reluctance of many psychiatrists of the psychotherapeutic school to establish close liaison with medical practitioners in their communities has provoked widespread disapproval by persons within and outside the profession, including Bailey(10), Felix(90),

Galton(29) and Appel(91). Gorman(85) has described the concern of many American educators about the unfortunate effects the various psychoanalytic institutes produced when they divorced American psychiatrists from American medical education. Commenting about the reciprocal loss which results from this estrangement, Appel(91) states, "the isolation of analysis from medical clinics, hospitals and faculties hinders its wholesome and effective development."

The battle continues to rage as to whether the art and science of psychotherapy should remain the exclusive province of the profession of psychiatry. A recent report of the Joint Commission of Mental Health(92) stresses the need to utilize other professions in meeting the mental health needs of the nation. Such eminent psychiatric scholars as Kubie(93) have questioned whether the medical degree alone is most appropriate for the profession of psychotherapy and has suggested an alternative degree in psychological medicine embodying training in both psychology and medicine as superior to the traditional requirement. Rogers(94) has suggested that 6 months of training for a genuine and empathic person, be he physician, clergyman, psychologist or sociologist, may suffice for the development of a skilled client-centered psychotherapist.

Psychiatrists have been roundly criticized by many for unwillingness to accept symptomatic relief and their insistence upon lengthy, ponderous psychotherapies. Psychiatrists have also been accused of an unwillingness to be involved in some of the less glamorous and less lucrative areas of practice, such as court work, administrative and institutional psychiatry. Bailey(10) urges psychiatrists to "return to the laboratories and asylums which they are so proud to have left." A number of critics both within and outside the profession, including Natenberg(95), Ludwig(96), Campbell(97), May(88) and Dean(89), are perplexed and dismayed at the "exorbitant costs" of psychiatric treatment and deplore the heavy expense and considerable investment of time which is involved. Someone has coined the expression, "What this country needs is a good five buck therapist."

SUMMARY

We have presented a small sampling of contemporary critical writings about psychiatry. Serious questions have been raised regarding almost every aspect of our theory, our practice, and our place in society. Understandably, any clinician actively involved in treatment activities needs to have a certain freedom from obsessive rumination and doubt. However, training and practice which occur in a setting that recognizes the possibility of truth in criticism while sometimes exquisitely painful may be the healthiest of all for the nurturing and growth of psychiatry. A mature psychiatrist hears what the critic has to say, without condescension, without automatic interpretation of malicious motivation and with recognition that the critic may be right. One may say, in the spirit of Milton's *Aeropagetica*, "Truth is compared in Scripture to a streaming fountain. If her waters flow not in a perpetual progression, they sicken into a muddy pool of conformity and tradition."

INCOMPETENCY TO STAND TRIAL : PROCEDURES, RESULTS, AND PROBLEMS¹

JOHN H. HESS, JR., M.D.,² AND HERBERT E. THOMAS, M.D.³

The determination of one's competency to be tried or punished for an alleged crime is not only an important legal question but, as all such, symbolizes a vital social principle. It represents mankind's painstaking efforts to deal with the problem of simultaneously safeguarding the rights and interests of both the individual and society. Any piece of law, regardless of its technical perfection, which fails to cope with this dual responsibility must soon be discarded ; for it is not the case that society derives its power and force from its law but rather it is society which provides meaning and authority to its law. It is, then, the fearsome spectre of an individual or a society out of control which lends to the question of competency to stand trial its deep legal and psychological significance, and which provides this question with its vital social relevance.

Recognition of such relevance has led some to question the very concept of competency to stand trial(3). But, in our opinion, such questions, all too often based solely on psychiatric theory or legal principle, are premature. Rather, we feel the first step is to examine what in fact takes place when this concept is applied and to assess the results of this application. In undertaking the research to be described, it was our hypothesis that both the individual and society have become the victims of a principle designed for their mutual protection.

The Principle of Competency to Stand Trial. In brief, the problem of competency to stand trial consists of a determination of

the accused's mental status not in relation to the crime, but in relation to his trial. The concept comes to us out of common law (4-6), which held that an individual could not be required to plead to an indictment or be tried for a crime when he was so mentally disturbed that he could not understand the nature and object of the proceedings against him, understand his own position with reference to such proceedings, and to assist in his defense. Michigan, like most states(3), has retained this common law test of incompetency in its statute and orders that if an individual be found to be incompetent by either judge or jury, he shall be sent to the Ionia State Hospital. The statute further requires that "two or more reputable physicians" and other relevant witnesses shall offer testimony at the incompetency hearing. The issue of incompetency can be raised by the accused, the prosecuting attorney, or the court. We wish to emphasize that in the Michigan statute the terminology used to describe what shall be done with an individual found to be incompetent does *not* use the word "incompetent." Rather it states that if an individual is found "insane" he shall be sent to Ionia State Hospital "to remain until restored to sanity"(7). This remarkable confusion of designations not only suggests the bewilderment of those who wrote the statute, but has had a powerful influence on what actually happens to persons committed as incompetent to stand trial.

The Study. We undertook to study the question of incompetency as it is handled under Michigan law with special attention to the respective roles of the psychiatrist, the lawyer, and the hospital, and to the consequences of incompetency proceedings for the client and for society. To carry out the project, two psychiatrists and two senior law students conducted field research at the Ionia State Hospital, to which place individuals found incompetent to stand trial in Michigan are committed.

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

³ Dept. of Psychiatry, Western Psychiatric Institute, Pittsburgh, Pa.

The patient population at Ionia was 1,484 as of Aug. 1960, of which 705 were those committed as incompetent to stand trial. Conclusions regarding these cases were based on a study of 77 records selected at random, representing approximately 10%. In addition to patients currently in the hospital, there was another category of individuals who had been returned to the committing courts. In a 6-year period, from July 1954 to Dec. 1960, 105 persons had been so processed. On the basis of a random selection of 1 in 5 records we studied 21 such cases. A third category consisted of 200 patients committed as incompetent who were currently on parole. Twenty records of such persons were studied as well as 11 records of persons who had been on parole at one time but had been discharged from parole with permission of the committing court, but without being returned to court for disposition. All records were examined for background information regarding the individual, the nature of the judicial proceeding with special emphasis on the legal and psychiatric role in such, the management of the individual at the hospital and his hospital experience and, in appropriate cases, the results of parole, discharge from parole, or return to committing court. In addition, the staff of Ionia State Hospital was interviewed and staff meetings were attended. Finally, 11 patients were interviewed by the participating psychiatrists.

A second phase of the investigation included a study of the pertinent statutes, and their content and intent was measured against the actual results of the incompetency proceedings.

Mention should be made of the difficulties in obtaining complete information. Such pertinent data as who initiated the incompetency proceedings, the physician's testimony, whether or not the defendant had counsel, various legal documents, and a multitude of other highly germane facts were missing from these records. Not only does this suggest deficiencies in recording and communicating information but it is, in our opinion, indicative of the understandable perplexities of those involved in the entire procedure of competency and reflects their confusion as to what the procedure is really about, what material has

significance, and what should be done with it.

RESULTS

Raising the Issue. The Michigan statute requires that the court shall hold a sanity hearing to determine the accused's competency when one accused of a felony "shall appear to be insane" and "if it is claimed that such a person became insane after the commission of the felony with which he is charged . . ." While these words may appear to be sufficiently clear and concise, our findings suggest that either they are not so clear as they might seem or that the courts tend to use the concept of competency for some purpose other than that intended by both common law tradition and the Michigan statutes. In support of this we point out that there was a marked discrepancy between different courts as to the use of the competency principle. This discrepancy was vastly greater than that which would be expected on the basis of statistically random occurrence of significant mental illness in those accused of committing a crime. This observation raised the question as to what sorts of factors were responsible for the initiation of competency proceedings.

In this regard, two factors were strikingly evident. One related to the crime and the other to the defendant. Crimes associated with incompetency proceedings were most often those that were especially heinous or revolting such as bizarre murders and sexual offenses, or crimes which were clearly pointless such as repetitive minor offenses without hope of material gain. The types of defendants involved in questions of incompetency were most frequently somehow pitiable or puzzling. They might be the very old or the very young, the borderline mental defective, or the physically handicapped. In many cases, nothing in the record indicated (unless the factors listed above be so interpreted) that the defendant appeared "to be insane" nor, in most records, was there anything to suggest that it might be "claimed that such a person became insane after the commission of the felony with which he is charged." Our conclusion is that the issue of the defendant's competency to be tried was most frequently

raised not on the basis of the defendant's mental status but rather was employed as a means of handling situations and solving problems for which there seemed to be no other recourse under the law.

Such findings coupled with the wording of the statute suggest an immediate and significant impasse in competency proceedings. It is difficult to understand how such proceedings could be related to the actual mental status of the defendant if non-psychologically trained and oriented personnel are charged with raising the issue. In such a situation, it seems inevitable that many offenders with less obvious and less bizarre yet serious mental illnesses which might constitute grounds for the finding of incompetency will be overlooked (4-6, 9).

The Psychiatrist's Role. As pointed out previously, the physician's or psychiatrist's role is quite clearly defined by law. The physician should function as an expert witness. It is his job to offer a scientific description of the individual to the court in a meaningful and serviceable fashion with clear-cut substantiation of his conclusions (2). It should be noted that the merits of such testimony and their relevance to the legal question of incompetency is a matter to be decided by the judge or jury. In this study we found that almost without exception the psychiatrist's role was grossly distorted. The vast majority of the records studied indicated that the psychiatrist confused the legal standards for incompetency with those of responsibility.⁴ Often part of the psychiatrist's report to the court would contain reference to standards of incompetency, and another part would refer to standards of responsibility. For example, one record stated, "This man does not know right from wrong, he is incompetent, he is not able to assist his counsel, he should be committed to an institution because he is insane and should be released only when he is found to be sane." It should be stated that the preceding example is in no way an

unusual or unique statement. In those records in which there was no confusion between standards of incompetency and standards of responsibility, such confusion was lacking by virtue of the use of a prepared statement. This statement consisted of simply parroting the language of the statute with the insertion of the appropriate negative or positive words. In only very rare cases were the grounds for the psychiatrist's opinion presented to the court. It was clear that the court had to depend upon the psychiatric opinion and conclusion and accept this or reject it on an arbitrary basis.

In addition, the concepts of incompetency and responsibility were often used interchangeably by the lawyers and the courts. This would suggest that if the psychiatrist were to perform his appropriate and defined role, the courts would in all likelihood not make use of such testimony. It seemed clear that the aim of many of the incompetency hearings was simply to dispose of the issue in as little time as possible, and that the courts requested that the psychiatrist tell them what to do.

Another distortion of the psychiatrist's role must be mentioned. The records studied at Ionia State Hospital revealed that frequently the psychiatrist assumed the role of judicial expert. In the case of P.F., the psychiatrist's report read, "This man is a chronic alcoholic. He is impulsive and extremely dangerous. He is not treatable and should be sent to the hospital for segregation for a good long time, if not for life." Not recognizing the purpose of the legal proceedings and not recognizing or misapprehending his role in these, the psychiatrist took it upon himself to make moral and judicial decisions.

The Legal Role(3). It must be remembered that the entire question of incompetency and the procedure for such a determination is a legal matter. Without some new approach or drastic innovation in the current approach, it must ultimately be the law's responsibility to see that the process and results of incompetency proceedings fit the intentions inherent in the legal principle. Our study indicates that this is not done. The difficulty appears at the outset when the courts fail to use the physician in his appropriate role. The majority of the

⁴ The Michigan standard for responsibility may be stated as follows: the individual must know the nature and quality of his act, must know that the act is wrong and must be able to adhere to the right and avoid the wrong. This, of course, applies to his mental status at the time of the commission of the act.

psychiatrists' reports were empty and meaningless, and yet were accepted and acted upon by the courts as if they contained information which could be construed as evidence and, as such, decided upon.

Considering the meaning and purpose of incompetency concepts, it would seem that if the court has any interest, it should be to ensure that the incompetent individual be tried as soon as he can be considered competent. With this in mind, we were amazed to learn of the almost total lack of interest the court took in the defendant after his commitment. On only rare occasions would the court contact the hospital regarding the status of the patient. In such cases the contact was either a mechanical follow-up by a clerk, or the crime involved was such as to create intense public pressure. The only really common communication between court and hospital occurred when the hospital requested permission for some specific program for the patient. In almost all cases such a request appeared to be granted automatically. It may be agreed that it is commendable that the courts cooperate with the treatment but it seems unwise that in so doing they lose their guiding influence on a procedure which has meaning only in a legal framework. Such a situation is epitomized in the Michigan practice of granting "with the committing court's permission" parole(7) to individuals committed as incompetent. Conceivably some patients might be both capable of parole and incapable of standing trial, but surely such individuals would be rare. The three-pronged test for competency can be considered not especially stringent. It is not nearly so stringent as the standards set by Ionia State Hospital for parole. Yet, the courts continue to grant permission for parole which can allow the "incompetent individual" to function in society for as long as three years before any final conclusion to the legal process.

If it be argued that the court, in employing the concept of competency for purposes other than those inherent in the common law tradition and statute and in relinquishing their interest in the defendant after his commitment, are attempting to reach toward some more humane goal than imprisonment, it can be pointed out that such humane goals are not reached in terms of

the aftermath of incompetency proceedings. To put the matter bluntly, in many cases a prison sentence would be preferable to the presumably more compassionate act of committing an individual as incompetent.

In essence, the result of Michigan's management of the problem of incompetency is the incarceration, often for life, of persons without benefit of trial or the safeguards of civil commitment procedures. For example, J.C., a 60-year-old man, was committed as incompetent pending trial on a charge of gross indecency in 1926. He is still under treatment and is now described as showing signs of "simple psychosis."

If it be argued that such situations are simply due to the realities of the chronic illness or to the feelings of understaffed and over-crowded hospitals, we would point out that it was our opinion that many persons were committed to Ionia State Hospital who were not in fact incompetent to be tried. Also, it was our judgment that with existing treatment methods and facilities, the majority of individuals committed as incompetent could be readied for trial within a matter of weeks or months. A final rebuttal to the possible argument that a court could have little influence on the illness of an individual committed as incompetent is our observation that when intervention on behalf of a patient by the court or lawyer (or even continued interest by the family) did occur, closer attention was invariably paid to the patient and usually resulted in the patient's return to court for trial.

Role of the Hospital. As might be expected, the processes and distortions we have described are not without their effect on the hospital. The confusion existing at the time of the incompetency hearing follows the defendant to the hospital. Cases were frequent in which the hospital staff disagreed with the diagnosis made by the examining psychiatrist at the time of the hearing. It was also not uncommon that the hospital staff, in view of the patient's mental status, could not understand why the patient had been committed. The label "incompetent" was a familiar one to hospital personnel, but the meaning and implications of this label were not clear. This being the case, it was not surprising that the goals of treatment were vague and in-

consistent. In an attempt to combat this, the staff apparently bypassed entirely the legal intent behind the incompetency principle and sought to perceive and manage the incompetent patient as they would patients committed to them for other reasons.

The problem is further complicated by the alternatives available with regard to disposition. The staff at Ionia State Hospital can, of course, continue to keep the incompetent individual as an inpatient; or, under the statute, the patient can be placed on parole. Finally, patients may be discharged to the committing court for further disposition. It seems obvious that the standards for these alternative dispositions would vary; and furthermore, that they would be related somehow to the grounds on which the patient was committed. This is not the case. Material from patients' records, including physicians' progress notes, reports of staff conferences, and discharge and parole certificates, left no doubt that the hospital staff was applying very high and invariant standards of mental health to these patients. Such phrases as "lacking in insight into his crime," "immaturity," "continues to be hostile," "uncooperative," "homosexual activity continues," and many other similar descriptions occurred constantly. In addition, less psychiatrically oriented criteria were applied, such as whether or not a patient would confess to his crime, whether or not a patient could recall his crime, and whether patients were cheerful, happy, well adjusted on the job, *etc.* At no time was any reference noted to the actual standards legally required for competency.

Another incongruity enters the picture when one considers the requirements to be met by an individual on parole. While on parole the patient is required to hold a job and make a successful social adjustment. He may not change his residence or marital status without permission from hospital authorities. Similarly, he must obtain permission to leave a circumscribed geographical area. He must not drink, drive a car except as necessary, or associate with questionable characters. Such standards of adjustment and control must be maintained for 3 years before he is eligible for discharge.

There is no question but that the requirements made of patients and parolees go far

beyond those necessitated by the legal test for competency and, indeed, would tax the psychological capacities of many "normal" persons.

Role of the Patient. We come now to what should be the most significant consideration in this entire process. Legal principle behind the concept of competency to stand trial is plainly the protection of the individual and society. It need not be said that the physician's duty is to his patient. How, then, has the client fared? It is most evident that his interests have not been served. The incomprehensible, inconsistent, and arbitrary operation of the incompetency procedure has left him as a *persona non grata*. In all likelihood, and this was borne out in interviews with patients, he has come to distrust the doctor, the legal system, and society itself. He is confused, as is the hospital, regarding his status and identity. Questions as to whether he is a criminal or a patient are left unanswered. Hopes and fears regarding the future remain unattached to any legal or psychological context or framework. Many patients are aware, in a conscious sense, of what they have done and why, and hence cannot conceive of what is expected of them or toward what they should strive. This internal confusion is reinforced by the perception of the perplexity and aimlessness of the hospital and of the lack of interest by outside persons and agencies. This leads to further hopelessness and eventual deterioration. It may be stated that many of the patients committed as incompetent to Ionia State Hospital do not consider it a hospital but rather a prison, and an extremely undesirable prison at that. For the majority it is a prison to which one is committed on an arbitrary and incomprehensible basis and one in which concepts of parole, treatment, or discharge gradually shift from unlikely possibilities to forlorn hopes, to psychotic delusions.

If such statements seem strong we may point out that our study indicates that in a 6-year period only 105 persons committed as incompetent were returned to the committing courts for further disposition. (This covers a period from Jan. 1954 to Jan. 1960.) Further, our findings indicate that well over one-half of the individuals committed

as incompetent will spend the rest of their lives confined to the hospital. In a strictly legal sense, many persons are deprived of the constitutional guarantee for a "speedy trial" (8), and hence deprived of the opportunity to be found innocent (1), not guilty by virtue of being not responsible, or at the very least, guilty with an earlier start on a prison term. (Time spent as incompetent in the hospital is "dead time" in terms of any future sentence (10).)

CONCLUSIONS

We have described the breakdown of a vital social system necessitating collaboration between two highly respected professions. The confused statute regarding incompetency to stand trial and its distorted application by both physician and lawyer tends to subvert the social and legal principle inherent in the concept of competency and in so doing to sacrifice the professional identity of both lawyer and physician as well as their appropriate functions as assigned by society and which their client has the right to expect.

In this process, the legal position becomes untenable. The court cannot use the psychiatrist effectively because it cannot understand him and because it does not demand that which could be understood. Therefore, in lieu of using his competence, it must accept his pronouncements and tacitly his usurpation of its role. The valued and traditional legal insistence on the right to determine fact is passively given over to the acceptance of opinion as fact. The result is that from start to finish the physician occupies a foremost yet counterfeited role in incompetency proceedings. The abhorrence of the psychiatric discipline for actions based on value judgments involving the moral and ethical behavior of the patient is well known. Yet, in dealing with his legal brethren, the psychiatrist seems willing not only to evaluate his client's psychological status but to judge his behavior, evaluate its social significance in an ethical sense, and to decide the fitting consequence of such behavior. In short, often the physician usurps the function of the law and in so doing relinquishes his therapeutic opportunity. The process all too often ends at the hospital where we have seen the therapeutic

confusion, the contradictory practice of parole, and the dismal treatment results.

The individual truly has been victimized by a process designed to protect his rights and it may be stated that a social system that victimizes its individuals will soon find itself the victim.

DISCUSSION

The findings presented suggest some readily available remedies for the difficulties in and the unhappy results of competency proceedings. We would suggest that attention be paid to the intentions and goals of competency proceedings so that such proceedings be restricted only to those criminal defendants who appear to be appropriate objects for competency determinations. In addition, courts and attorneys could profitably clarify in their own minds what sorts of information they would require from the psychiatric expert, inform him accordingly, and take steps to ensure that the expert provides this in understandable terms and with sufficient scientific data to support his conclusions. Finally, the law should recognize that the entire matter of competency to stand trial is a legal matter and that the legal influence does not stop when an individual is found to be incompetent. Undoubtedly, efforts should be expended to educate psychiatrists, particularly those responsible for the hospital management of the incompetent individual, as to the goals of the competency proceedings. Specifically, it should be pointed out that such proceedings do not stand in lieu of other types of legal disposition, but rather they represent a step in the legal process leading toward some more definitive disposition.

Turning to the psychiatrist and hospital, we suggest that they also have a responsibility for many of the problems which we have elucidated. Those psychiatrists and those hospitals who will, of necessity, be involved in legal proceedings, specifically incompetency proceedings, should attempt to familiarize themselves with the legal framework within which they will be asked to work and to attempt to arrive at some understanding of the methods and objectives of this framework. Certainly, no psychiatrist should continue to provide some

type of psychiatric service if he is unaware of what is required of him. Under such circumstances, he should directly request information as to what is required and if he is unable to obtain such, or does not feel that he can function within the specific context, he should then remove himself. Caution should be exerted so as to ensure that the concept of competency and the proceedings of the competency determination are not used by the psychiatrist for other purposes regardless of how rational such purposes might seem. In essence, it appears that several changes could be readily wrought which would correct some of the procedural and mechanical difficulties described. Still, we would ask whether even if all such changes were instituted, any real progress would be made with regard to the basic question which the concept of competency to stand trial seeks to answer.

We submit that the true difficulty underlying the surface problems which arise from competency proceedings lies in the fact that on both sides, namely, law and psychiatry, there exists an assumption of the existence of a comprehensible standard of competency to stand trial which can be applied to a human being, assessed within a human being, and communicated to other human beings. In support of this, we would like to analyze the competency criteria as used in Michigan. The first two of these criteria, *i.e.*, "whether such person is (1) capable of understanding the nature and object of the proceedings against him and (2) of comprehending his own condition in reference to such proceedings . . .", seem to us to be inseparable. The question is, what is the actual meaning of these criteria in terms of the parties involved? Surely, with regard to the defendant, and excepting a few severely regressed mentally ill persons or severely organically damaged persons, any person is capable of understanding what is happening to him and his position in regard to this, at least in terms of his current or characteristic way of appraising his external environment. It seems to us that in terms of "understanding," one's understanding is just as valid if he presumes that he is the victim of a widespread communist conspiracy to imprison him or if he is aware that he has acted so as to be

the object of the normal machinery of the legal system. Therefore, it would seem that if we apply the standard in terms of the defendant, that all, excepting a very few, could be considered competent. However, it is true that if we apply these criteria as translated into the legal framework, a given defendant might well not be able to understand the nature of the legal proceedings and his position with reference to them. This, however, raises the question as to whether any person other than perhaps a lawyer is really capable of understanding the complex legal apparatus with which he is associated. Surely, the intricate system of legal tradition, statutory law, philosophy, *etc.*, and the multiple implicit and explicit ramifications of these cannot be truly comprehended by a person outside the legal context. By the same token, we should not expect that a given defendant could truly comprehend standards of competency as translated into the terminology of ego psychology as employed by a psychiatrist. It seems that depending upon one's context and framework that almost all defendants can be considered competent or that almost all can be considered incompetent.

Turning now to the third criterion for determining one's competency, *i.e.*, that such a person be capable of "assisting in his defense in a rational or reasonable manner," we find a similar problem. If we presume that the intent of a criminal trial is to arrive at the facts surrounding the behavior in question and that among those facts, the concept of *mens rea* is to be considered, then it would seem that all that has happened, including what the defendant thinks has happened or thinks about what has happened, should constitute assistance to his defense. Using the example above, it would seem important to the individual's defense and to those charged with deciding on some appropriate disposition of the individual to know whether he performed the criminal act on the basis of irrational or perhaps psychotic imaginings of a communist conspiracy or that he feels that he performed the criminal act as a result of an illegal and antisocial wish to take for himself that which belonged to another. It is hard for us to conceive how any individual, again perhaps excepting

certain deeply regressed mentally ill persons or severely damaged organically ill persons, could not be of assistance in his own defense. Again, if, however, we consider the individual's ability to assist in his defense from the legal viewpoint, which might include such things as specific recall of each event complete with times, places, persons, *etc.*, and particularly if we rely on this individual to assist his counsel with regard to his motives and thoughts concerning the crime, then surely many defendants must be considered incompetent. In this sense, again we must raise the question as to the extent to which any person could be considered fully competent. Such difficulties also present themselves with regard to the psychiatric framework. And, again, as with the first two criteria, none or all defendants can be considered competent or incompetent.

It seems clear that concurrence of opinion between psychiatry and law can take place only in the case of those defendants who are so ill, either psychically or organically, as to be uncommunicative or to present such a public spectacle as to embarrass our sensibilities of fairness and decorum.⁵ While we grant that such cases seem to validate the existence of comprehensible criteria regarding a defendant's competency to be tried, we also point out that such persons hardly require the expert testimony of psychiatrists as to their incompetency, or elaborate proceedings to establish this. In other words, it is in just those cases in which the nature of the emotional disturbance is such as to tax the capacities of both lawyer and psychiatrist in their attempts to deal with him in some fair and appropriate fashion, and who most require some safeguard which might ensure this, that we find ourselves unable to establish satisfactory criteria or communications.

We would like to offer two suggestions which seem more truly relevant to the problem of competency to stand trial. Admitted-

ly, these suggestions raise highly complicated and controversial issues with which we do not intend to deal in this paper, but it seems that the issues must be raised. First, attention must be given to welding criteria which, while admitting that they can never have complete relevance to the aims and methodologies of both law and psychiatry, can at least be sufficiently relevant so as to serve the mutual goals of all concerned. In this regard, it must be borne in mind that "all concerned" includes not only law and psychiatry, but the individual and society. A second and somewhat broader approach would be to give consideration to the total contexts in which persons accused of criminal behavior are to be handled. Is it wise to handle such persons as we now do in what is essentially a strictly legal context with occasional consultative contributions from the behavioral sciences, or would it be wiser to deal with such individuals within the context of the behavioral sciences while providing certain safeguards and procedural requirements from the legal system?

While it has been said repeatedly, it remains true, that if rehabilitative efforts using the current available knowledge regarding the management and treatment of those who have demonstrated themselves to be psychically and socially deviant were applied, problems such as one's competency to be tried or one's responsibility to be punished would tend to disappear.

⁵ It is interesting to note that the conclusion that any real use of the concept of competency can only apply to certain extremely ill and obviously inappropriate individuals is identical to the conclusions reached by many with regard to M'Naghten's rules for responsibility.

THE FACADE OF CHRONOLOGICAL AGE : AN INTERPRETATIVE SUMMARY¹

ROBERT N. BUTLER, M.D.²

To look anew at some of the prevailing ideas and previously reported findings concerning both the processes of human aging and the nature of aged persons, we undertook a series of collaborative studies involving 21 investigators representing a number of separate academic disciplines and medical specialties in a pilot project beginning in Dec. 1955. We had two basic research strategies in mind: first, the selection of the medically healthy, community-dwelling aged, so that we might maximize the opportunity of studying the effects of *time*, or chronological aging, itself and minimize the effects of sickness, institutionalization, and social adversity; second, the introduction of the collaborative, multidisciplinary approach to enhance the opportunity for a more comprehensive evaluation of the many factors known, or believed, to determine the façade of chronological aging.

Such an approach seemed particularly appropriate in view of the fact that so much of the literature concerning the aged and aging had heretofore derived principally from studies of the sick and institutionalized. The dominant theme had been upon *decline*. Little appeared to be known about healthy and socially autonomous aging. We knew that certain cultural stereotypes affected the contemporary picture of the aged and the process of aging.

We conceived aging to be a process of change involving all aspects of the organism but not necessarily occurring in an inter-related or synchronous manner. In order to examine a broad range of physical, physiological, psychological, psychodynamic, and social processes to gain some understanding of the changes occurring with advancing age, we therefore undertook an intensive study of "normal" men above the age of 65 years. How might we disentangle the

contributions of disease, social losses, pre-existing personality, and the like from changes that might more properly be regarded as age-specific? This was the broad screening question.

Illustrative of some specific questions which investigators held in mind were: 1. Are the changes in cerebral blood flow and cerebral metabolic rate previously described in the literature the result of aging of the nervous system or the result of disease? 2. To what extent is the postulated slowing in speed of psychomotor skills the result of a general process of change in the CNS? 3. What personality factors contribute to adaptation and maladaptation of the community-dwelling older individual to the crises of late life? 4. How do environmental factors, of cultural background and of immediate circumstances, contribute to adaptation (maladaptation) of the aged?

The term "aging" may be used to denote characteristic patterns of late life changes, which are eventually shown by all persons though differing in rate and degree. Models of aging may vary and different antecedents of biological, environmental, social or random nature have been advanced. Models will continue to be introduced so long as the phenomenon remains the mystery that it is to us today.

Although the purpose of the report is to emphasize findings and interpretations likely to be of *particular interest to the psychiatrist*, this multidisciplinary project on human aging as a whole is our subject.³

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

NIMH multidisciplinary study of community-resident healthy aged.

² Research Psychiatrist, National Institute of Mental Health, Bethesda, Md.

³ Dr. Seymour Perlin, now Chief, Division of Psychiatry, Montefiore Hospital, New York, N. Y., and I were the psychiatrists participating in this project. Dr. James E. Birren acted as coordinator. A volume, *Human Aging: A Biological and Behavioral Study* (1) reporting the methods, findings and interpretations of the entire project, was edited with Drs. James E. Birren, Samuel W. Greenhouse, Louis Sokoloff and Marian Yarrow, representing psychology, statistics, neurophysiology and social psychology respectively. Dr. Walter Obrist, presently of Duke University, conducted the EEG studies. Drs. Mark Lane and Thomas Vates, and later Dr. Leslie Libow, served as the medical internists in this project.

Sample. Males were chosen as subjects for several reasons. The likelihood of profound endocrinological changes in the female suggested the advantage of male subjects in our pilot study. The predominant use of male subjects in the research literature on aging provided opportunities for comparison. Limiting the study to one sex also simplified research administration.

Screening for medical health was stringent and a final sample of 47 male volunteers with a mean age of 71 and range of 65 to 91 was obtained.⁴ The sample is not offered as representative⁵ and, in fact, certain features raise issues as to the general applicability of the findings. However, we believe that careful specification of the population makes possible comparisons with other groups. We also believe that wherein relationships were found (as opposed to descriptive characterization), the likelihood of general applicability, or at least its further testing, is possible.

The social and cultural data should be of particular interest to the growing field of social psychiatry. These subjects lived in urban environments at the time of the study and in most cases had done so for long periods. Twenty had been born in foreign countries, having migrated in childhood or early youth. The religious breakdown was not representative of the American population as a whole. There was a wide range of educational background—men with college degrees, men with almost no formal education. (The actual educational level of any aging group is extremely difficult to estimate in terms of our present educational structure.) The estimated median years of formal education of the 47 men was 9.5 years, which is somewhat higher than the median indicated by the 1950 census for the same age group in the general urban population of the United States (8.3 years).

Many occupations were involved, over-representing the higher status white-collar

occupations and under-representing the lower status manual occupations, e.g., 23% had been professional persons during their work careers. Of the 47 men, 32 were fully retired at the time of the study and had been so for an average of 7 years. The annual average income received between 40 and 60 years of age was \$4,300 with a range of \$1,200 to \$10,000. At the time of study, the median income was \$3,100 with a range of \$500 to \$14,000. (Because of certain internal discrepancies within the data there was reason to wonder at the reliability of income figures.) The later years of life had brought fairly severe income reductions for almost half the men. The majority were living in intact families, 31 in their own households with their wives and 6 in the households of relatives.⁶

In summary, it may be seen that the men in this sample appeared to be in somewhat more fortunate circumstances than the general aged population of the United States. Not only did they have generally excellent health, one of the basic reasons for their selection, but they had better than average educational backgrounds and better than average incomes: they tended to retire with fair economic comfort and to continue to exist in private households with their wives in urban environments.

Except for the fact of community residence, selection did not depend upon other social and cultural characteristics. Since there were variations within social and cultural categories, however, it was possible to examine for any effects.

Medical Characterization. On the basis of extensive medical examinations, the sample was further divided into two groups: Group 1, with 27 subjects, was of optimal health without apparent disease; Group 2, with 20 subjects, was also of good health, but evidence for asymptomatic or subclinical disease was found. Of these volunteers 10 showed signs of minimal, essentially extra-cerebral, arteriosclerosis, such as elongation and tortuosity of the aorta, EKG abnormalities, absent peripheral pulses, x-ray evidence of calcification in the aorta or carotid siphon, or retinal arteriosclerosis.

⁴ We are deeply indebted to Mr. Arthur Waldman, Mrs. Sara Blumberg, Drs. Nathan Blumberg and Stanley A. Tauber of the Home for the Jewish Aged in Philadelphia, Pa.; and to the National Association for Retired Civil Service Employees, Mr. Frank J. Wilson, President.

⁵ It would have been desirable to have obtained subjects at random from the community by some procedure of probability sampling.

⁶ According to the 1950 census, 3.1% of the population 65 and over were in institutions, including mental hospitals, but not general hospitals.

The clinical diagnosis of arteriosclerosis is limited by current methods of detection. Group 1 had no detectable evidence of arteriosclerosis; the 10 in Group 2 did. The remaining 10 members of Group 2 were so classified because of such findings as minimal to moderate rheumatoid arthritis, asymptomatic elevation of the level of blood uric acid, and diet-controlled diabetes.

That arteriosclerotic changes may be present in the vascular system of Group 1 is more than possible. Nonetheless, it seemed appropriate to classify our subjects on the bases for detection available. In view of our significant findings, we consider our classification to have been useful.

Moreover, in our 5-year follow-up, it was found that arteriosclerosis, as classified here, statistically significantly related to mortality.

Methods. Two broad research strategies have already been described: a third major tool was that of statistical control and analysis of the data. All data collected by individual investigators were maintained by the statisticians and the findings of each discipline were not made known to other investigators to minimize the possibilities of bias. In addition to the application of customary statistical analytical techniques, the data of individual disciplines were reduced and various principal component and regression analyses undertaken.

Each of the 47 men were brought to the Clinical Center at Bethesda, Md. where they remained for 2 weeks and proceeded through the series of investigations following a routine schedule.⁷ They resided on a unit for experimental subjects (normal controls) where nursing observation as well as customary research nursing care was conducted.

Methods of Individual Disciplines. The nitrous oxide procedure of Kety-Schmidt was utilized in the study of cerebral blood flow and metabolism.

EEG's were recorded on an 8-channel Grass electroencephalograph, using both bipolar and monopolar techniques. Frequency analysis was used as well as clinical reading of the tracings.

Twenty-three tests for measuring cognition and psychomotor responses were done, ranging from traditional procedures such as the Wechsler Adult Intelligence Scale to special techniques such as Perception of Line Difference Test (developed by Birren and Botwinick in 1955)(3). Hotelling's Principal Component method was employed in an attempt to determine the minimum number of factors necessary to account for the common variance in a wide range of psychological measurements in older men, and for purposes of interdisciplinary correlation. (Rorschach, TAT and other projective tests were administered, but the results will not be discussed here.)

Three psychiatric interviews (2 to 3 hours in length) were conducted under standard conditions; these were observed through a one-way vision mirror by an observer-psychiatrist, and were recorded and audited in an adjoining room. Systematic rotation of the roles of interviewer and observer was introduced to minimize systematic bias. In addition to traditional psychiatric evaluation, exploration of topics believed to be of particular significance to the aged was undertaken (*e.g.*, experience of changes, attitudes toward the future and toward death). Attempts were made to objectify and quantify observations and interview material, through the use of rating scales, content analyses and independent judges.

Detailed interview guides were used in the social psychological studies which involved a significant family member as well as the volunteer; the resulting data were coded independently by two of the investigators. Eighty percent was set arbitrarily as the necessary level of coder agreement. Like other social psychological studies of the aged, the primary data source was the self-reports of the aged, but unlike them, the accounts of intimate informants and observations of the volunteers during their residence were additional sources of data, providing a check on validity.

FINDINGS⁸

This sample of aged volunteers was quite

⁸ Since more than 600 variables were measured or observed, the results of this project cannot be reported in full. To Drs. Samuel W. Greenhouse and Donald Morrison, we are indebted for contributions to design and for statistical analysis.

⁷ The study period began Dec. 1955 and ended June 1957.

different from and superior to other samples of aged persons that have been previously described. This might have been expected from the selection for medical health and social competence. Broadly speaking, our men were vigorous, candid, interesting and deeply involved in everyday living. In marked contradiction to the usual stereotype of "rigidity" of the aged, these individuals generally demonstrated mental flexibility and alertness. They continued to be constructive in their living; they were resourceful and optimistic.

Medicine(1). The internists were also very impressed by the over-all excellence of health and physical vigor of the sample. Comparatively few differences were demonstrated in the many functions tested in the medical survey between the aged and the young. Hematological, blood, chemical and urinary studies as well as more specialized studies revealed no statistically significant differences with a few important exceptions. These studies were conducted in the same laboratories and facilities, and the normal mean values of the Clinical Center were utilized in the comparisons. Moreover, few correlations were found to age within the limited age range of our sample.

Serum albumin, as measured by both electrophoresis and the chemical method, was significantly lower in the aged. This difference is believed to be an important lead for further study of the fundamental processes of aging since, *e.g.*, nutrition, *etc.*, do not explain the decreased albumin.

Although directly measured mean arterial blood pressure correlated positively with age, clinically obtained systolic and diastolic blood pressures did not. The optimally-healthy Group 1 had mean blood pressure values similar to Master's 20-40-year-old group: Group 2 resembled Master's old age group(4, 5). It is suggested that the capacity to raise blood pressure in the presence of arteriosclerosis has a protective function, *i.e.*, maintenance of blood supply.

Results of pulmonary function studies (including maximal breathing capacity, M.B.C., times and untimed vital capacity, *etc.*) generally revealed excellent functioning without evidence of clinical pathology. Arterial oxygen saturation was, however, decreased in both subgroups of the aged,

for unknown reasons. From some of the results of this study, the designation "senile emphysema" appears questionable. Chronic, heavy cigarette smokers (over a pack per day for 35-60 years) had reduced M.B.C., but surprisingly few other physiological changes.

Retinal arteriosclerosis, which was minimal, appeared to be insignificant in the total evaluation of physical and mental health, was not related to cerebral blood flow, oxygen consumption or vascular resistance, and was not associated with roentgenographic evidence of cerebrovascular calcification.

Cerebral Physiology(6). In contrast to the previous literature and expectations, the studies of cerebral circulation and metabolism revealed no significant difference in cerebral blood flow and oxygen consumption between a group of normal young subjects (mean age 21 years) and the elderly men (mean age 71 years), selected as described. Where reductions in cerebral blood flow did occur it was found to be a function of those subjects with evidence of arteriosclerosis (Group 2). It is suggested, therefore, that decreases in cerebral blood flow and oxygen consumption found in older people are not the consequence of chronological aging, *per se*, but rather of arteriosclerosis, which causes first a relative cerebral circulatory insufficiency and hypoxia and ultimately a secondary reduction in cerebral metabolic rate(6).

Electroencephalography(7). The incidence of clinically normal EEGs within this population was 81% which compares favorably to the findings on young people. In contrast to previous aging studies only 9% of the cases had temporal lobe foci. Groups 1 and 2 did not differ with respect to incidence or type of abnormality. However, frequency analysis did give a mean spectrum with a peak frequency of 9 cps., a full cycle slower than reported for young adults. The entire spectrum, especially the major frequencies, appear to have shifted to the slow side. As in the case of the cerebral physiological findings, there appeared to be effects on the EEG associated with those subjects who were diagnosed arteriosclerosis; there were slower individual peak frequencies in Group 2.

Cognitive Processes(8). Intellectual performance in this sample was superior to the young normal controls who were also tested and with the previously studied aged samples; however the psychologists did find evidence of some slowing in speed which they attributed to aging.

Group 1 (optimally healthy subjects) scored better than Group 2 when the 23 psychological tests were taken as a whole (less than .01), suggesting the sensitivity of cognition to health. Five principal components were derived from analysis undertaken, the first and fourth of which were interpreted as a general intellectual factor and a speed factor, respectively.

Psychiatry(9). Functional psychiatric disorders occur in the medically healthy, community-resident elderly which are not a function of either cerebrovascular disease, so far as present methods can detect it, nor of chronological age itself. The healthy aged are subject to disorders which appear similar to those affecting the young and these disorders, including depression, do not correlate with cerebral physiological variables.

The prevalence of functional psychopathology in our elderly sample was similar to that which has been reported in various studies of younger volunteer populations (10, 11). Mild reactive depression constituted the most common single diagnostic class (19% of the entire sample).

Searching for early prodromal signs of senility, it was found that among the individuals who were evaluated as exhibiting "senile qualities," common characteristics were observed involving intellectual functions and feelings; namely, decreased comprehension, memory, attention, and set, as well as reduced emotional responsiveness. It should be emphasized that "senile quality," perhaps in retrospect a poor term, means mild, early mental decline. Chronological age did not differ between the senile and the normal aging or senescent individuals, suggesting that senility is not an inevitable consequence of aging itself. Indeed, the importance of chronological age as an over-riding factor in the psychiatric disorders of the aging appears questionable as a result of this study; the significance of other factors including personality, psycho-

social disruptions and losses, diseases and the like was recognized.

Efforts were directed toward further defining the aging experience of an individual in terms of intrinsic and environmental changes and reactions to them(12). All volunteers described changes, the mean number of which was 15. The greatest number of changes reported were physical, followed by personality-affective, socio-psychological and cognitive changes. However, changes were not uniformly viewed as deficit in character by the aged subject as they are so frequently described in the literature pertaining to old age. Changes were often reported as positive and constructive. Nor were changes uniformly viewed as unalterable. Although acceptance was the most frequently reported reaction to physical decreases, compensations were reported to social psychological decreases.

Importance of personality in response to losses and disruptions (we have grouped such events under the term crises) was apparent. The effective use of insight involving accurate perception of the changed circumstances of old age and appropriate behavioral modifications was a common occurrence. Other adaptive patterns included the use of activity to extreme counter-phobic maneuvers, in which the aged person undertakes excessive, at times personally dangerous, activities to demonstrate his youth, his prowess and his fearlessness before aging and death. Denial of aging changes was found to be a useful reparative measure against depression(13). The adaptive use of life long psychopathology (e.g., schizoid and obsessive mechanisms), maladaptive prior to the aging period, was observed. Maintenance of a functional sense of identity seemed to be crucial to successful adaptation. An apparent alternative to the shattering of functional identity was the acceptance of a stereotype identity of an aging person. In addition to age crises in identity, severe psychological isolation and depression were especially frequent maladaptive clinical patterns.

In contrast to other age groups where diagnosis is reasonably predictive of adaptation, in the aged the discrepancy between diagnosis and adaptation seemed to be

much greater, suggesting a need for revision of diagnostic assessment in the aged. There was evidence of the importance of evaluating the relationship of morale to the nature and effectiveness of adaptive techniques in the contemporary aging experience.

Social Psychology (14). Previous notions to the effect that arbitrary retirement per se results in unfortunate consequences require qualification, according to this study. It was found here that it was the man who arrived at retirement through conflicting internal and external pressures who seemed to suffer the most ill effects.

The familiar sociological groupings of educational and occupational levels and ethnic classifications were not found to be related to highly differentiated patterns of function. In short, there appeared to be a "leveling" which may have resulted partly from the tendency for these men to drop their specializations, to find similar hobbies, to use common recreations afforded by the culture and to engage in many "maintenance" activities of the household. Inner resourcefulness in finding sustaining involvements was by no means the sole property of the more educated among these men.

Factors of the immediate environment were found to be very closely related to the aged person's behavior and attitudes. As the environment shows qualities of deprivation or displacement of the person (in loss of intimate persons, loss of income, in cultural displacement), the attitudes and behaviors of the aged show more deteriorative qualities and/or depressive manifestations. Losses of significant persons are especially associated with deteriorative functioning. In light of the findings on the effects of the immediate environment, the question of life setting influences might be refined. It seems probable that different life settings (group or family culture, education, etc.) build up, selectively and specifically, different strengths and vulnerabilities in the individual; also that different settings of earlier adult years make the occurrence of certain environmental circumstances in old age more or less likely.

Intercorrelations. Here we can only detail a few of the more provocative and significant findings, or lack of findings, of inter-

relationships between the various disciplines. There was evidence suggesting that in the presence of cardiovascular disease increased blood pressure tends to protect against the slowing of the EEG (*cf.*, *Medicine* section).

There was a lack of correlations between cerebral circulatory and metabolic variables on the one hand and EEG measurements on the other hand which was probably the consequence of the absence of notable pathological changes in this select group of healthy old volunteers. It is considered likely that the EEG is influenced by circulatory and metabolic factors but probably only when pathological processes intervene to produce cerebral vascular insufficiency and hypoxia. Although there was evidence of such processes in the arteriosclerotic subjects in Group 2, the decrease in blood flow was nevertheless still of insufficient magnitude to limit the cerebral oxygen consumption or influence the EEG.

There was also a general absence of correlations between physiological variables (*e.g.*, EEG measurements) and the general intellectual factor. Again it was felt that such correlations which were expected would be more likely to appear in a population with greater pathology. There was, however, a correlation of .55 between the cerebral metabolic rate and the general intellectual factor but this occurred only in Group 2. The interdisciplinary investigation failed to provide a neurophysiological basis for the apparent decline in speed of response in the healthy aged.

It was of considerable interest that psychiatrically evaluated depression was significantly associated with mean reaction time at the .05 level. This finding is consonant with most writings reporting relationships between depression and psychomotor and physiological retardation. There was not, however, any relationship between depression and cerebral circulatory, metabolic or electrical measurements.

Coupled with the findings that health status and increased arterial blood pressure also significantly correlated (and decreased audition interacted) with mean reaction time, the question arose as to whether the hypothesized slowing of speed as a CNS process characteristic of aging required

qualification. In any event, it is most important to consider this question since it is reasonable to suppose that effects intrinsic to aging are less likely to be subject to modification than are the causes and effects of morbid states.

Individuals evaluated as showing senile qualities were found to show statistically significant reductions in cognitive test scores compared to their non-senile peers but senile quality did not affect speed of response. There was some evidence to support the belief that cerebral arteriosclerosis with consequent reduction in cerebral blood flow and oxygen consumption was one pathway in production of manifestations of senility, perhaps prodromal to the development of an organic brain disorder. However, senile manifestations could not be totally explained in this way. There were individuals with early senile manifestations who did not have diagnosed arteriosclerosis or evidence of cerebral circulatory or metabolic changes. We are left with the realization that both senility and arteriosclerosis are fairly common occurrences in old age and that they may not, in fact, bear any essential pathogenic relationship to each other. It would seem reasonable to conclude, however, that when arteriosclerosis does occur with sufficient intensity cerebral circulation and metabolism are affected and senile manifestations may be produced (15). Other pathways to senility are possible. Either a non-vascular, neuronal degeneration, or a functional basis may be hypothesized.

Significant relationships which were found between measures of cerebral physiology and measures of social functioning were unexpected. Specific dimensions of organization of daily activity, maintenance of goals in living and maintenance of social contacts, as well as a summary score of social responsiveness, each significantly was associated with one or more of the physiological measures of cerebral blood flow, cerebral oxygen consumption and cerebral glucose consumption.

A significant association was found between contemporaneous environmental deficits as measured by the social psychologist and depressive trends as evaluated by the psychiatrist. A significant correlation was found between mean reaction time and

severity of environmental deficits ($r=.35$). There was also a significant association between principal component IV ("mental speed time") and environmental deficit ($r=.31$). It is suggested that the effects of losses may be mediated through the depressive state of the individual which in turn may be responsible for the slower reaction time.

SUMMARY

Old age is a period of rapid, profound and multiple changes of varying intensities, physiological and social, which influence subjective experience, behavior and adaptation. Characteristics possessed prior to old age modify the extent and the nature of these influences but do not fully account for the changes themselves. Clarification of the nature of these changes and their age-specificity is exceedingly difficult since chronological aging is imbedded in a matrix of many other factors ranging from social to physiological.

In general this sample, as might have been expected from its selection for medical health and social competence, was quite different from other samples of aged reported previously. The belief, for example, that cerebral blood flow and oxygen consumption necessarily decrease as the consequence of chronological aging per se was not confirmed: rather it was found that when such changes did occur they were the probable result of arteriosclerosis. Although some EEG changes occurred, particularly a showing in peak frequency, they were minimal and again became marked largely in the presence of arteriosclerotic disease. Cognitive performance in this sample compared favorably with the young but the psychologists found evidence of some slowing in speed processes as a consequence of aging. Moreover, psychometric tests appeared unusually sensitive to the presence of minimal disease states including arteriosclerosis. Whether alteration in speed is an intrinsic process associated with aging and whether it is a centrally-occurring process may require further clarification. Environmental deficits, health status, arterial blood pressure, depression (and indirectly audition) were major factors that did influence both mean reaction time and a general speed

factor which was extracted by means of a principal component analysis from the psychometric data.

Social, personality, and health variables would therefore appear to be of considerable importance towards explaining the manifestations of aging. Indeed, it was very striking to us that in a population purposively biased in its selection for medical health and community-residence the powerful influences of these factors would still be revealed.

It is a fundamental problem in geriatric medicine, including psychiatry, to determine how to extract aging from other factors producing overt manifestations of disturbance. It is of particular interest to the psychiatrist that disease, particularly arteriosclerosis, sensory deficits and social deprivation, has far-reaching effects; these findings are important both to evaluation and to the conduct of any treatment and care program (16). If arteriosclerosis should become preventable or reversible, for example, the entire façade of aging may change surprisingly.

Our broad conclusion may be stated as follows: As a consequence of a careful multidisciplinary pilot study, we have found evidence to suggest that many manifestations heretofore associated with aging per se reflect instead medical illness, personality variables, and social-cultural effects. It is hoped that future research may further disentangle the contributions of disease, social losses, pre-existent personality, so that we may know more clearly what changes should be regarded as age-specific. Indeed, various types of investigations, complementing one another, would be useful. Intensive studies, involving frequent contact over considerable periods of time, based upon the growing personal relationship between the investigator and the older person, would contribute to our understanding of the subjective experience of aging and approaching death (16, 17). Longitudinal studies, of course, would enhance our opportunities of classifying changes as to whether they are age-specific, disease-linked, etc. Our own follow-up, after 5 years, is nearly complete and added new dimensions, notably data pertinent to mortality and survival (2). If we can get behind

the façade of chronological aging we open up the possibility of modification through both prevention and treatment. In our lifetime (if at all) it is not likely that the inexorable processes of aging will be amenable to human intervention but it cannot be too greatly emphasized that it is necessary to be able to recognize those factors which are open to change.

A COMMUNITY PROJECT FOR THE COOPERATIVE CARE OF MENTAL HOSPITAL PATIENTS: THE COOPERATIVE CARE PROJECT¹

JULES V. COLEMAN, M.D.²

A group of five agencies, including the Connecticut Valley Hospital of the Connecticut State Dept. of Mental Health, the psychiatric clinic of the Grace-New Haven Community Hospital, Family Service of New Haven, the Visiting Nurse Association of New Haven, and the Bureau of Vocational Rehabilitation of the Connecticut State Dept. of Education, have established a community project for the cooperative care of New Haven residents admitted to the State mental hospital. Under the sponsorship of the New Haven Community Council, the main purpose of the project is to assure a high level of continuous service for patients and their families from the time the patient enters the hospital until, after return home, treatment or service is no longer needed. It is assumed that it might be possible to prevent chronic psychiatric disability by the services the project provides.

Project funds have been used to add an extra worker to each of the five "project" agencies, so that time is available for coordinated activity and for additional service. When a resident of New Haven is admitted to the hospital, he is seen by one of the project workers to learn about the circumstances leading to admission, and to obtain information about the patient's family. A home visit is soon made to the patient's family, either by a social worker or a nurse one of the project agencies to ascertain the family's need for service and to make appropriate disposition, either for continued

service by the visiting worker, or by referral to another community agency. On leaving the hospital, the patient is usually referred to the psychiatric clinic of the Grace-New Haven Community Hospital for aftercare treatment. Family Service and Visiting Nurse Association also deal with aftercare problems of patients and families, cooperatively with the clinic, or at times on their own, with the clinic carrying medical responsibility if consultation is needed.

Agency workers visit the hospital regularly to establish close working relations with the hospital staff, to discuss problems of patients and their families, and to get to know the patients themselves. Cases referred to Family Service, Visiting Nurse Association and psychiatric clinic are accepted on an integrated basis, *i.e.*, they are assigned to members of the entire staff in the same way as other cases. Psychiatrists on the staff of psychiatric clinic, as well as psychiatric consultants of the agencies themselves, are available for consultation on all cases assigned to project agencies, or any other agencies which are dealing with the problems of a project patient or his family. Homemaker service is provided by Family Service to assist a female patient in again picking up her responsibilities as a mother. The rehabilitation counselor does vocational testing, guidance, and job evaluation and placement. She keeps in touch with other agencies and employers to learn of job openings, company and union policies, job training opportunities, attitudes about hiring ex-mental patients, *etc.*

The patients come mostly from lower and working class families. From the point of view of their problems, they fall into three large groups: 1) those with a primary diagnosis of alcoholism, about 35% of admissions; 2) those with a broad range of "functional" psychiatric conditions, including the schizophrenias, depressions, personality disorders, and acute transient, situational reactions, representing about half

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

The project was made possible through the financial assistance of the National Institute of Mental Health through a 5-year grant.

² Clinical Professor of Psychiatry and Public Health, Yale University School of Medicine; director, Cooperative Care Project. Co-directors are Mr. John Nichols, executive director, Family Service of New Haven, and Dr. Charles Meredith, asst. superintendent, Connecticut Valley Hospital.

the admissions; and 3) patients with disorders associated with the aging process, about 15% of the admissions, and with a high mortality rate. The hospital seemed to be an appropriate resource only for the "functional" disorders, and it was felt that the other two groups would be better served in other, local community facilities.

At this point, I shall discuss the assumptions and hypotheses which form the basis of the project, in the light of almost 1½ years' experience. We have not established a new service but a new pattern of community cooperation and endeavor. The project represents a community commitment to become professionally involved in the problems of the mentally ill and their families. Community agencies had been active in extending care to many of the families of the mentally ill, and often to patients, too, but never in a systematic, inclusive fashion. The decision to offer routine service to families was founded on the assumption that psychiatric illness, particularly in the form of the acute episode, depends on a disturbance in the interaction of the patient with other members of his family, or with other significant persons. It was thought that such disturbance led to a series of aggravation of the problems of all members of the family to the point where it seemed necessary for the patient to be hospitalized.

We are accustomed to look at the patient as the primary if not the exclusive focus of interest. In the project, however, we assume that the patient reacts in a situation over an extended period of time, and that all significant elements in the situation are of equal interest in understanding and treating the mental illness. The "elements in the situation" will generally be the members of the patient's family with whom he shares important relationships. We also assume that the moment of hospitalization represents a climax of aggravated tensions, and that participant study of the situation at this point is necessary both for diagnostic and therapeutic reasons (to understand what has happened, how it has happened, and how it might be put right). In other words, we assume that the acute symptomatology of the illness (as differentiated from the ingrained, characterological reaction modes) is the end-result of a process of

struggle within a family group for assertion and validation of competing needs, and that the outbreak of fresh symptoms represents partly a cry for help (by more than one member of the family, or perhaps just by the patient himself), and partly a reaching out for new and better adaptive measures.

Hospitalization would seem to be more often prompted by a convergence of circumstance than by medical indication, if such exists at all in this field. The major use of the mental hospital is as refuge or asylum in the face of an unbearable situation; and the most sensitive and reliable indication is the patient's own need to be away, a need which to be sure is not always easily expressed. Persons with vulnerable personality organization are most likely to develop acute psychotic or other deeply disturbed reactions, which usually resolve spontaneously as anxiety is allayed, in hospital or out. These are occasions when the social buttressing ordinarily available begins to fail the patient, and he reaches out for any other means of support, protection, refuge, or escape he finds at hand.

There is no suggestion here that patients will not continue to need hospital care, or that hospitalization as such is in any way undesirable. What we are interested in is a re-evaluation of the relationship between the hospital and the communities which send them patients, as well as of the functions of the hospital and community agencies in the coordinated care of mental illness. It is of interest, in this connection, that once hospitalized the patient generally ceases to be of concern to the community. It might be said that throughout the history of the State mental hospital program in this country, the patient has had relatively few and relatively inadequate services to help him maintain his ties to family and community; and that there has been a conspicuous lack of established procedures for re-integrating him into life in the community, of helping him to regain his place in his family or on his job. These services have been present in New Haven but not as an organized effort toward helping the mentally ill patient and his family, so that one might say that the psychiatric patient has been more or less neglected by the service agencies of the community. Basic to this

neglect is the assumption that the psychiatric patient is the responsibility of the hospital and not of the community.

In the project, we say that the community joins the hospital in sharing responsibility for the care of the patient, and one may ask, what does this mean, how is one to think about it? It is useful to keep in mind that the hospital is a closed institutional system, with norms and standards for the patient's adaptation and improvement which are based upon staff's knowledge of his response to the experience of hospitalization. The hospital's compact with the patient is that he achieve an expected level of adaptation to hospital living, whereupon he will be permitted to leave, conditionally, *i.e.*, remaining under continued medical supervision, or unconditionally. The hospital has no way of interesting itself meaningfully in the patient's family, or in the patient's life at home and in the community, since it cannot in its practice simultaneously encompass two different cultures, that of the hospital and that of family and community. Where hospital staff maintain contact with patients after they leave, they readily find themselves attempting to continue institutional controls, *e.g.*, by mandating on frequency of visits, or by continuing medication for indefinite periods. There is no doubt that these are useful procedures for many patients whose dependency needs or whose fear of their own impulses lead them to welcome such controls, but they are also both undesirable and

ineffective for a great many others.

Community services, on the other hand, are characterized by a recognition and acceptance of individual autonomy as the distinctive value of life in an open community, and as the desired goal of treatment. It is assumed that regardless of his diagnosis, the patient will strive spontaneously toward the recovery of his sense of autonomy, and treatment procedures are oriented toward facilitating such tendencies. These two differing points of view, each having validity in its own time and place, are brought into coordinated relation with each other through the administrative devices of the project.

CONCLUSION

This has been a pioneering venture, in which a community undertakes to share responsibility for the mentally ill with its State mental hospital. In the project, we have developed routines and methods which take advantage of existing community resources to bring about greater coordination of effort in understanding and meeting the problems of patients and their families. Inevitably, a great deal of contact and exchange of views and information between hospital staff and staff members of the participating community agencies have taken place, leading to increased mutual understanding and acceptance. A new kind of team relationship of social agencies and medical facilities has been set up as an integral part of the project, for the benefit of the mentally ill patient and his family.

INTRAFAMILIAL DETERMINANTS OF DIVERGENT SEXUAL BEHAVIOR IN TWINS¹

ALVIN M. MESNIKOFF, M.D., JOHN D. RAINER, M.D.,
LAWRENCE C. KOLB, M.D., AND ARTHUR C. CARR, Ph.D.²

Studies of the influences determining heterosexual and homosexual behavior have focused on various aspects of the continuum of genetic, physiological, intrafamilial, and cultural factors (1-5). The broad assumption contained in these investigative efforts is that behavior derives from the organism's inherited biological makeup interacting with the physical, social, and familial environment. A goal of such studies is to isolate a particular pattern of behavior and then search for genetic predispositional configurations and the particular familial and social transactions leading to the overt behavior under scrutiny.

The study of twins is an admirable approach to this goal (6). Genetic studies have been concerned largely with the demonstration of the frequency of particular types of personality disorganization in one-egg co-twins of affected individuals as compared with the frequency of such disorder in two-egg co-twins and siblings, thus providing a measure of the genetic influence. Large scale investigations of consecutive series of monozygotic and dizygotic twins can indicate the degree of significance to be accorded to genetic transmission of a particular condition or trait. Thus, in schizophrenia, concordance in one-egg twins has been of the order of 86%, with two-egg twins in such series similar to siblings of different ages (7). In male homosexuality, one study (2) revealed over 95% concordance in 40 monozygotic twin pairs with only 11.5% in a comparable series of dizygotic pairs. Such findings emphasize the similarity of behavior in one-egg twins while providing the unusual opportunity for elucidation of those influences leading to apparently rare divergent sexual orientation in one-egg twins.

The present report is the second devoted to the examination of factors responsible for divergent development of behavioral traits in monozygotic twins. In our first report, two pairs of twins were studied (8).

The design of the study involves the examination of such twins using currently available physical, biochemical, and cellular techniques, psychological and psychoanalytic methods, including studies of the parents. These data are evaluated to determine possible correlations with the divergent behavioral trait. The material presented here is focused on factors possibly responsible for divergent sexual behavior. Clearly, such studies provide the unique opportunity for more precise isolation of significant intrafamilial determinants of psychosexual role in a group of individuals who are genotypically the same. The comparison of the developmental process of one twin with his co-twin and with other twin pairs presenting similar differences in behavior offers the additional possibility of determining whether some weighting, which may be designated emotional valence, might be given to postnatal transactions that influence the evolution of a particular sexual role. Similar valence may also be applied to experiences effecting the development of character traits, ego structure and defense mechanisms. Such studies require investigation of one-egg twins concordant and discordant for the trait, as well as of two-egg twins and siblings.

The potential value of this approach is evident, but its complexity must not be overlooked. Modification of gene action in one-egg twins may occur as a result of minor shifts in the balance of forces in the total chromosomal or nuclear structure which then perpetuate themselves by different biochemical pathways in the separated individuals. Intrauterine forces may affect one or the other of the two growing organisms before the postnatal influences of the family operate. Actually, such differential effect

² From the Dept. of Psychiatry, College of Physicians and Surgeons, Columbia University; and the New York State Psychiatric Institute.

in utero is more likely in monozygotic twins than in dizygotic twins because of frequent competition for the available maternal placental circulation(9). Interactional patterns during embryonic life may lead to gross phenotypic differences, broadly subsumed under the heading of expressivity. In an analogous manner, important intrafamilial influences affecting psychosexual development may be enhanced or diminished by subsequent life experiences. Thus, the pathway from a given genetic structure to the appearance of a behavioral trait in later life is indeed tortuous.

As Burlingham(10) points out, in their development twins are subjected to pressures which emphasize their similarities, closeness, mutual love, superior friendship, and uniqueness. Rivalry problems may be denied and minimized by the twins adopting the same desires and sacrificing individual drives. Jealousy generated between the twins exaggerates hostile death wishes, which in turn demand compensatory efforts at repression, resulting in the twins maintaining their close relationship. Such forces make it difficult for the twins to establish a clear self image as they usually tend to identify with each other. The ego development resulting from these forces has been designated by Kolb as "inverted identification"(11). Judging from Kallmann's studies of homosexuality in twins and psychoanalytic reports of ego development, the inverted type of identification is most frequently encountered as far as determination of psychosexual identity is concerned. The pressures toward sameness are great, but there are simultaneous pressures promoting differences in the twins. In noting differences, emphasis is placed on appearance, *e.g.*, one looking like the mother and one like the father; behavior, such as crying and greediness; intelligence; and character. Distinguishing features are important to the mother as she has a feeling of failure if she cannot tell the twins apart and adjust her interactions with the appropriate twin. This inability to distinguish the twins may be equated by her with lack of love. It would appear that these efforts to differentiate the twins are less potent than the influences toward sameness. Identification patterns affected by such influences may be called

"everted identification." In our study, it has been found that certain experiential factors have made more significant the twin differences, thus making possible divergent sexual development.

OBSERVATIONS

The data reveal certain intrafamilial determinants of divergent sexual behavior in four sets of monozygotic twins and one dizygotic male pair. Diagnostically, three identical male pairs were classified as psychoneurotic while the female one-egg pair and the two-egg male pair were schizophrenic. The same factors were studied in the two-egg as in the one-egg pairs to assay the influence of the intrafamilial experiences on divergent development. One homosexual and one heterosexual twin, not of the same pair, were in psychoanalysis. The female pair and the two-egg male twins were in psychotherapy. Except for one twin who was not available at this time, information from the other twins was derived from interviews. In three cases, data were obtained from the parents.

The genetic studies of zygosity were carried out by the similarity method of Smith and Penrose(12). In three male twin pairs the chromosomal sex was determined using specimens of the buccal mucosa(13). All agreed with the male phenotype. In one pair, steroid analyses with identification of 11 different substances was prepared on 24-hour urine specimens. These studies did not reveal any significant biological differences in the one-egg twins.

The intrafamilial forces which were examined were found variously, alone and in combination, to represent condensations and foci of parental attitudes, which later unfolded in interpersonal transactions influencing psychosexual role definition. It was not expected to find that in every family the focal points would either be the same or have equal weight since these points are reflections of the individual personalities of the parents and the structure of the family.

The data derived from the psychological and familial forces studied are presented in summary.

1. Prenatal fantasies and wishes of each parent as to the sex of the expected child.

In one male pair, the mother's prenatal wishes were strong and clearly expressed. She hoped for girls, influenced by the presence of two sets of female twins in the extended family group. After allocating the second born male, later homosexual, to be her "girl," she subsequently exclaimed, "That's why he is like a girl." In the female pair after initial rejection with an attempt at abortion, the parents resigned themselves to the pregnancy. When learning of twins, they wished for a boy and girl. On the birth of the twin girls, one was given a name similar to a boy. The fantasies of the parents in the other twins included either wishes for a boy where a girl was born the preceding year, or denial of any particular fantasy. Thus, in two of the monozygotic twin pairs the prenatal fantasies of the parents clearly failed to match the actual sex of the children.

2. Prenatal attitudes to twins' birth.

In one pair an attitude of rejection of the second born, later heterosexual, male was established at birth. The mother attributed to him the difficulties in parturition and difficult labor, blaming him for her subsequent invalidism. She bestowed preferential treatment on the first born, whom she felt was the weaker twin. In the other twins, the attitudes were those more usually found. They were a mixture of rejection of the twins as burdensome, with pride in them as evidence of sexual capacity.

3. The family significance of the naming.

In all four male pairs, the child whose name is most closely associated with the father evolved the masculine role. Naming, perhaps, is the clearest indicator of later identification patterns and eventual sexual role. In these families naming appeared to be a concrete manifestation of the allocation of the twin to either the mother or father. In one case where the homosexual twin was given one name after his father, it was later learned upon interviewing the parents that the heterosexual twin had initially received his first and middle name after the father. Later, feeling guilty about this obviously preferential distribution, the parents divided the father's name between the two. This change in names occurred after a physical distinguishing feature, a slight protuberance on one ear, already had clearly identified the second born twin that the mother had allocated to be her "girl." In the female pair, the first born and later heterosexually oriented twin was given the preferred name for the paternal grandmother, whereas, the second born was given a less valued name after a maternal

aunt. The latter name was then given masculine significance by being made similar to a boy's name, Roberta. This name subsequently became involved in the girl's delusional idea about being a boy.

4. Parental efforts at differentiating the twins.

The findings of parental anxiety leading to efforts to differentiate the twins were similar to those reported by Burlingham. With the differentiating features of prenatal fantasies, attitude toward the twin's birth, and naming, already noted, the search for distinguishing marks is especially significant as a means of concretely separating the twins. By this means, e.g., the mother could identify the twin who she felt had caused her difficult parturition, or the male twin whom she wanted to be her "girl," as well as to support the allocation of the twins noted in the names. Therefore, slight anatomical differences take on added significance.

5. The occurrence of physical distinguishing features in the twins.

In one male pair, a defective closure in the median labial fissure was slightly more pronounced in the maternally preferred and later homosexual twin. In another male pair, a protuberance on the right upper ear was used by the mother as a distinguishing feature and made it possible for her to identify easily the second born child whom she had wanted to be the female of the pair. In the third one-egg male pair, a birthmark on the lower back was noted in one twin, who also was found to have congenital heart disease. In this pair, the birthmark was used to identify the twin named for the father, whereas the mother's preference was for the physically healthy twin who helped her care for the sickly brother. In the single female pair, birthmarks on the upper lip and upper left forearm were sought out to differentiate the twins.

6. Emotional significance of such features to the parents and the extended family.

In the cases noted above, the twin with the distinguishing physical characteristics received greater handling from family members and others as these features were sought out in order to differentiate them.

It appears that the twin who received greater maternal care and handling, regardless of whether the twin was later to become homosexual or heterosexual, had greater ego security and more effective psychological defenses.

7. The differing object relations of the twins from birth.

In our series, the parental emphasis on differentiation influenced the subsequent object relations. Thus, in one male pair, the mother encouraged one twin to play with dolls, to learn dancing, and taught him to play the piano as she did. She discouraged him from activities that his brother, named for the father, engaged in, such as rough sports and play with boys. By the age of 6, the father stated it was clear that one was like a boy while the other was like a girl and he subsequently treated them accordingly.

A similar situation occurred in the female pair, where the twin with the boy's name attempted to find companionship with the neighborhood boys. She joined with them in games, was considered a valuable baseball player, and competed effectively with them. She rejected the role her sister had pre-empted, *i.e.*, assisting the mother, dressing like a girl, and having feminine interests, and attempted to find her place outside the home and as a boy. Later, with the onset of menstruation, she attempted to deny her sex and developed delusional ideas about being a male.

One heterosexual twin, rejected by the mother, found a sympathetic and non-threatening relationship with his nurse. In his psychoanalysis, this relationship was found to be significant in facilitating selection of females as genital object choices.

In one pair, the heterosexual twin had congenital heart disease and, at age 10, contracted poliomyelitis and rheumatic fever. Here, the physically healthy twin was severely inhibited in the expression of rage toward his sickly brother and shared with the mother in his care. Later homosexual, the healthy twin never enjoyed competitive sports, followed in the shadow of his ill brother, and had severe inhibition in assertion and in claiming credit for his work.

8. Attitude of twin to his body, to his self as perceived and as seen ideally.

In the three one-egg male pairs, both twins maintained a critical attitude toward the body. The heterosexual and homosexual twin who were in psychoanalysis revealed greater dissatisfaction than their co-twins. The two homosexual twins who were not interested in therapy and who apparently accepted their sexual roles found less dissatisfaction with their bodies, expressed a narcissistic satisfaction with the male physique and critically commented on the "unattractive" female body.

In the female pair, the homosexual twin, unlike her sister, was confused about her genitalia, denied the female body structure, and in her delusion, sought to repair the imagined castration by having a substitute penis displaced to her forearm, where she felt she had a vein like a boy.

9. Fantasy life of the twins, particularly in the sexual area.

In two male cases, the fantasy life of the homosexual twin was exclusively homosexual and the sexual relationships were consistently so. In these cases, the initial factors in the selection of the twin for his sexual role occurred in the prenatal and immediate post-natal period. Their acceptance of homosexuality and the unwillingness and lack of motivation to change was profound.

In the third psychoneurotic pair, where the homosexual twin was less closely tied to the mother whose interest and concern also rested on his brother with heart disease, his later behavior involved the aggressive role with rectal intercourse, emphasizing the power aspects of the relationship. The diminished intensity of his feminine identification reflected the influence of the father, which attenuated the effect of the maternal relationship.

In the female pair, the homosexual twin fantasied herself as a boy in relationship to the female.

10. Super-ego growth of the twins, especially in relation to allowed and prohibited forms of sexual activity.

In two cases, prohibitions against homosexual activity (provided by the father, the major object choice) were internalized, while the twin selected by the mother and identifying with her accepted her permissive attitude toward homosexual interests and her prohibitions against heterosexual objects. In one case, when the homosexual twin began a career in ballet, he was warned by the mother not to marry as it would interfere with and ruin his career. Similarly, the mother of another homosexual twin warned him of betrayal by girls he would meet.

The differing super-ego attitudes were also reflected in the twins' relationship to each other. In three cases, the homosexual twin struggling with his libidinal ties to his twin, attempted to influence him toward homosexual activity. One twin commented, "Twins are the same," as he tried to seduce his brother into homosexuality with the expectation that his brother would be similarly interested. The

In one male pair, the mother's prenatal wishes were strong and clearly expressed. She hoped for girls, influenced by the presence of two sets of female twins in the extended family group. After allocating the second born male, later homosexual, to be her "girl," she subsequently exclaimed, "That's why he is like a girl." In the female pair after initial rejection with an attempt at abortion, the parents resigned themselves to the pregnancy. When learning of twins, they wished for a boy and girl. On the birth of the twin girls, one was given a name similar to a boy. The fantasies of the parents in the other twins included either wishes for a boy where a girl was born the preceding year, or denial of any particular fantasy. Thus, in two of the monozygotic twin pairs the prenatal fantasies of the parents clearly failed to match the actual sex of the children.

2. Prenatal attitudes to twins' birth.

In one pair an attitude of rejection of the second born, later heterosexual, male was established at birth. The mother attributed to him the difficulties in parturition and difficult labor, blaming him for her subsequent invalidism. She bestowed preferential treatment on the first born, whom she felt was the weaker twin. In the other twins, the attitudes were those more usually found. They were a mixture of rejection of the twins as burdensome, with pride in them as evidence of sexual capacity.

In the female pair, the homosexual twin, unlike her sister, was confused about her genitalia, denied the female body structure, and in her delusion, sought to repair the imagined castration by having a substitute penis displaced to her forearm, where she felt she had a vein like a boy.

9. Fantasy life of the twins, particularly in the sexual area.

In two male cases, the fantasy life of the homosexual twin was exclusively homosexual and the sexual relationships were consistently so. In these cases, the initial factors in the selection of the twin for his sexual role occurred in the prenatal and immediate postnatal period. Their acceptance of homosexuality and the unwillingness and lack of motivation to change was profound.

In the third psychoneurotic pair, where the homosexual twin was less closely tied to the mother whose interest and concern also rested on his brother with heart disease, his later behavior involved the aggressive role with rectal intercourse, emphasizing the power aspects of the relationship. The diminished intensity of his feminine identification reflected the influence of the father, which attenuated the effect of the maternal relationship.

In the female pair, the homosexual twin fantasied herself as a boy in relationship to the female.

10. Super-ego growth of the twins, especially in relation to allowed and prohibited forms of sexual activity.

In two cases, prohibitions against homosexual activity (provided by the father, the major object choice) were internalized, while the twin selected by the mother and identifying with her accepted her permissive attitude toward homosexual interests and her prohibitions against heterosexual objects. In one case, when the homosexual twin began a career in ballet, he was warned by the mother not to marry as it would interfere with and ruin his career. Similarly, the mother of another homosexual twin warned him of betrayal by girls he would meet.

The differing super-ego attitudes were also reflected in the twins' relationship to each other. In three cases, the homosexual twin struggling with his libidinal ties to his twin, attempted to influence him toward homosexual activity. One twin commented, "Twins are the same," as he tried to seduce his brother into homosexuality with the expectation that his brother would be similarly interested. The

rejection of this entreaty proved to be significant in establishing a heterosexual orientation and was a source of self-esteem to the heterosexual twin in the struggle for identity and separation. These twins lived together and the open flaunting of his sexual activities by the homosexual was significant in establishing for the heterosexual twin his sense of being different, thus reinforcing his identification with the father.

In each of the male cases, the mother was the dominant parent. The father was openly and actively derogated in three cases and in the fourth assumed a passive role in the family. In these instances, the child associated with the father was identified with a dependent and unaggressive male figure. This identification, begun early in life and supported by subsequent events, was influential in permitting separation of the twins with regard to sexual role.

In the three psychoneurotic male pairs, ego security was greater in the twin receiving greater maternal care. In two cases, the twin was homosexual, whereas in the third, the sick twin with congenital heart disease became heterosexual. In the latter case, although the sick twin received greater maternal care, he was able to carry to fruition his identification with the father. In the two-egg male pair, who were schizophrenic, the maternally preferred homosexual twin was also the more secure and assertive. The separation of these twins led to the first psychotic decompensation of the heterosexual twin. Later, the homosexual brother became psychotic (14). In the female pair, the girl closest to the mother was more successful in maintaining her integration, although both were periodically psychotic.

In the two cases in psychoanalysis, one homosexual and the other heterosexual, not of the same pair, dynamic factors were ascertained which influenced the outcome of the oedipal conflict. In the case of the homosexual twin, his repressed rage at his sick brother who got extra attention was joined with guilt over his sexual attraction to his openly seductive mother, to which he responded by withdrawal. At the onset of adolescence, he felt betrayed by his mother who engaged in a much publicized affair. Disappointed and shamed by his mother, burdened by repressed rage at his brother, and inhibited in realistic assertion, he adopted an aggressive position in homosexual activities by engaging as the active partner in rectal intercourse.

In the other case, the heterosexual twin, rejected by his mother, adopted a passive attitude in the oedipal period, accepting his

brother's preferential position with his mother. However, he was not without some encouragement in his relations to women, having had the opportunity for closeness with a surrogate mother figure.

One additional case of divergent sexual behavior in one-egg twins has been brought to our attention by Professor L. A. Hurst of the University of Witwatersrand, South Africa. The twin closer to the mother was also homosexual. In his object relations, he was directed toward playing with girls as a child. At age 6, he wanted to be a girl and had desires to dress in girl's clothing. Later his longings to change his sex were more pronounced and he entertained the hope of undergoing an operation to become a female. The heterosexual twin was more outgoing and associated with male playmates. The homosexual twin's sexual fantasies were of himself as a girl and he experienced no erotic arousal with females. Information regarding parental prenatal fantasies, naming, and anatomical difference were not available.

DISCUSSION

It must be emphasized that the finding of suitable subjects is most difficult for this type of case study. In this small series of four identical twin pairs, only two twins were available for psychoanalysis, one heterosexual and one homosexual, not from the same pair. Complete analysis provided insight in depth and brought forth with singular clarity the importance of early object relations for establishment of sexual identity. The complex interplay of the initial foci with later events, adding to or decreasing their effect, can only be traced by the detailed investigation permitted by the psychoanalytic tool. In the cases not so studied, the finding of similar influences suggests that these factors may be significant hallmarks reflecting the underlying transactions between the parents themselves and the parents with their children. However, it must be pointed out that the analytic process alone failed to elucidate important factors concerning the parental fantasies, naming, and anatomical markings.

Freud postulated homosexuality as resulting from the interaction of constitutional and environmental factors. Subsequently, other investigators have focused on various aspects of this continuum emphasizing the importance of particular genetic or experi-

ential influences. Psychoanalytic formulations have emphasized oral fixation(13), the identification process, the oedipal conflict (1), dependency and power strivings(16), pre-adolescent relationships(17), and parental permissiveness toward homosexual activities(18).

In the present report, study of parental personality patterns and attitudes unfolding in transactions with their twin children reveal certain salient factors. Thereby, several factors are suggested as being generally significant and perhaps fundamental in revealing important areas affecting the development of specific behavioral patterns. These factors are the prenatal fantasies of the parent with regard to the sex of the twin, the difficulties occurring in parturition, the naming, the anatomical differences, and the position of the father in the family. These forces set in motion a series of transactions which leads to the preference of one twin by one parent and the other twin by the other. Once established, these attitudes are reinforced by subsequent transactions affecting the rearing of the child. These attitudes are carried over into the types of object relations encouraged by the parents and their activities in the home and with other children, thus developing into a consistent pattern. Such transactions affect the intensity of the oedipal conflict and its outcome. It appears that the pre-oedipal identification with the mother may lead to avoidance and repression of erotic interest in females which also effects later sexual experimentation. Prohibition against homosexual activity seemed to be effective in preventing eruption of such behavior only in the cases of the twin associated with the father, whereas prohibition against relationships with girls seemed to determine the choice of sexual object and sexual acting out in the homosexual twins. Where attenuating dynamic factors operated, as was the case in one homosexual twin, he was less rigid in his homosexual orientation and more subject to favorable outcome in psychoanalysis.

Accepting the complexity and the limitations due to the rarity of such twin cases, this study reveals certain intrafamilial determinants of divergent sexual behavior in four sets of one-egg twins and one two-egg

male twin pair. The data were obtained from psychoanalytic and psychotherapeutic treatment, interviews with the parents and the non-treated twin, psychological tests, and biological tests for zygosity. Certain factors, alone and in combination, were found variously to represent condensations and foci of parental attitudes later to unfold in interpersonal transactions determining psychosexual role definition.

The male twin who became homosexual was most closely associated with the mother. Forces leading to such selection included: prenatal fantasies of the mother for a girl and allocation of one twin to this role; greater maternal care given to the weaker child; slight anatomical differences leading to easy identification and special maternal interest and handling; and difficulties in parturition leading to rejection of one twin. In all four male twin cases, the child whose name is most closely associated with the father evolved the masculine role. In the female pair, the first born, heterosexually oriented, was given the preferred name for the paternal grandmother whereas the second was given a less valued name and one with male significance. These factors appear to be significant focal points in the identification process. The pre-oedipal factors unfolding in interpersonal relationships influenced the nature and resolution of the oedipal conflict, attitudes toward playmates and activities, and later genital object choice influencing the eventual definition of the sexual role.

The male twin who was closer to the mother adopted the homosexual role, whereas the female twin closer to the mother was heterosexual. It is suggested that early prenatal and immediate postnatal association of the male twin with the mother leads to acceptance of the homosexual role with little interest in treatment or change. The male twin who identified with the father adopted a heterosexual role and in the case of the female, homosexual orientation with masculine attributes. In the families of the male twins, the mother was the dominant partner with the father playing a passive role or was actively derogated by the mother. However, out of such conflict may arise strivings in the twin who identifies with the father to attain an ego

ideal of the appropriate social and biological role, even though the parental stimulus was relatively weak or degraded as was the case with the degraded father figures in this study.

Generally, the twin who received the more active mothering had greater ego strength and adaptive capacity and more effective psychological defenses.

Findings in the two-egg male pair similar to those in the one-egg male pair lend support to the hypothesis that in the cases studied the intrafamilial experiences are significant determinants of the sexual role.

A SURVEY OF SELECTED GERIATRIC-PSYCHIATRIC FACILITIES IN NORTHERN EUROPE

PART I: ENGLAND

STANLEY H. CATH, M.D.¹

Under the sponsorship of the Boston Society for Gerontologic Psychiatry² an attempt was made to determine both current status and foreseeable progress in attitudes, practices, and facilities in caring for the aged in the following lands: England, Norway, Sweden, Denmark, Holland and France. A personal interest and objective was to learn of psychological attitudes towards, values placed in, and consequences of three-generational homes in differing cultures, and to compare them with our own. While this report is not considered in any way to be comprehensive, it could not be isolated from the general medical, sociological, psychological, cultural, political and economic way of life of the nations surveyed.

A survey is an attempt to gain knowledge of an external reality, but, as we see through our own particular observing lenses, what we see represents an evaluation restricted by one's prejudice, regulated by one's experiences and colored by affective responses related to the meaning and content, which may be particularly threatening if it is "in conflict" with cherished notions and expectations of how the observed should be. This then is a very personal account of my observations as they filtered through my own psychiatric lenses.

First in the itinerary were the British Isles. The number of people in England over the age of 75 has increased 25% in the last 10 years. Nearly 95 of 100 elderly people live in their own homes, either alone, with relatives or with friends. There is no doubt this is where they prefer to be,

and only if there is no one to help, and as a last resort will they reluctantly seek admission to residential homes(1).

Many of the "normal retired" in Great Britain, if fit and well, go to the southern coast where they may enjoy a more moderate climate(2). They rent small bungalows, usually with a little garden, but tend to remain isolated, often without either energy or interest in establishing new friendships. Generally they become acquainted with the people that are adjacent—over the garden walls, on either side or across the street, but less frequently with those "in back" or down the street. It is an English impression that English people seek and welcome isolation. As social workers have been, and still are, regarded predominantly as snoopers, it was thought that our type of general program for aging, so often integrated with case work, would not go at all well in Great Britain. On the other hand, domestic help through local authorities is usually available to people who are not able to care for themselves, and this is welcomed(3).

Dr. Davison, consultant geriatrician for Cambridge University, has pointed out in a recent publication that, historically speaking, the needs of the elderly nearly swamped the National Health Service when it was founded thirteen years ago(4). A great number of beds was needed, and the care of the chronically ill aged generally fell to the general practitioner. While he believes geriatrics should be realized as a specialty, the geriatric specialist's responsibility is, perforce, to return the patient to his home and the general practitioner as soon as possible. Accordingly, it is planned that complete care requires beds for long-stay cases, day hospitals for patients who can sleep at home, outpatient services and diagnostic services—usually based in the nearest general hospital. This must include physio- and occupational therapy departments. The aim of the country health offices

¹ Asst. Clin. Prof., Tufts Medical School, Secretary, The Boston Society for Gerontologic Psychiatry, Inc.

² The Boston Society for Gerontologic Psychiatry, Inc., was organized in July, 1960, by its President, Dr. Martin Berezin. The object of this group "shall be to further by all proper and legitimate agencies and means the study, research, teaching and clinical applications of the principles of gerontologic psychiatry."

of Cambridgeshire, for example, is to link the hospital, general practitioner and local authority by an integrated service. It is the responsibility of the state to care for the aged; but, as they cannot "legislate for loneliness and rejection," these are factors little attended.

Barton, *et al.* (5), tell us that in order to make it possible for most older people to stay in their homes, steps have been taken to provide assistance at many levels.³ The government does build housing units, often of the one-bedroom type. In England the family doctor's service is free, as are day centers and hospital clinics, which are increasing in number. Home services for the elderly include health visitors, home nurses, domestic help, sitters in, and volunteers who do laundry, medical dressings, help with bathing, and perform many, day-to-day chores including preparing meals; an Old People's Welfare Committee⁴ supplies information about available services.

"Assessment units" attached to general hospitals evaluate problems of geriatrics as they arise and a geriatric psychiatrist is available to all doctors and clinics for consultation.

In London I was received by Dr. Jeffrey Tooth, the principal medical officer in the Ministry of Health, and his assistant in geriatrics, Dr. C. A. Boucher. Approximately 30% of the mental hospital population is over 65. Most of the problems are not created by irreversible cases but by those who "with just a push" might be activated and would hopefully reduce hospital population by 50%. A great deal depends on the attitudes of the personnel, as most older people stay in the hospital longer than their physical needs demand. The duration of stay is at least 6 weeks, and they try to maintain a revolving-door policy so pa-

tients may come and go. As there is no overcrowding in any mental hospital at present in England, this policy seems effective. An effort is being made to break up large mental hospitals and make them part of smaller general units. It is expected this trend will facilitate geriatric care, thus taking the burden off mental hospitals.

Geriatric patients requiring inpatient care fall into 3 main groups, according to length of stay. Most hospitals admit all patients into a special unit or group of wards for investigation and treatment, and almost three quarters of these patients are now discharged within 3 months. This is called the "short-stay group." Others are transferred to wards that are usually situated in the main section of the hospital where 80% of the resident population are housed. The majority of these are able to leave within 2 years, and 4% of all discharges occur after the 5th year (6).

In English medical schools, as in ours, no special time is allotted to the problem of geriatric training. However, as doctors are being confronted more and more with the elderly, something will have to be done in a short time. Those who have become specialists usually have completed a year or two of work in a geriatric unit after their "qualification," as well as a year or more of post-graduate training. Occasionally, early in practice application for the post as consultant to a geriatric hospital is made, but this is not the general rule.

In Oxford I had a brief interview with Dr. L. Z. Cosin who lost no time in acquainting me with our "antiquated" geriatric practices in America. In his opinion, we are unaware particularly of the epidemiological problems involved and tend to make problems where none exist at all. His emphasis is on getting patients out of the hospital at any cost, but in the best condition possible, and returning them even to isolated rooms where they may be alone day or night, no matter if confused, dirty and generally regressed. It is at this point the English appear "one up" on us or meet the problem with practical—even if distant, by our standards—ingenuity. Dr. Cosin believes that most illnesses and psychological regression associated with aging are precipitated by the battle for [physical] sur-

³ *Impressions of European Psychiatry*, a new book by Dr. Walter Barton, *et al.*, which I had the pleasure to read just before I left for Europe, provided me with much valuable background and comparable data that enriched my own understanding of all that I saw. My indebtedness to these authors is great indeed, and with their permission I have quoted portions liberally where it seemed appropriate.

⁴ National Old People's Welfare Council, administered by Miss Bucke, 28 Bedford Square, WC1, London.

vival. One always has first to help calm the acute medical condition that has prompted the regression(5). Here at Cowley Road, under his administration, is a "particularly comprehensive unit" that is described as "remedial." Only 40 or 50 are in admittance at any one time and most of the survivors are successfully activated and, accordingly, expected to leave the hospital within a very short period. In fact, there are only 6 permanent beds for bed-fast patients. Interest is lacking in home care programs, but if a patient is returned to sleep alone at home and needs help, then volunteers are used, as described above.

The psychiatrist, then, is part of the medical team and engages almost in direct medical care. There are home visiting teams who attempt to keep people out of hospitals, but in this particular center in Oxford a most utilitarian setup exists: if someone is found at home in need of socializing, he will be picked up in the morning by bus, transported to a geriatric day hospital and returned home in the evening, on the theory that the family, if spared a full day's contact with a demanding, confused, senile patient, will be more able to tolerate him in the remaining hours together. Active treatment programs of occupational therapy are encouraged, but none of this takes precedent over the intensive medical care which is necessary to cope with the disorder that initiated the process. Every effort is made to restore and "maintain painless physical independence" and thereby keep the patient in the community, and it is surely in this regard that this setting is unique.

Barton gives the following picture of the movement of patients in and out of Cowley Road Hospital, as well as an orientation to care :

Possibly up to 40% of the patients first admitted will die, most of them in the first 30 to 60 days. In 90 days only 14 remain in need of full medical and nursing care. (The figure drops to 3% after 6 months.) Fifty percent of the survivors can be discharged, and only 18% require continued residence in the long-stay annexes. The others are soon up, ambulated, and seldom in the hospital more than 14 days.

Gradually, those who remain are moved successfully to less-staffed sections and may

be sent to an ambulatory care unit, if not home. As soon as a person can care for his own room and make a proper pot of tea, he is considered ready for discharge. Cosin uses five approaches to restore patients to independence :

1. Pathological and biochemical. He studies people to determine hypoxia, electrolytic imbalance, cardiac decompensation, *etc.*, and attempts to restore physiological equilibrium. He checks hemoglobin regularly and prescribes a high protein diet with high vitamin B intake. Even in his day center, he is said to be most careful about diet.

2. Psychological. He attempts to restore interest, relieve loneliness, and helps the individual feel wanted and important to someone.

3. Sociological. Attempts are expended to solve family problems and ease economic burdens.

4. Therapeutic. This is an acute comprehensive medical program—physical therapy, occupational therapy, *etc.*, graded as to what the patient can do, and small groups with social interaction as soon as possible. In addition, they have a 3-day geriatric hospital where a patient can be admitted for study alone and where others can come to recuperate, if only for a day.

5. Special Rehabilitation. Assessment is made of residual disability and, if feasible, steps are taken to restore as much self sufficiency as can be.

My informants cared little about the prevalence or significance of three-generation homes, or, for that matter, conflicts within the individual or his environs. The mention of dynamic problems led Cosin to discuss how we neglected our opportunity to work with older people by worrying too much about what happens to them. This general expectation that the patient will manage by himself and assume responsibility for his own care seemed strikingly inconsistent with the concepts of socialized medicine but in accord with the notion that long hospitalization may augment regressive changes and dependency. The value of this policy in terms of family stress or its effect on the course of the individual's life was not discussed. Psychotherapy seemed held in little esteem as a therapeutic tool.

COMMENT

A very personal impression is that English geriatric patients as a group seem to

demand less, are easier comforted and appear less regressed than many of their American counterparts. Whether this is, as Barton suggests, part of the British reaction to authority or related to other factors is not an issue here, but one should never evaluate such discreet observations as a necessarily desirable state of affairs. As McKenzie points out in his chapter in the same book on European psychiatry(5), Scottish school children are polite and respect authority, but at the same display extreme sadism to their fellow students. A deep conviction that the British have met a practical problem head on with all they have is shared, with the observation that they have only begun to scratch the surface. Their very respectable program is admittedly inadequate. In this observer's opinion, it is one that hardly maintains or exploits the dignity or potential worth of the elder citizen any more than does our own. Isolation, even with partial or complete self care, is no barrier to the increasingly regressive changes apt to occur without mental and social stimulation. Much evidence exists in England, as well as in the United States, for the need to be stimulated continually by interaction with others as a barrier to psychological regression and increased narcissistic withdrawal. Their approach does have the advantage of decreasing the communities' needs for hospitals and, accordingly, the financial ex-

penditures of the National Health Program. The attitude, "One cannot legislate for loneliness and unhappiness," unfortunately contains sufficient truth to discourage the kind of effort contemplated and already instituted in some cities by many American thinkers facing similar problems(7). I would agree the problem is not legislative by nature, but nevertheless requires intelligent legislation and planning for support. This would be directed towards making available "crisis consultation" at certain turning points in life when external forces may help tip the scales in unfavorable directions.

MALE HOMOSEXUALITY, PARANOIA, AND THE SCHIZOPHRENIAS¹

ROBERT A. MOORE, M.D., AND MELVIN L. SELZER, M.D.²

The possible role of homosexuality in the etiology of paranoia was described by Freud following his analysis of Dr. Schreber's autobiography published in 1911(1). From the simple, and consciously unacceptable statement, "I love him," he demonstrated the changes necessary for the patient's conscious acceptance that lead to various misconceptions frequently held by paranoids. By changing the subject, *i.e.*, "She loves him," the individual develops morbid jealousy, thus eliminating projection. Changing the object results in, "I love her," which by projection becomes, "She loves me," or erotomania. Changing the verb leads to "I hate him," which projected becomes, "He hates me," or delusions of persecution. Finally, protection is obtained by saying, "I do not love at all, I do not love anyone," which restated is, "I love only myself," leading to megalomania.

Considering the significance of these ideas, relatively little research has appeared attempting to prove or disprove the above, much of it suffering from strong opinion, small samples, or lack of adequate research design.

Theoretical papers have been contributed by Ferenczi(2-5) and others(6-10), including Freud's "Certain Neurotic Mechanisms in Jealousy, Paranoia, and Homosexuality" (1922) (11). Other authors have suggested modifications or entirely different causes for paranoia. Nunberg(12) suggests the sufferer wishes to counter his feelings of weakness by absorbing the other male's strength through fellatio. Salzman(13) sees a pathologic denial of low self esteem leading to grandiosity, then inevitable rebuff and projected blame leading to delusions. Szasz(14) emphasizes not homosexuality, but interest in one's own body as the last remaining object to which to relate. Ehrenwald

(15) sees these as symbiotic patients who have a choice of compliance with the omnipotent parent leading to passive homosexuality or rebellion leading to paranoia. Lastly, Knight(16) feels that before the love (of him) is hatred which is hidden by love of the father.

Papers of greater research orientation have tended to confirm the theoretical ideas of Freud(17-19) including several unpublished psychology doctoral dissertations(20-24).³ Others have not been confirmatory (25, 26). A study by Klaf(27) revealed equivocal results when women paranoids were examined. Most of the studies reported have limited themselves to males.⁴ Finally, Cameron has this to say in the *American Handbook of Psychiatry*: "When we come to the primacy of homosexual fixations (in paranoia) we encounter less contemporary agreement"(28).

Klaf and Davis(29), in their study of 150 male paranoid schizophrenics and 150 controls, found the paranoids were 7 times more frequently preoccupied with homosexuality, had twice the incidence of overt homosexual experiences, and had 8 times the recorded incidence of religious preoccupation (the significance of the latter to homosexuality was discussed by Freud in *The Future of an Illusion*(30)). In addition, 84.7% of the paranoids felt they had male persecutors, 5.3% female, and 10% both sexes.

In the foregoing study, the controls were non-psychotic, non-paranoid patients, *i.e.*, having 2 major variables from the test sample. Is it possible the schizophrenia-non-schizophrenia variable was as important a determinant as the paranoia—has a non-

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Dept. of Psychiatry, University of Michigan Medical School, Ann Arbor.

³ We are indebted to Howard M. Wolowitz, Ph.D., Univ. of Mich., Psychol. Dept., for the unpublished doctoral dissertation references.

⁴ A study of women paranoids by Moore, R. A., Benedek, E., and Wallace, J., using the same research design as this study and asking the same questions was abandoned due to inadequate records. Apparently, women paranoids and male psychiatrists are less likely to talk about homosexuality than male paranoids and male psychiatrists.

paranoid variable? Clinical observation repeatedly demonstrates the regressed state of ego functioning in schizophrenia, with archaic fusions of self and object world, ease of identifications, and amorphous sexuality. In discussing the mechanisms of paranoia relative to Schreber, Freud emphasized fixation to an infantile auto-erotic state in schizophrenia which he differentiated from paranoia, stating, "Moreover, it is not at all likely that homosexual impulses, which are so frequently (perhaps invariably) to be found in paranoia, play an equally important part in the aetiology of that far more comprehensive disorder, dementia praecox"(1). In any case, we felt it justified to reduce the variables by using only schizophrenics as controls.

Two hundred and five male schizophrenics hospitalized for intensive psychotherapy at the Veterans Readjustment Center, a Unit of the University of Michigan Medical Center, were chosen for the study. They do not represent all patients with schizophrenia admitted during the period 1946-1959. It is, however, a group selected only in the sense that they were schizophrenic without question according to current nomenclature. All charts were carefully studied independently by four raters and not used if one rater doubted the diagnosis.⁵

Of the 205 patients, 128 were paranoid. The 77 non-paranoid schizophrenic patients used as a control group consisted of 54 undifferentiated, 12 simple, 6 catatonic, 4 schizo-affective, and 1 hebephrenic. Average age of the paranoids was 30.0 years and of the non-paranoids 29.1. Seventy-five of the paranoids were married, 10 divorced, and 43 single, while 37 of the non-paranoids were married, 3 divorced, and 37 single.

Data used in the charts included hour by hour psychotherapy transactions, case conference summaries and opinions, psychological tests, social service histories, observations of behavior by nurses, and occupational and recreational therapists. Since no

consistent and specific effort was made to get information on homosexuality, this material was generally produced spontaneously during therapy. Whether this technique obtained data nearer the "truth" than asking specific questions is unknown. In addition, it is not possible to determine if theoretical expectation made the observers more sensitive to positive data regarding homosexuality given by paranoids.

The authors surveyed each chart looking for history of pubertal overt homosexual activity, occasional adult overt practice and predominant adult homosexuality. By homosexuality, we are referring to oral or anal practices or mutual masturbation. During psychotherapy, patients frequently raised the subject of homosexuality, perhaps feeling accused of this by others, accusing others, or wondering if they themselves were homosexual. We recorded if the subject was raised once, twice, or more than twice. While these items are relatively objective, the data, wherein the psychiatrist or testing psychologist stated that the patient was latently homosexual, were more subjective. For this, a positive rating required a specific recorded opinion by either the psychiatrist or the psychologist.

RESULTS

Table 1 shows a comparison of the data obtained from the 128 paranoid schizophrenics and 77 non-paranoid schizophrenics. There is a statistically significant greater incidence of total overt homosexuality ($P > .02$), total adult homosexuality ($P < .02$), and occasional adult practice ($P < .05$) among the paranoids but an insignificantly greater incidence of pubertal acts only and predominant adult homosexuality.

Paranoids show a significantly greater amount of homosexual preoccupation during psychotherapy, both for total amount, as well as where found more than twice ($P < .001$). They were judged significantly more often to be latent homosexuals by both psychiatrists ($P < .001$) and psychologists ($P > .001$) alone, and in total number allowing for over-lap of opinion ($P < .001$). Finally, taking all data and opinions, something positive regarding homosexuality was found in 78% of the paranoids and 47% of

⁵ We were assisted in the earlier case selection by Frieda Ramsuer, MSW, Supervisor of Social Service, and Marvin Brandwin, M.A., staff psychologist, both from the Veterans Readjustment Center.

TABLE 1
Comparison of Data Indicating Latent or Overt
Homosexuality

	(128) PARANOID SCHIZOPHRENIA	(77) NON-PARANOID SCHIZOPHRENIA	CHI SQUARE	P
Overt homosexuality	38 (30%)	12 (16%)	5.18	>.02
Puberty only	12 (9%)	6 (8%)	N.S.	
Adult	26 (20%)	6 (8%)	5.72	<.02
occasional	21 (17%)	5 (6%)	4.27	<.05
predominate	5 (4%)	1 (1%)	N.S.	
Homosexual preoccupation	78 (61%)	23 (30%)	18.57	<.001
Once during therapy	19 (15%)	5 (6%)	N.S.	
Twice during therapy	17 (13%)	9 (12%)	N.S.	
Over twice during therapy	42 (33%)	9 (12%)	11.49	<.001
Latent homosexuality	86 (67%)	29 (38%)	17.03	<.001
Psychiatrist's opinion	75 (59%)	20 (26%)	20.56	<.001
Psychologist's opinion	54 (49%) (111 tested)	17 (25%) (69 tested)	10.31	>.001
Positive history or opinion	100 (78%)	36 (47%)	21.33	<.001

the non-paranoids, a highly significant difference ($P < .001$).

In an attempt to find more graphic representation, an arbitrary point system was established on a basis of 0 to 10. Zero meant no suggestion of homosexuality and 10 the most positive suggestion possible from this type of data. One point was given for pubertal activity, 2 for occasional adult, 3 for predominant adult practice, 1 for preoccupation once in therapy, 2 for twice and 3 for more than twice, 2 for the psychiatrist's opinion of latent homosexuality and 1 for a similar opinion by the testing psychologist.

TABLE 2
Average Points by Marital Status and Diagnosis

	N	AVERAGE POINTS
Paranoid schizophrenia	128	3.63
Married	75	3.15
Divorced	10	2.80
Single	43	4.67
Non-paranoid schizophrenia	77	1.61
Married	37	1.16
Divorced	3	2.33
Single	37	2.00

Table 2 demonstrates that the paranoids had an average of 3.63 points per patient and the non-paranoids 1.61 points per pa-

tient. Conceivably, marital status could be a crucial variable. If by coincidence the paranoids were more likely unmarried, and if unmarried men showed greater homosexual orientation, it might mean we were comparing a group of largely unmarried men with a group of largely married men. The paranoia might be coincidental in the low-marriage group. However, the opposite occurs in that the paranoids rate higher in points per man and also are more likely to be married. It is noted that unmarried men in each group have a higher average point score.

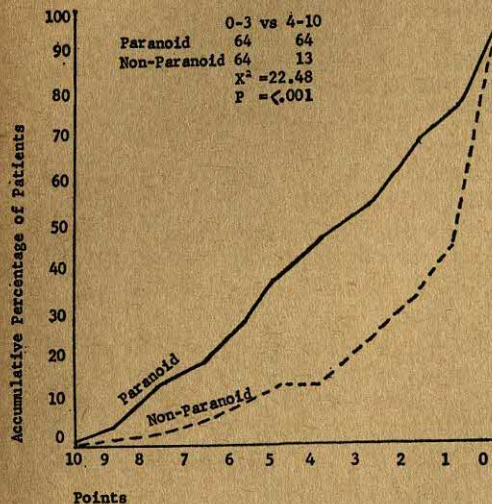

Figure 1 contrasts the differences in points per patient, plotting an accumulative percentage of cases against points per patient. The more the curve is to the left, the greater the homosexuality. At the mid-point for the paranoid group, 64 have 4 to 10 points and 64 3 or less. At this point, of the 77 non-paranoids, only 13 have 4 to 10 points with 64 3 or less. This difference is highly significant ($P < .001$).

COMMENT

These findings demonstrate a consistency in that each item studied for homosexuality—overt behavior, preoccupation, and examiner's opinion—is significantly higher for the paranoid schizophrenic group than the non-

FIGURE 1

Comparison by Points per Patient

paranoid schizophrenic group. Our results are in the direction of most previous studies, especially that of Klaf and Davis (27). The reservation we had of their study in which paranoids schizophrenics were compared with non-paranoid non-schizophrenics appears to be unjustified. The variable of schizophrenia versus non-schizophrenia does not seem to be a significant factor.

An important question remains when such subjective data are used. How many patients were not candid? The chances seem that a considerably greater number might be positively scored if our insight were greater. All that can be concluded is that the paranoids were more likely to *tell* of their overt experiences, more likely to *talk* about homosexuality, and more likely to *impress* the examiners with their homosexual traits.

The preoccupation with homosexuality usually involved a defensive reaction of projection, in the paranoids usually to a delusional degree. Still, the paranoids showed a higher incidence of *overt* homosexual behavior (30% versus 16%), something the paranoid mechanism is supposed to help them avoid. Unfortunately, the data did not reveal when the overt acts occurred, but it is our impression this was predominately earlier in life before the paranoid psychosis developed. This would be consistent with the concept of the paranoid system acting to prevent emergence or re-

emergence of overt urges. Overt homosexuality was rare during the florid paranoid psychosis.

The long held opinion that paranoia is a defensive device against unacceptable homosexual urges has been supported, but by no means proven by this study. This information may be helpful in planning the treatment of paranoids, particularly in an inpatient setting. Circumstances that point to or stimulate the paranoid's homosexual strivings often precipitate a storm. This would include assignment of the paranoid to a male psychiatrist with feminine mannerisms, admission to the same ward of an effeminate or overtly homosexual patient, inadvertent touching of the patient by the psychiatrist or another patient, startling the patient by approaching him quietly from the rear, and so on. During therapy, attempts to bring such urges to consciousness or the development of homosexual feelings for the psychiatrist may provoke an angry or frightened withdrawal or an increase in delusional thinking. Thus, with expectant "insight," it is possible to avoid those circumstances that may be too threatening to the paranoid. If we must handle the problem of homosexual feelings with the paranoid, we must do it more gingerly and supportively than with other patients.

It should be noted that there was some suggestion of homosexuality in 47% of the non-paranoid schizophrenics (Table 1). How much greater this is than would be found in a normal population is unknown since the techniques of this study could not be applied to a normal population. The results suggest that the non-paranoid schizophrenic may be very anxious in this area too. However, it seems generally easier to handle this fear more directly in therapy, perhaps, because we are usually less fearful of being frank with non-paranoid schizophrenics. Another significance of the finding of considerable homosexuality among non-paranoids is that the factor of defense against homosexuality cannot be the only decisive factor leading to a paranoid type of schizophrenia.

SUMMARY

Two hundred and five male schizophrenic inpatients receiving intensive psycho-

therapy were studied to determine the relative estimate of homosexual orientation between 128 paranoid schizophrenics and a control group of 77 non-paranoid schizophrenics. Previous theoretical and research publications suggested a difference would be found, and this was found to be true.

To a statistically significant degree, the paranoids showed greater incidence of past overt homosexual acts, preoccupation during therapy with homosexuality, and were judged latently homosexual more often by both psychiatrists and testing psychologists.

Anticipation of homosexuality as a great threat to paranoids aids in planning their therapy to avoid unnecessary storms or frightened withdrawal.

Since a considerable number of non-paranoid schizophrenics is also troubled by homosexual desires, latent or overt, other factors must be sought if we are to understand why paranoids are paranoid.

AN EFFECT OF RESEARCH TRAINING IN THE STUDY OF PSYCHIATRIC DRUG TREATMENT

RICHARD M. DUNHAM, Ph.D.,¹ AND KAY HOWARD²

Recently some results of a survey of the adequacy of reporting and design of chemotherapy research studies appearing in psychiatric journals were published(9). The present article will record the results of a supplementary analysis of the same data, completed after the first analysis had been presented at the fifth Annual Conference on Chemotherapy in Psychiatry of the Veterans Administration in March 1961. The basic article presented a general assessment of the literature. The authors hoped to encourage further interest in thorough reporting and methodological care, and also to encourage others to study the literature of psychopharmacology systematically and critically to understand and improve it. The more recent analysis provides results primarily of interest to psychologists and to persons responsible for the development or support of research in psychiatric drug treatment.

The reader may consult the original article for details of procedure and results. Briefly, however, the authors surveyed 6 psychiatric journals for the fiscal years 1957 and 1960 and identified articles (45 in 1957 and 61 in 1960) which were primarily concerned with the therapeutic value of tranquilizing and energizing drugs. Each article was subsequently read and reevaluated using a checklist based on "Recommendations for Reporting Studies of Psychiatric Drugs" (2).

The checklist included 28 items of information that might be expected to be reported in such literature; these dealt with treatment setting, the selection and description of patients, drug administration, and the evaluation of change. There were 7 additional items representing methodological features commonly considered desirable in psychiatric drug research; these were checks for the formal statement of a hy-

pothesis, evidence of concern for the reliability and/or validity of the assessment technique, the use of statistical analysis to avoid false conclusions, the double-blind procedure in drug administration and patient evaluation, definition of the criteria used in evaluating change, the use of control conditions, and the use of a companion substance (active or inert) as a form of control.

By tallying the reporting and the methodology items, it was possible to obtain an "R" score and an "M" score for each article. The R score, with a possible range of 0-28, indicates the amount of specific information reported; and the M score, with a possible range of 0-7, the number of well-accepted methodological features utilized in the work.³ The distributions of M and R scores for the 2 years are presented in Figure 1. As was predicted, a statistically significant ($p < .05$) improvement in reporting adequacy was found. However, the mean increase in R scores was attributable to an increase in the number of articles of modal reporting quality and to a relative decrease in the amount of very poorly reported literature, rather than to an increase in the number of very well reported articles. The bimodal distribution of M scores was not expected and did not support the prediction made in the original work that this type of literature was improving in methodological quality. On the contrary, in this area of publication there appears to be a large increase in the number of articles of the least methodological adequacy.

The present analysis was inspired, in part, by the bimodality of the M score distributions, a finding the more striking because it was unexpected and was repeated in both years surveyed. The bimodality suggests,

¹ Now at NASA-Manned Spacecraft Center, Langley Field, Va.

² Psychology Dept., Duke University, Durham, N. C.

³ The R and M scores seemed to be only minimally related. A scatter plot of M scores against R scores for each article did not suggest a relationship, except possibly that the highest M scores ($M=6.7$) were always associated with high R scores. *Eta*, which exceeds *rho* in such data, was 0.35 ($F=1.96$; d.f. 7.98; $.10 > p > .05$).

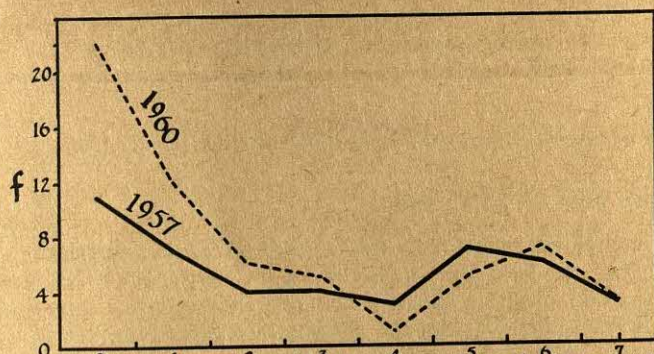

Fig-1 a. Comparison of M score distributions 1957-1960

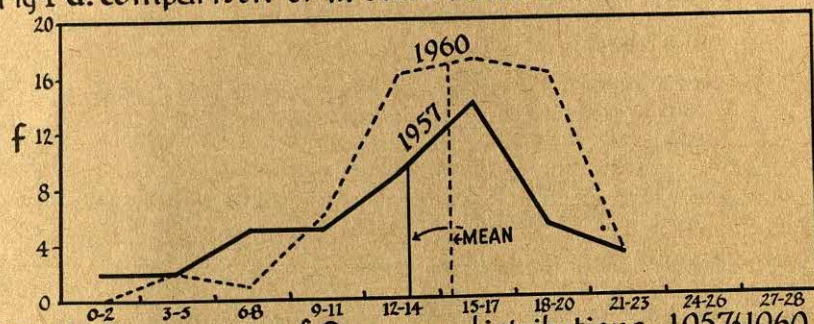

Fig-1 b. Comparison of R score distributions 1957-1960

of course, the presence of two unrecognized factors, one yielding a roughly normal distribution and associated with relatively sophisticated research design, and the other a J-shaped distribution of poorly designed studies. Another interesting consideration was the apparent constancy of area under the upper modal region in contrast with the increase in area under the lower mode.

From the original analysis, it was already known that 3 of the standard methodological features, use of the double-blind technique, use of control conditions, and the definition of evaluation criteria, were all associated with somewhat better reporting and much better procedure. Reasoning that the use of these features might be associated with the investigator's training in research design, the authors reviewed all the articles in the survey to determine as nearly as possible the training background of the investigators. Since it had also been established that articles originating in VA settings showed a similar pattern of somewhat higher R scores and definitely higher M scores, the type of setting of each article was also tabulated. The categories for type of investigator and setting are shown in Table 1, together

with the number of publications falling into each category for both years of the study. R and M score comparisons were made between categories. Formal directional hypotheses were not made, however, because no direct evidence on which to base predictions was known.

RESULTS

The results were first examined separately for 1957 and 1960, and where no statistically significant ($p < .05$) differences existed the data were pooled across years for simplicity of presentation. Because it was necessary to make a large number of t-tests in comparing investigators and settings with respect to M and R scores, a conservative level of significance ($p < .01$) was adopted to minimize the risk of falsely concluding a difference existed. Since there were no directional hypotheses, probability levels reported are for two-tailed tests.

Among the investigator categories, in both 1957 and 1960, the largest number of articles falls in the *MD Only* group (see Table 1). Furthermore, the increase from 1957 to 1960 in number of articles published occurs entirely within the *MD Only* category. The

TABLE 1
Definitions and Frequencies for Categories of Investigator and Setting

CATEGORY	DESCRIPTION	f	
		1957	1960
Investigator			
MD only	All authors listed only an MD degree.	19	41
PhD author	One or more of the authors had a PhD, no doubt usually in psychology. (In a few cases there were no MD's among the authors, but for the large majority of articles falling in this category the implication is that technical training in medicine and also in research design were represented in the team responsible for the research.)	13	13
PhD acknowledged	No PhD author, but the assistance of a PhD was acknowledged, usually in a footnote.	5	1
Other	No PhD author, but the authors did include someone other than an MD, such as graduate students, sub-doctoral individuals, or RN's.	8	6
Setting			
Federal	Any Federal setting. (All but one of these articles originated in VA settings, mainly hospitals.)	8	5
State	Any state setting. (Usually these articles were from state hospitals.)	19	25
Medical school	Any article apparently authored by medical school personnel and conducted in a hospital associated with the school.	5	7
Private practice	Any article authored by an MD listing a non-institutional address and not specifying an institutional source for the subject sample.	4	12
Other	Setting not included in the above categories (e.g., foreign).	3	5
Combined	Any combination of the above categories.	6	7

frequency for *PhD Author* remains constant and the frequencies for *PhD Acknowledged* and *Other* categories are smaller and relatively constant.

The M score data for the investigator categories are summarized in Table 2. Per-

TABLE 2
M and R Scores for Each Category of Investigator

CATEGORY	f	M		R	
		MEAN	S.D.	MEAN	S.D.
PhD author	26	5.0	1.7	15.7	4.5
PhD acknowledged	6	2.8	2.8	12.8	6.1
Other	14	2.8	2.3	14.4	3.0
MD only	60	1.3	1.7	See Table 2a	

TABLE 2A
R Scores for PhD Author and MD Only for 1957 and 1960

INVESTIGATOR	1957			1960		
	f	MEAN	S.D.	f	MEAN	S.D.
PhD author	13	15.8	5.5	13	15.7	3.4
MD only	19	11.7	4.8	41	15.1	4.2

PhD Acknowledged, where $p < .03$). The difference between the *PhD Author* and *MD Only* categories is especially large and reaches a high degree of statistical significance ($t=9.14$, $df=58$). Considered along with the findings concerning the frequencies of articles in the *MD Only* and *PhD Author* groups, this difference accounts for all the main features of the M score distributions in Figure 1, that is, the areas and bimodality, the relative areas under each mode, the change from 1957 to 1960 in the lower

happens the most outstanding finding in this report is the difference in M score between the *PhD Author* category and each of the remaining categories ($p < .01$, except for

mode area and the constancy from year to year under the upper mode. Figure 2 and Table 3 help to clarify these points.

Only group. There were no other significant differences between investigators in R scores.

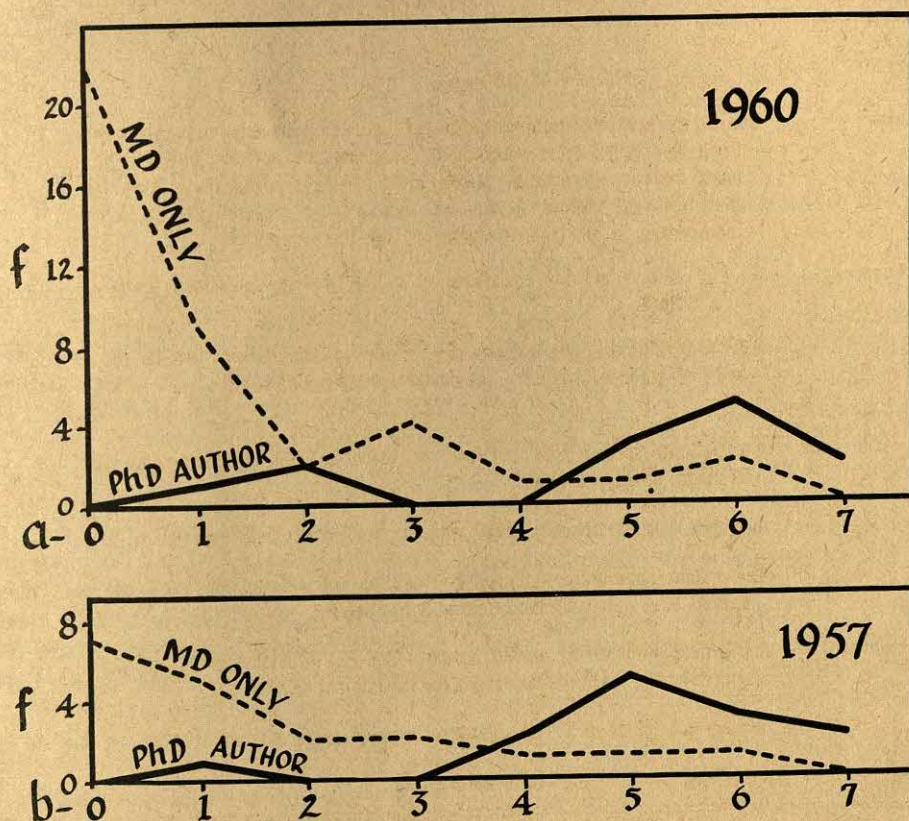

Fig 2. M score distributions for *PhD Author* and *MD Only* categories 1957 & 1960

TABLE 3
Percent of MD Only and PhD Author Articles at
Two Levels of M Scores

M SCORE LEVEL	MD ONLY	PhD AUTHOR
4-7	11.7%	84.6%
0-3	88.3%	15.4%
0-7	100.0%	100.0%

As can be seen in Table 2 and 2A, the differences between categories of investigators in R scores were not so pronounced. In 1957, the *PhD Author* group was significantly higher than the *MD Only* group, but this difference was eliminated in 1960 by a significant improvement in the MD

With respect to setting, Table 1 shows that *State* settings produced the most articles in both years surveyed, and that there was a 32% increase in the number of articles from this type of setting. By contrast, the *Federal* settings produced fewer articles in 1960, and accounted for only a small proportion of the articles in either year. Also, there were notably more articles produced in *Private Practice* settings in 1960 than in 1957. The remaining categories are characterized by small, relatively constant frequencies.

The M and R data for the setting categories are given in Table 4. Articles from *Federal* settings were significantly higher in M score than those from any other type

TABLE 4
M and R Scores for Settings

CATEGORY	F	M		R	
		MEAN	S.D.	MEAN	S.D.
Federal	13	5.2	2.0	16.1	4.6
State	44	2.7	2.4	15.0	4.4
Combined	13	2.4	2.6	14.1	4.9
Medical school	12	2.3	2.0	12.8	4.5
Other	8	1.6	1.8	12.8	4.7
Private practice	16	0.2	0.4	13.8	4.4

of setting; and articles from *Private Practice* were significantly and homogeneously lower than all except the *Other* setting. R score differences were less outstanding but showed a pattern similar to that found for the M score differences.

It is possible to demonstrate to some degree the extent to which the frequency and quality variations within the investigator and setting categories are interrelated. Table 5 shows the major correspondence of

TABLE 5
The Contingency of Investigator Categories with Setting Categories During Each Year *

SETTING	1957		1960	
	MD ONLY	PhD AUTHOR	MD ONLY	PhD AUTHOR
Federal	1	7	1	4
State	11	2	18	5
Medical school	1	2	6	1
Private practice	3	0	11	1

* Cells involving omitted categories all contained few articles; almost half contained none and no cell frequencies exceeded three.

investigators with settings by frequency. As might be expected, articles originating in the *Private Practice* settings were virtually always authored by MD's only. At the other extreme, articles from *Federal* settings were very likely to have PhD's listed among the authors. This polarity parallels that found for M scores. One finding that might not have been expected is that *Medical School* publications in the area of chemotherapy do not typically include PhDs among their authors.

DISCUSSION

It seems clear that the overriding implica-

tions of these data concern the value of research teams in the study of psychiatric drug treatments. The participation in research of this type by physicians is to be expected; it is always implied even in those rare studies when it is not made explicit in authorship. Thus the contributions to this research that follow from medical training ordinarily will be present. What may or may not be present is the influence of training in research design and quantitative methods generally, such as is commonly found in PhD training in the sciences. From the present data it appears that participation of PhDs is the primary determinant of methodological adequacy in this work. Where PhDs participate as investigators, desirable methodological features are typically present; where PhDs do not participate as investigators, these safeguards are not typically present.

It is noteworthy that team research in psychiatric drug treatment occurs with relatively small frequency. There are, of course, relatively few PhDs available and still fewer with active interest in psychopharmacology. In the light of the present data, it would seem desirable to seek ways in which to encourage an increase in their participation.

One may object that the desirability of methodological trappings may be called in question. After all, the tradition of acute observation is valid in this research area (4, 5), as in others. The objection does not seem relevant here, however. The low M articles, as a group, are not considered to be characterized by keen observations or by clever methodological innovations. They frequently have been deplored as nonspecific comparisons (1, 7) and as containing serious subjective biases (3, 6), and they have inspired numerous efforts to encourage methodological care (8, 10).

SUMMARY

Psychiatric journals for fiscal years 1957 and 1960 were surveyed for articles reporting research on the therapeutic value of tranquilizing and energizing drugs. Data concerning the adequacy of reporting and of methodology were collected. There were 36% more articles in 1960 than in 1957. In an initial analysis it was found that most of

the articles in both years and that virtually all of the increase fell at the lower levels of methodological adequacy. In a subsequent analysis it was found that, in general, the increase constituted the contribution of physicians in private practice, medical schools and state hospitals, working without the collaboration of persons trained in the conduct of scientific research. Articles in which such persons had collaborated were found to contain most of the methodological features commonly considered desirable in this research area. The findings were interpreted as supporting the use of interdisciplinary teams in chemotherapy research in psychiatry.

MURDER AND INSANITY: A SURVEY

JOHN LANZKRON, M.D.¹

If any man think he can judge herein,
'Tis much too weighty ;
neither were it lawful that I try murder,
wreaked in wrath.

Murder is as ancient a problem as human history. The Bible starts with the story of creation, continues with temptation and procreation and then, as soon as a family "unit" is in existence, reports on sibling rivalry, frustration resulting in wrath and fratricide.

The very question of Cain "Am I my brother's keeper?" as well as the description in the Bible(1) of the rituals of symbolic hand-washing of "all the elders of that city that are next unto the slain man," "slain by unknown hand" implies our moral responsibility for a murder committed in our midst.

The psychiatrist has to use his expert knowledge in terms of predictability of anticipated deviant social behavior in order to prevent homicide committed by mental patients. The Mental Hygiene Law (of the State of New York) provides the legal basis for prevention by regulating the commitment and release of "all patients known to be or likely to become dangerous to themselves or others."

The two scientific avenues for research of predictability of deviant social behavior are the statistical and individual. In this paper statistical data are compiled in an attempt to correlate sociological and psychopathological variables.

One hundred and fifty consecutive case records of mental patients committed to Matteawan State Hospital over five years (1956-1961), charged or indicted with murder, were reviewed and evaluated. They were committed because of their "present insanity," *i.e.*, their mental condition at the time of their arraignment in court. We have not included those homicide cases who were committed to our hospital under Section 85 of the Mental Hygiene Law (New York

State) as dangerously mentally ill after having committed homicide while hospitalized in a civil hospital. A survey of such cases has been published previously(2).

It is an axiom that the male offender is more aggressive and violent than the female offender. This explains the ratio 4:1, male versus female killers.

Of female cases, 43% are accounted for by the murder of 10 infants and 4 children by their mothers. Another 40% killed their husband or respective boyfriend.

It is noteworthy that 32 wives were murdered by their husbands whereas only 6 husbands were murdered by their wives. Five times more husbands killed their wives than vice versa; however the ratio of male to female, killing their respective girl or boy friend, is about 2:1.

Concerning the religious denomination one can only note that the percentage of homicidal patients among Jews (2.6%) is disproportionately low in relation to their percentage of the general population. This might be partly due to the moderate use of alcohol by the Jewish population(3) and partly to their religious values. One cannot draw too many conclusions from the high percentage of Catholics among our group;

this is coincidental with demographic and ethnic factors especially in New York City where 4/5 of major crimes in New York State are committed. In a survey of homicide cases made in Baltimore involving family members Guttmacher(4) came to just the opposite result.

Marital status: the disproportionately high number of widowed patients (over 21%) is due to the fact that on admission to our hospital those patients who killed their spouses were statistically carried as widowed. The high percentage of divorced or separated patients will not come as a surprise to those familiar with psychopathic patients. One-third of the patients are single, which also does not come as a surprise to those familiar with schizophrenic patients.

Age group: C. A. DeLeon(5) states in an article about homicide: "... and comparative youth (most slayers are between 21 and 45 years old)." This was found for all homicide cases in the U. S. A. (7,815 in 1958) as well as in our group (2/3).

Victims: 150 homicidal patients killed 157 victims; 4 patients each killed 2 persons, one mother killed her 2 children, another mother killed her 3 children. Seventy-three of the victims (47%) involved family members.

Methods: with the exception of several very brutal, sadistic killings by schizophrenic murderers, 65% of the murders were committed by gun and knife, 12% by strangulation which apparently does not differ much from the methods used by the "sane" killer.

Alcohol: W. C. Wilents and J. P. Brady (6) write "Alcohol was a factor in 31% of homicides..." This coincides with our findings; in 34% intemperate use of alcohol was a contributing factor. However only in 12.7% severe intoxication during the commitment of the crime could be elicited from the records. Addiction to drugs is an insignificant factor in our cases.

As a whole our patients had about 43% previous hospitalizations and 46% criminal records before committing murder. If however we examine separately the schizophrenic group (including paranoia) we arrive at 55% previous hospitalization and about 48% of criminal records. Among psychopaths 30% previous hospitalization and

previous criminal records of over 50% are on record. The number of previous psychiatric treatment would be higher if we would include all psychiatric facilities used before the murder.

The "paranoid group" as such—schizophrenia, paranoid type, paranoid condition, involuntal psychosis, paranoid type (in Europe still often called "Spaetschizophrenie"—late schizophrenia), psychosis due to alcohol, paranoid type, including psychosis due to arteriosclerosis, paranoid type—comprises about 40% (60 patients) of our cases. These homicides occurred as offspring of a delusional system and must therefore be grouped together.

Concerning our psychopathic patients (with asocial or amoral trends, with pathological emotionality or pathological sexuality) we have to emphasize that they were committed because they showed reactive features *after* their arrest for homicide. Reactive features are varying from a depressive reaction with or without suicidal attempts, Ganser syndrome, paranoid trends, sometimes shortlasting schizophrenic-like episodes, etc.

It is sometimes difficult to squeeze a patient's clinical picture into the strait jacket of our scientific classification. As Bleuler stated (7): "... at what stage of the anomaly anyone should be designated as a 'schizoid' psychopath, or as a schizophrenic mentally diseased, cannot at all be decided as yet." This should be paraphrased in the light of our present knowledge: "... as a 'schizoid' psychopath or as a pseudopsychopathic schizophrenic..." Unlike the psychopath, most psychotic patients show evidence of irrational thinking. Many are influenced by delusional ideas or by hallucinations that make their aberrant behavior more understandable, and, in an important sense, more rational. If a schizophrenic patient hears a voice that he genuinely believes to be God's voice telling him to kill or to commit some other grave offense, and if his delusional ideas furthermore afford him reason to do so, his proceeding to carry out such a regrettable act is not logically incomprehensible(8). This phenomenon of "rational, logical thinking without correction by an 'affective' element" is described by the French authors Minkowski and Rogue de

Fursac(9) under the name of "morbid rationalism."

Cleckley(8) corroborates our statement about differential diagnostic problems in certain psychopaths: "On the other hand, we see the psychopath repeatedly carry out acts as self-damaging, disastrous, and inappropriate as many that are considered characteristic of schizophrenia, without the delusional or hallucinatory prompting." Our schizophrenic patients do not hesitate to describe in gruesome details their often atrocious crimes without any emotion. The psychopath on the other hand often complains of amnesia for the crime or tries to rationalize it as self-defense or intoxication.

Morbid jealousy and delusions of infidelity were prominent in 30 (20%) of our cases. Our survey confirms some of the assertions of other investigators in England(10). A paper, "Murder as a Reaction to Paranoid Delusions in Involutional Psychosis and its Prevention," was published by this author stressing the malignant nature of delusions of infidelity in the involutional period(11).

The relatively high percentage of patients functioning at the moron level of intelligence as well as the relatively high percentage of borderline and dull normal intelligence level among our homicidal patients is similar to other statistical surveys of criminal offenders. The same applies to the relatively high percentage of unskilled workers among our patients.

CONCLUSION

A statistical evaluation of 150 homicidal patients was presented. The ratio of male : female patients was 4:1. One hundred and fifty-seven persons were killed by 150 patients. Of the victims 73 (47%) involved family members. Thirty-two male patients (27%) killed their wives, whereas 6 wives (19%) killed their husbands. Fifteen men (13%) killed their girlfriends; 7 female patients (22%) killed their boyfriends. Infanticide and murder of children amounted to 22 (14%) of the victims (40% of the female murderers killed their infants and/or children).

The cases may, *grosso modo*, be classified as follows(13) :

1. Those in which the homicide was the

direct offspring of delusions (paranoid group as described in this paper) : 40% ;

2. Those in which the homicide was committed during a paroxysm of insanity and/or was committed by manifestly insane persons, from motives and conditions which might influence the "sane mind" such as anger, revenge, jealousy, *etc.* : 32.6% ;

3. Those in which the insanity was said to have developed *after* the homicide which was committed for motives such as robbery (9), morbid jealousy, sex crimes, anger, "cuckolding-reaction," revenge, *etc.* (psychosis w/psychopathic personality) : 27.3%.

In most of the cases classified under Group 1 (40%) forebodings of the malignant nature of patients' mental illness were present over a long period ; the malignant nature of persistent delusions of infidelity in the involutional psychosis has been previously described(11). The remaining diagnostic groups (described under 2) usually unfold the symptoms of their mental illness over a long period. Prevention in Group 3 is often more a penal than a psychiatric problem.

Intemperate use of alcohol was a contributing factor in 34% of our cases, whereas severe intoxication at the time of the crime could be elicited from the records in 12.5% of the cases.

It is suggested that an interdisciplinary team consisting of specialists collaborating with each other in cultural, constitutional, psychological, neurological, genetic and dynamic studies run their data concerning homicidal patients through a computing machine and establish prediction tables for the various mental illnesses which would be used as a yardstick for prevention. I would like to conclude with A. Wikler's(12) definition and goals of psychiatric research :

that sort of activity which is directed to the accumulation of data that are useful for the purpose of prediction and control of observable phenomena. The phenomena with which the psychiatrist is concerned are largely those related to the interpersonal activities of human beings. He wishes to be able to predict such behavior and where necessary for the patient, society, or both, to alter it.

WRITING PSYCHIATRIC REPORTS

EDWARD S. DEAN, M.D.¹

Just how helpful are reports made by psychiatrists? Do they cause any actual harm? How can they be made to accomplish their function more effectively? Any psychiatrist who prepares reports for lay readers sooner or later will ask himself such questions.

Not long ago, a patient was seen by a psychiatrist in the admitting office of a large general hospital, and the psychiatrist referred him to an alcoholic clinic. A few days later, a call was received from the State Department of Employment, requesting the psychiatric diagnosis. A new member of the clerical staff, not aware of established procedures in such cases, read the diagnosis over the telephone: "Ambulatory schizophrenia." After that, a call was received from the patient's employer who asked in a tone of alarm if the patient was dangerous and what steps should he take in regard to him.

Thus, professional jargon conveyed to psychiatrically unsophisticated persons the impression that the patient suffered from a serious mental illness and could be dangerous. But a nonprofessional observer of human nature might have described him simply as a man who drank too much and stopped off his mother.

Most psychiatrists would not knowingly allow any such misunderstandings to arise in their relations with the public. But psychiatrists, like the rest of humanity, are creatures of habit. They are a product of their training, which, in most cases, has proceeded along traditional lines. Typically, a psychiatrist begins in a hospital where he is required to write reports according to standard form. The hospital provides him with an outline with a list of headings, subheadings, and possibly an elaborate list of details that he is to search for in his history and examination. At the conclusion is a summary-formulation with diagnosis, prognosis, and recommendation. It is assumed, of course, that diagnosis determines prognosis and treatment. After all, that has been

the case throughout medicine, and who dares to imply that psychiatry can be different from medicine?

As a beginning psychiatrist, I was introduced to Cheney's *Outlines for Psychiatric Examinations*,² and I thought that when I followed Cheney I was doing right. It seems to me now that I was right only in having complied with an established authority. But as for doing good, that is, for the patient and those whose lives were involved with him, more likely I was doing wrong.

This kind of psychiatric reporting is still much in use, particularly in large, well-staffed hospitals. It is much in demand where administration is the overriding concern. Under these circumstances, classification of patients is emphasized and insisted upon. Unfortunately, hospitals, like other institutions, have lives of their own which they seek to maintain and reproduce, possibly at the expense of the purpose for which they were originally established. Thus, many rules of procedure are designed to protect the hospital, and the welfare of patients can be overlooked.

But in clinics where emphasis is on psychotherapy, adherence to form is much more relaxed. Still, even in such clinics some formalization of reports is required, and an insistence on diagnosis remains. But, I am told, how else can we keep statistics, and statistics are the cornerstone of research. Such is the objection you are likely to hear if you propose to drop diagnosis from psychiatric reports.

In their emphasis on diagnosis, psychiatrists tend to act as if psychiatric classifications existed in nature and were not made by man. But do not misunderstand me. I do not deny that general paresis is an organic condition produced by the *Treponema pallidum*. I am talking about the functional mental disorders which exist as classifications assigned by man for the purpose

² Cheney, Clarence O.: *Outlines for Psychiatric Examinations*, 2nd Ed. Utica, N. Y.: State Hospitals Press, 1938.

¹ 450 Sutter St., San Francisco, Calif.

of giving order to varieties of behavior.

In this connection, the words of Adolf Meyer³ have a pointed significance. In 1906, he said :

The superstition about the value of a diagnosis of a disease prompts many to believe that a diagnosis once made puts them into a position to solve the queries about the case not with the facts presented by it . . . but by a system of rules and deductions from the meaning of the newly defined disease entities . . .

What we act on should be facts. If the facts do not constitute a diagnosis we nevertheless must act on the facts. To jump from the facts at an arbitrary diagnosis and then to act on that abstract diagnosis is a procedure hardly ever needed in psychiatry, and bound to lead to self-deceit and confusion of the minds of all concerned.

Well schooled in their diagnostic classifications, psychiatrists discourse upon them fluently and glibly. As long as they talk only to one another, they can remain unaware of the harmful effects of their terminology. They construct a private universe in which only the adept—the psychiatrists and their colleagues in related fields—feel at home. They have learned to stomach their terms, I suspect, by taking them with several grains of salt.

But give a psychiatric report to an educated layman and this private wonderland of psychiatrists becomes a Pandora's box. Such reactions are well known, not only to psychiatrists, but to physicians in general. Otherwise, why should medical records be kept so zealously out of the hands of patients? When physicians say, "These records are confidential," they tend to forget that confidentiality is intended to protect patients, not physicians. The patient's confidences, of course, should be protected at any cost.

Suppose that you, as a psychiatrist, knew that the report you are preparing would be read by the patient you are describing. Very likely it would be written in quite different language from what you are accustomed to using. If anyone doubts this,

I suggest that he try the experiment for himself.

Of course, psychiatrists do not write reports primarily to be read by the subjects of their investigation. But if they wrote reports which *could* be read by them, then the reports would be more meaningful—and less misleading—to judges, lawyers, probation officers, social workers, teachers, school counsellors, deans, employers, and personnel officers. Further, these individuals would thereby be spared the burden of entering into a conspiracy to keep the contents of the report secret from the subject-person concerned. After all, judges and so on are not accustomed to keeping secrets from their clients.

Adhering to traditional forms and technical terminology out of routine and habit—and also from a desire to demonstrate professional competence—psychiatrists tend to forget that their words have consequences. They make diagnoses, such as ambulatory schizophrenia, where none is needed and none is asked. And then they are puzzled and irritated by the alarm they have caused. They feel that they have done what was right, but ignorant meddlers have spread confusion and alarm.

I suggest that psychiatrists need to change the form of their reports and the language they use. *Schizophrenic reaction, chronic undifferentiated type* may be a useful term, possibly, for the statistics of a state hospital, but it is of hardly any use in a world of men-in-action. No general practitioner of medicine could find much meaning in that term, let alone a personnel director or peace officer.

My suggestion is that a psychiatric report be conceived as a guide to action. It differs from all other reports which describe, evaluate, and recommend preferred decisions only in that it is based on the experience that is peculiar to those who are engaged in the psychiatric profession. But it should be completely free from professional jargon, and it should convey intelligence to the educated layman in ordinary language.

The psychiatric report should be a factual account. If psychiatrists indulge their well-known propensity for speculation, the

³ Lief, Alfred (Ed.): *The Commonsense Psychiatry of Dr. Adolf Meyer*. New York: McGraw-Hill, 1948. pp. 154, 168. Quoted by permission.

speculative nature of what they say should be clearly indicated. Speculation, or opinion, should be separated from what is thought to be fact. And the facts upon which speculation is based should be fully stated, so that any non-psychiatric person could draw the same inference. If any leap is required, then any such speculation should be omitted.

Further, if psychiatrists wrote reports in such a way that they would not object to their being read by the subject himself, then their reports would be free from jargon, contain a minimum of speculation, and be confined to established facts. One is not likely to use the term *paranoid* if a paranoid person is going to read the report. The information communicated will not be diminished if, instead of using the term *paranoid*, the fears and suspicions which make up this paranoid state are specified in detail. Further, no misinformation will be communicated, such as is connoted by *paranoid*. Nor will any patient be disturbed if he has learned that he is supposed to be paranoid and then goes to an encyclopedia and under *paranoia* reads what his prognosis is presumed to be. Happily, many paranoid states are transitory, and the fears and suspicions that constitute their substance wax and wane.

If, after an interview, a psychiatrist makes a note, seals it in an envelope, and gives it to the patient to take to another psychiatrist who reads it with a dead-pan expression and then says, "Now tell me about the problem that brings you here," the patient will have reason for feeling some strong emotion. Should such an exchange of information occur behind the patient's back and should the patient know that there is a case record which is always kept out of sight, then this constitutes nothing less than encouraging paranoia.

I have shown my reports to patients many times, and my relationship with them was usually strengthened as a result. In one such case I had written, "He suspects that his wife is being held prisoner in an apartment in the same building where he lives." Upon reading this, the patient told me that this idea was merely a thought, not a belief. I always welcome information that indicates a delusion is not fixed, but fluid.

Also, in case a psychiatrist suspects that he does not have adequate facts, he should try showing the draft of his report to the patient. He may learn much more, and besides, the patient may have the happy experience of discovering that his psychiatrist is a person he can trust.

It is because of such considerations that I do not recommend Cheney's *Outlines*. Such detailed outlines may be of help to a beginner in psychiatry, because he does not know what to look for. He needs practice to feel at home in the field. And he needs to learn what his job is and what he should expect of himself. And he needs to know what his forebears have done, in order to depart from their practices with full security.

But a detailed outline is less than useful for one accustomed to the field of psychiatry. It may be a definite hindrance, because it tends to make one fail to see the forest for the trees. The danger is that a mass of detailed information is collected, but nothing is done to make sense of it. And it is hard to make sense of disparate kinds of information that are put down without reference to a central theme. In reading such reports, one is impressed by a mass of irrelevant verbiage.

But a report does need to have form. It needs to have a beginning, a middle, and an end. Its beginning poses a problem, its middle elaborates—elucidates—that problem, and its end proposes a solution. The problem should be so defined that alternative treatments, or managements, of the problem are implicit in its definition, and then these are expressly stated in the conclusion. It is the problem at hand that determines the organization of the report, including its length, scope, and presentation of facts and inferences.

The end of the report should be a definite conclusion, and it should contain a prescription for action, possibly a definite action, or perhaps only a change in attitude. A report should build to its conclusion. It should contain all the information that leads to its conclusion. It should contain also all the information that contradicts its conclusion, and this contradicting information should be evaluated in relation to

the whole. Nothing should be left out that belongs in the report, and nothing need be put in that does not belong. Every part of the report should contribute to the whole. It should be organized into a narrative, factual account which culminates in an effect that is its conclusion.

So, my suggestion is that outlines and technical terminology are of limited usefulness in writing psychiatric reports. Their effects may be definitely harmful, both to the understanding of the reader and the psychiatrist who makes the report. Strict adherence to an outline can hinder the process of thought by which the psychi-

atrist comes to an understanding of the presenting problem. And adherence to an outline can prevent effective communication of the problem and its proposed solutions to the intended reader. Instead, organization of the report should be determined by the problem at hand. The well-organized report will culminate in a conclusion which is the psychiatrist's proposed solution-in-action. The writer of the report should bear in mind the needs and limitations of his reader. He can avoid the harmful effects of professional jargon by keeping to a description of facts and having in mind the subject-person as the ultimate reader.

THE CLOSED GROUP CONCEPT IN OPEN PSYCHIATRIC HOSPITALS¹

BERTRAM MANDELBROTE, M.B., D.P.M.,² AND
HUGH FREEMAN, B.M., D.P.M.³

The transition of a hospital with locked units to an open hospital presents many difficulties and anxieties. Most of these stem from the problems of assessing which patients are determined to leave the hospital, if given the opportunity, and to what extent they may be potentially dangerous, or become a burden to themselves or the community. In the initial stages, careful assessment and grouping of patients and the development of an organised hospital programme can reduce the problem until there are only a limited number of closed wards. Subsequently, one closed ward may be considered sufficient. Because of the difficulties presented by a few patients who will remain a hospital and community problem if no hospital units are locked, it is not uncommon for a ward containing a large number to remain locked.

In an attempt to deal with the problem in Gloucester, one of us (B.M.M.) established a special programme for a small group of patients in this category, called the "Closed Group"⁴(1). This meant that within the confines of an open ward, a small group of patients were managed in a special way, under constant skilled supervision by the nursing staff. The ingenuity of both nurses and doctors was taxed to devise activity programmes and means of communication which would overcome the special difficulties involved. These stemmed from the patients' lack of insight, and failure to cooperate or identify with the hospital. Subsequently, we have both been associated in a similar programme at Oxford.

Procedure with Absconders. The Closed Group was used for patients who repeatedly showed an unwillingness to cooperate in the hospital regime. In the first instance, each patient who absconded from the hospital was interviewed by one of the authors, together with the medical and nursing staff concerned, in an attempt to understand his reasons for going. These reasons included social factors, commendable initiative in long-stay patients, response to hallucinatory voices and an adamant wish by some patients not to stay in hospital.

We then tried to piece together where the patient went, and what he wanted to do. Where the situation could not be modified to meet the patient's needs, it was explained to him that the hospital was run on the basis of mutual trust and that unless we could trust him, a different policy might have to be adopted. It was emphasised that escaping from the hospital was easy and that the real challenge was whether he could prove he was worth trusting. Unless the patient was considered dangerous or in need of special treatment, he was given another chance. On the next occasion of absconding, he was placed on the Closed Group.

In Gloucester, it was found necessary to have two Closed Groups—for men and women respectively. At Oxford, experience with the grouping and classification of patients led to the formation of a Closed Group for men, but this special need for women has not arisen. An extensive outpatient and domiciliary service enables psychiatrists to screen and classify new patients needing admission. These new referrals are admitted to several appropriate wards, used for admissions. As a result, many recent admissions with behavioural difficulties, both men and women, have been managed in open units dealing with disturbed patients who require intensive nursing supervision for short periods. Some male patients who could not be managed in that setting

¹ Based on an address to the Psychotherapy and Social Psychiatry Section, Royal Medico-Psychological Association, London, Nov. 1961.

² Littlemore Hospital, Littlemore, Oxford, England.

³ Salford Royal Hospital, Salford, Lancs., England.

⁴ This is an entirely different sense from that used in group therapy, where it refers to constant composition of the group.

have been transferred to the Closed Group.

Patients and Treatments. To obtain a more accurate picture of the patients in the Closed Group, we carried out an analysis at Littlemore Hospital, Oxford, of all patients who had belonged to it in the 12-month period October 1959 to September 1960. The number of individual patients who had been on it at any time was 61, and the breakdown by diagnosis is given in Table 1.

TABLE 1

PATIENTS OF THE CLOSED GROUP BY DIAGNOSIS	
Schizophrenia	38
Manic-depressive psychosis	10
Psychopathic personality	3
Subnormality	3
Subnormality with schizophrenia	2
Psychoneurosis	2
Alcoholism	2
Senile dementia	1

During this period 641 patients were admitted to hospital, and of the 250 men, 31 were admitted directly to the group. The other 30 members of the Closed Group were transfers from other wards where they could not be managed satisfactorily.

Examination of the disposal of these patients (Table 2) shows that 29 became

TABLE 2

DISPOSAL OF PATIENTS ADMITTED TO THE CLOSED GROUP (OCT. 1959-SEPT. 1960)	
Transferred to other wards	29
Discharged from the hospital	16
Remaining on the ward (not under Closed Group supervision)	13
Uninterruptedly in the Closed Group	3

suitable to be transferred to other wards, 16 were discharged from the hospital, 13 remained on the same ward but were not under Closed Group supervision, and 3 had remained uninterruptedly in the Closed Group. Of the transferred patients, 3 were subsequently readmitted to the Closed Group. The average length of stay for each entry to the group (rather than for each individual patient) was 24 days.

These figures show how relatively small is the hard core problem of patients requiring

continuous intensive supervision. The decision to release a patient from Closed Group supervision was taken after consultation between the medical and nursing staff.

Some acutely disturbed patients are not able initially to take part in the group activities although technically under Closed Group supervision. These patients would tend to upset the equilibrium of the Group, and to take up an undue amount of the nurses' attention. They are nursed separately in the ward (which is empty during most work periods), and might have to spend up to 24 hours in bed, or be allowed only a dressing gown and pyjamas. This individual management, however, rarely lasts more than a few days, and patients are then usually able to participate in the full group programme.

Disturbed psychotic patients are treated routinely with intensive phenothiazine medication. This is usually chlorpromazine in the first instance, although trifluoperazine, perphenazine and thioridazine have also been used in some cases. Some authors(2) emphasize the value of ECT in the initial treatment period for disturbed psychotics, but we have not found this necessary. The tranquillisers have proved most efficacious in controlling aggressive and disturbed behaviour, but they have not influenced the wandering propensity of a number of patients who continue to require Closed Group supervision over a long period. Injection treatment is usually reserved for patients who are unwilling, or cannot be relied on to take oral medication (which in general we have found quite rapid enough, even with acute illnesses).

Although the entire ward (consisting predominantly of chronic, deteriorated patients) is managed on group lines, with an intensive programme of activities, there has been no attempt at formal psychotherapy—group or individual. Analytically orientated therapy has not been thought appropriate to the problems managed in this unit. However, there are weekly meetings between the doctor and nursing staff at which any difficulties are discussed.

Regime. The patients composing the Group present a variety of problems, and its character is therefore a heterogeneous one. Management is very much easier if it is

possible to create some common bonds amongst the patients, and this may be achieved through occupational and recreational activities which are generally acceptable. If they can also be of a team-like character, to make the patients to some extent dependent on each other, this will encourage positive interactions among the Group members, and reduce the demands made on the staff.

The best working response occurs with tasks which are creative, and which allow a sense of personal involvement—particularly when a project can be carried through from start to finish. The work this Closed Group has done includes laying out a garden, painting and renovating a veranda, clearing the site for a new social centre, and demolishing a derelict building in the hospital grounds. The Group is now in great demand within the hospital for working projects of this sort.

It is better if participation in this work is confined to the Group; in this way, as patients become interested in the job, they will tend to regard the Closed Group as a working team, rather than as a number of specially supervised patients. As a result, some patients actually become so attached to the Group that they are reluctant to leave it, even when well enough to do so. Some of these "ex-members" have been allowed to remain attached to the Group during working periods, although no longer under close supervision. Being well known to the current Group members, they are not regarded as outsiders.

The Group also takes part in a variety of recreations including football, cricket, badminton, darts, billiards, table tennis and tombola. In addition, they are included in entertainments for the whole ward, or for several wards, though remaining under the supervision of their nursing staff. In this way, the invisible barriers of the Group are diminished, as they are by visits outside the hospital. With adequate staff supervision, there is no difficulty about most members of the Group going on shopping expeditions, to the swimming baths, or to places of interest. These measures are all valuable in reducing tension which might otherwise build up within the Group situation. In fact, the combination of fostering a wide field of

social relationships around the Group, together with work projects which promote integration, has proved generally beneficial.

An amusing sideline to this discussion comes from an article, "Life in a Closed Group," which appeared recently in the patients' magazine. It was written by a chronic schizophrenic patient, an inveterate absconder, and a permanent member of the Group. He writes: "I think 'Closed Group' is a misnomer, because we are not really confined, but free to go anywhere inside or outside the hospital with the nurse who looks after us. . . . We all work as a happy family in the open air, gardening and painting. I like work; it helps us to keep fit." It should be added that this tribute to the regime was entirely unsolicited!

Nursing the Group. Of course, supervision of the Closed Group represents one of the most onerous duties of the nursing staff in the ward, and indeed in the whole hospital. In spite of treatment, many Closed Group patients are likely to be difficult and resentful, at least for a time. Without keys, or any other kind of physical restraint, it is the function of the nurse to draw such patients into the Group, so that they may benefit from it.

This is done by persuasion, by exercising patience, and by promoting a constructive and interesting programme in which group members may use their own initiative as far as possible. If nurses have an appreciation of the patients' personal interests they can help to form a nucleus around which the group is constructed. This relationship we presume to be a therapeutic force of its own, and there is no doubt that the success of Closed Group management rests fundamentally on the quality of its nursing staff.

The ward normally contains about 38 patients, of whom not more than 8 would be under Closed Group supervision. For these patients, there are 4 or 5 male nurses⁵ on each shift (of whom not more than 2 would be fully trained) and 2 of these are normally allocated to the Closed Group. At certain times only one nurse would be

⁵ The term nurse is used to include both trained nurses and assistants (aides).

available for this purpose, but if the group numbers more than 5 it is very difficult for a single person to exercise adequate supervision.

One of the charge nurses (A.R.H.) of this particular unit writes(3),

When patients are nursed in a Closed Group in an otherwise open ward, they are more readily able to discover the temporary nature of their confinement than would be the case in a locked ward, since they are actually able to observe the progress of patients whose mental condition has improved and who have left the Closed Group to take their place in the comparative freedom of the open ward. Since the nursing staff are not able to rely on keys in order to ensure the safety of their patients, they must institute a stimulating ward programme to maintain the interests of their patients. This naturally results in close interpersonal relationships between the nursing staff and patients and a consequent speedier response to treatment.

Absconsions. In the period under survey, there have been 9 incidents when patients absconded from the unit, of which 4 occurred in the first month of the experiment. One patient succeeded in absconding twice, and is still on the Closed Group. These patients were returned to the hospital on the same day, because of the efficiency of the supervision, except for one who remained out of hospital for 4 days. Of the 8 patients who absconded, 2 are still in hospital, while the remainder have improved and been discharged.

CONCLUSIONS

The new Mental Health Act (1959) in Great Britain has captured the spirit of progress which has been taking place in British mental hospitals over the past 10 years, and it facilitates admission to psychiatric hospitals without formality. It has also taken more account than previous legislation of human dignity and freedom—so much emphasised in the development of therapeutic communities and open door hospitals. These measures have done much to reduce the dependence of the long-stay patient and the custodial atmosphere that prevailed in many mental hospitals.

The "Closed Group" has proved invaluable in facilitating a rapid transition to the open door hospital philosophy. One should not, however, minimise the energy and enthusiasm required in the development of a high community morale in the hospital. Nor does it reduce the need for a full activity programme, careful grouping and assessment of patients, improvement of community relationships and provision of facilities within the community (outpatient, day hospital and domiciliary) which permit adequate screening and classification of patients by psychiatrists prior to admission.

Littlemore Hospital serves a population of 350,000 people covering an area of approximately 900 square miles (Oxford City, Oxford County, parts of Berkshire and Gloucestershire). It accepts all types of psychiatric admissions and is responsible for the final provision of inpatient accommodation for any resident in this area requiring treatment, even if he comes before the Courts.

During the recent development of this hospital, it has been possible to change the status of patients so that the vast majority are now informal (*i.e.*, under no legal restriction). When the experiment began two years ago, there were 902 patients at Littlemore; 445 voluntary, 10 short term observation and treatment and 447 compulsorily detained. Through the improved functioning of the hospital and its community services, many patients have been discharged back into the community. The present hospital population (September 1961) is 707 patients; 690 (97.6%) are informal; 12 are on short term (3-28 days) orders for observation and treatment, and 5 are compulsorily detained (4 of them by order of the Courts following a criminal offence). No wards are locked at present, and we believe that the use of the Closed Group has played an important part in this development.

SUMMARY

1. The concept of the Closed Group in the development of an open psychiatric hospital in Oxford is elaborated and its composition, management and regime are described.

2. In this hospital (a traditional mental hospital responsible for all types of psychiatric admissions), 97.6% of the patients are informal and less than 1% compulsorily detained; this includes cases referred from the Courts. No wards are locked.

THE PROBLEM OF PROGNOSIS IN PSYCHONEUROTIC ILLNESS

A. H. CHAPMAN, M.D.¹

The prognoses of most psychoneurotic illnesses are not known. The future life course of a young adult with an anxiety state, phobia or conversion reaction remains speculative. There are no studies which make clear what his psychiatric status will probably be 10 or 20 years afterwards.

The prognoses of psychotic illnesses are better understood. Psychotic patients are usually hospitalized and follow-up contacts are often maintained for a while after discharge. Recurrence of the illness usually results in rehospitalization, allowing at least a crude appraisal of the long term course. Such illnesses are often treated in large public hospitals where statistics are kept on the outcome of the patients. The patient who relapses often returns to the same hospital. A statistical appraisal of the course and outcome of psychotic illness is in time possible. Such studies as the excellent ones from the New York state hospital system (1) give reasonable estimates of the courses and prognoses of psychotic illnesses.

The case is different with psychoneurotic cases. Patients with psychoneurotic problems less frequently receive attention from public hospitals. They are usually not incapacitated by their illnesses, and seek help on an outpatient basis. The capacity of outpatient clinics to appraise their long term course and outcome is much less than in the case of hospitalized psychotic patients. The psychoneurotic patient often does not return to a former treatment source if his problems return or undergo an exacerbation. If he does not feel he is making good progress in treatment, he may go to another therapist or clinic, or he may seek help from lay counselling services. It is difficult and expensive to trace psychoneurotic patients for 5-, 10- or 20-year follow-ups, and sometimes they are resistant to extensive re-evaluation when they are approached.

The records of large university and public psychiatric outpatient clinics are difficult to evaluate. Such clinics usually have fre-

quent turnover in personnel as new groups of resident physicians and young instructors come and go. It is difficult to piece together the reports of many observers into a coherent long range picture, and often there are not enough details in the clinical record to enable evaluation of the patient from this source.

The prognoses of psychoneurotic illnesses remain a matter of individual opinion and speculation. Each psychiatrist has his own impressions based on his own experience. His impressions are limited and distorted by the type of practice he does and the theoretical approach he uses. Despite much psychiatric research, no studies have yet appeared to lift this crucial problem out of the realm of individual speculation and opinion.

The evaluation of treatment results of the psychoneuroses is impossible until the prognosis of psychoneuroses is known. It is of little use to know what percentage of patients improve in treatment unless we know what percentage would have gotten better or worse without it. It does not clarify the matter to know what percentage of patients are still doing well 3 or 5 years after completing treatment unless we have some idea what percentage of patients would be doing well 3 or 5 years later even if they had had no treatment.

The absence of accurate information about the prognoses of psychoneuroses has made the evaluation of psychotherapy difficult and treacherous. The results of psychotherapy must remain a matter of the speculations and opinions of individual therapists, since none of these therapists can be sure how their patients would have done without their treatment.

The unknown prognoses of psychoneuroses lead to the confused claims and counterclaims of the various schools of psychotherapy about their respective validity and effectiveness. The impartial observer in the end often concludes that the results of all schools of psychotherapy, when conscientiously applied, are about the same (2).

¹ Dept. of Psychiatry, University of Kansas School of Medicine, Kansas City, Kansas.

Though almost all psychotherapists feel sure they help many of their patients, none can be scientifically sure of it, and none has a clear scientific basis for feeling his approach is better than that of other therapists of different theoretical orientations and procedures (3).

Some therapists solve this painful dilemma by the comforting but unsound assumption that if the patient improves *during* the treatment he improves *because of* the treatment. Alluring as this assumption may be, it is not sound. It is clear that many patients improve with passage of time without treatment, and the patient who is being treated might well have been one who would have improved if he had not been treated. Nevertheless, the assumption that improvement during treatment is always produced by the treatment is widespread among psychotherapists of all orientations.

This same erroneous assumption has often been present during the historical evolution of psychotherapy. For example, though he never specifically stated so, it is clear that Freud assumed that improvement of a patient during treatment was the result of the treatment. Freud never considered, at least in his writings, whether the improvement was possibly unrelated to his treatment and merely a function of time or the natural course of the disease. Freud also assumed that improvement of the patient confirmed the validity of his theoretical conclusions about the cause of the illness.

Some therapists attempt to substantiate their psychological theories by citing the recoveries of patients to whom their techniques were applied. They reason that recovery proves that the theories were sound. Until the prognoses of psychoneuroses are clearly known, such inferences are untenable. They may comfort the therapist, but they contribute little to our understanding of emotional illness and how to treat it.

The validity of a theoretical system in psychiatry cannot be based entirely on whether it achieves a certain amount of therapeutic success. Many patients are relieved of psychogenic symptoms by the application of a wide variety of exhortative and inspirational procedures, but this does not indisputably prove the existence of basic truth in any of these methods. Wheth-

er or not patients improve under treatment with a particular theoretical orientation can be considered as part of the data in evaluating the validity of the theory, but it does not settle the matter. This is particularly so when the prognosis of the illness is unpredictable.

The problem of the prognoses of psychoneuroses is further complicated by the fact that psychoneuroses vary so much in intensity. The range from mild to severe is much greater than in any other type of medical problem. The precise point at which normal tensions are separated from abnormal anxieties is often a matter of individual opinion. It is probable, but not certain, that prognosis varies with the intensity of the symptoms. Even this cannot be stated for certain, however. For example, an untreated severe obsessive illness may in time disappear entirely, whereas a minor obsession may be present for decades. The reverse may be true in other patients.

It is currently fashionable to advocate widespread, expensive plans for the treatment of large numbers of psychoneurotic patients. Though such plans may be motivated by well-meant humanitarian feelings, it is difficult to justify them on the basis of available statistical results of such treatment. The crux of the matter is the problem of the unknown prognoses of these illnesses. Yet this question is rarely raised when such plans are considered, even by those who oppose these plans.

The solution of the problem of prognosis in psychoneurotic illness lies in careful, well-financed, long term research. The government and private foundations spend much money on psychiatric research, and some of it should be put into research on the prognosis and course of psychoneurotic illness.

Such research should be conducted by investigators who are willing to devote themselves to it for many years. One of the problems in such research is that the personnel undergoes continual change over the years. Young investigators leave the study to accept offers of academic advancement in other cities or they enter private practice after a few years. Their replacements have many typed reports on the patients, but no direct clinical knowl-

edge of them. Over a period of 10 years the entire personnel of a long range research project may change several times.

The solution lies in carefully selecting a hard core of well-financed investigators who will stick with the project over a significant period. Such a team of investigators could eventually begin to clarify some of the problems in the prognosis of psychoneurotic illness. Such investigations would be expensive, but when one considers how much current psychiatric research is rendered of little value by the absence of such data the expense becomes justifiable and necessary.

Until such data are available on the prognoses of psychoneuroses, the individual psychotherapist must, if he is intellectually honest with himself, face a painful dilemma. It is his duty and role to go on treating his

patients in the best manner he knows. However, if he bluntly faces the unknown prognoses of the illnesses he is treating he must realize that he is proceeding on the basis of his own opinions and upon those of his teachers and the authorities whose system he follows. Such a realization may lead to greater humility and flexibility in the therapist and to a greater tolerance toward other therapists whose convictions he does not share. It is quite possible, however, that more humility, flexibility and tolerance for various opinions would be a good thing for psychiatry in its present stage of development.

EFFECT OF SOLITARY CONFINEMENT ON PRISONERS¹

RICHARD H. WALTERS, Ph.D., JOHN E. CALLAGAN, Ph.D.,² AND
ALBERT F. NEWMAN, M.A.³

The reports of Ribble(5) and Spitz(8) on the consequences of maternal deprivation in infancy have, during the past fifteen years, stimulated a great deal of interest in the effects of restricted social contact. Until recently, however, there have been relatively few experimental studies with human subjects in which degree of social contact has been experimentally manipulated. Moreover, studies of prolonged isolation have, for the most part, been inspired by interest in the role of exteroceptive stimulation; consequently, the experimental subjects have been both perceptually and socially isolated.

In two studies of perceptual isolation, isolated subjects have shown increased susceptibility to social influence. In one of these(6), isolated subjects were found to be more influenced by persuasive communications than were nonisolated subjects; in the other(3), isolation appeared to increase suggestibility in a body-sway test.

Other investigators(1, 2, 10, 11), using children as subjects, have provided evidence that both brief social isolation and restricted social contact may increase the effectiveness of social reinforcers. These findings suggest that the increased suggestibility of the perceptually isolated adult subjects may have been due to the restricted social contact which was a concomitant of the perceptual isolation. The study reported in this paper was aimed primarily at investigating the effects of prolonged social isolation on susceptibility to social influence. Some restric-

tions were necessarily imposed on the perceptual experiences of the subjects, but there was no direct interference with sensory input during the isolation period.

METHOD

Forty long-term prisoners at a federal penitentiary volunteered for a study of solitary confinement. Twenty of the volunteers were placed in isolation cells for 4 days; the remainder served as controls. All but 1 of the experimental subjects remained in isolation for a full 96-hour period.

The isolation cells were approximately 12 ft. by 6 ft. and contained only a wooden-board bed with mattress, a toilet, and a hand-basin. During the day the cell was illuminated by a single electric light adequate for reading and by light from a 3 ft. by 4 ft. window high up on the wall of the cell. A dim light remained on during the night. While in isolation prisoners had no social contacts except those necessary for exchange of food and dirty crockery. They were allowed to smoke and were given regular diet, but reading matter and mail were not permitted. Prisoners were told only that they would be tested before and after isolation. No indication was given that their behavior might undergo change or that their thoughts and feelings might be influenced by the experience.

Experimental subjects were tested immediately before and immediately after isolation. Control subjects were tested on 2 occasions, 4 days apart; during the intervening period, they carried out their normal prison routines.

Subjects were given 3 tests of susceptibility to social influence:

1. *Body sway test.* The subject stood with his feet together and eyes closed. The repeated suggestion, "You are falling, falling forward," which was recorded on tape, was played to the subject for approximately 2 minutes. The same procedure was used in both the pre-test and post-test periods.

2. *Autokinetic test.* The subject was

³ Research Assistant, Department of Psychology, Queen's University, Kingston, Ont.

shown a stationary pinpoint of light on a dark background and was told that it would move. He was asked to judge, on 10 trials, how far the light had moved. A further 10 trials were given during the post-test period after the subject had been informed that his previous estimates had been too small. An attempt was then made to condition him to give judgments of a specific size.

3. *Conditioning of meaning.* A technique devised by Staats and Staats(9) was utilized in an attempt to change the subject's evaluation of concepts. During the pre-test period the subject rated 4 concepts on 7 bipolar scales defined by the adjectives "pleasant" and "unpleasant." During the post-test period one of the concepts was repeatedly paired with words having high positive loadings on Osgood's evaluative force(4), the other with words having high negative loadings on this factor. The subject was then asked to re-rate the concepts.

The prisoners' reactions to the experimental procedures were assessed by the several paper-and-pencil tests: 1. Subjects were asked, during the pre-test and post-test periods, to indicate, by means of self-ratings, how anxious they felt about participating in the study. 2. During the post-test period, subjects rated 5 concepts—punishment, solitary, prison, authority, and society—on 5 scales defined by bipolar pairs of adjectives with high loadings on Osgood's evaluative factor. 3. The Maudsley Personality Inventory was used in both pre-test and post-test sessions to obtain scores for neuroticism and introversion. 4. A brief aggression scale, devised by Zaks and Walters(13), was used during both sessions to assess the subject's level of aggression.

Since a number of investigators have reported perceptual-motor and cognitive impairment in subjects who have experienced sensory deprivation, the prisoners were given a manual dexterity test and the Shipley-Hartford Abstraction Test. During the post-test period, all subjects were also given a brief test of verbal productivity, in which they were asked to give their comments on recently proposed prison reforms. The comments were recorded on tape and transcribed.

RESULTS

More isolated than nonisolated prisoners reported an increase in anxiety from the pre-test to post-test period ($p=.038$; Fisher's Exact Probability Test)(7). In contrast, following isolation the experimental subjects rated the concepts "solitary" more positively, and "society" more negatively, than did prisoners who had remained in regular prison routines ($p<.05$ in each case; Mann-Whitney Test)(7). The isolation subjects were also somewhat less verbally productive ($p<.10$; Mann-Whitney Test)(7). A similar decrease in verbal productivity following isolation has been found for adolescents(12). There were no differences on any of the remaining tests.

DISCUSSION

This study suggests that while social isolation may produce some change in subjective feelings, it does not result in mental or psychomotor deterioration or in increased susceptibility to social influence.

The largely negative findings may, of course, be due in part to the personality characteristics and the past experiences of the subjects of this study. In the first place, the subjects were volunteers who were apparently not too frightened by the prospect of 4 days of isolation. Consequently, it is possible that their affiliative or dependency responses were, in some respects, only weakly developed.

Secondly, prisoners who live in cell-blocks or dormitories suffer from lack of privacy; thus, a 4-day period of isolation may have had pleasant, as well as unpleasant, aspects. This latter consideration may, in fact, explain the rather perplexing finding that, while reporting relatively high anxiety, the isolated prisoners gave a more positive evaluation of the concept "solitary" than did the nonisolated controls.

The study, nevertheless, suggests that the deleterious consequences of social isolation have been too greatly emphasized. Prisoners may not be representative of the general population; however, the same can be said of the college students and regular servicemen who have served as subjects in other studies.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinion of the Journal.)

CHLORDIAZEPOXIDE : AN EFFECTIVE ADJUNCT TO PSYCHOTHERAPY OF THE NEUROTIC STATES

S. GEORGE BROWN, M.D.¹

One component common to all the neuroses is anxiety, whether overtly expressed as the so-called "free-floating" form, or classified as an anxiety reaction. Displaced by, or converted or channeled into the defensive mechanisms of the obsessions, compulsions, conversion states and phobias, it assumes disguises which serve to lessen its directly perceived form(1).

None the less, anxiety or the underlying threat of it presents a major problem in many patients during therapy. Its presence (covert or apparent) can be damagingly obstructive to progress in both analysis and the supportive psychotherapies. To aid in alleviating anxiety, hence removing this major block, the tranquilizing drugs from the outset appeared to hold great promise. Unfortunately, my considerable experience with a variety of the psychosedatives had proven disappointing: some fell short of their purported objectives; others caused systemic toxicity, while the few which did relieve anxiety and tension also produced drowsiness or over-relaxation—sufficient to make the patient lethargic, hence as unresponsive to therapy as when tense with anxiety without the drug.

Consequently, when chlordiazepoxide,² the first of a unique class of compounds (the benzodiazepines) was reported to exert a specific anti-anxiety action without oversedation(2-6), my interest was aroused. Under treatment at this time were a number of patients whose responses to previously tried tranquilizers had been negligible; whose progress in psychotherapy was slow, difficult and unsatisfactory. Thus, this ap-

peared an opportune time to observe the drug's effects in this problem group.

Chlordiazepoxide, in conjunction with analysis or supportive therapy, was administered orally to 57 patients (41 male, 16 female) ranging in ages from 12 to 66 years—72% were under age 40.

Diagnoses included anxiety with hysteria in 17 patients, phobic and depressive reactions in 10 each, and obsessive-compulsive states in 5; mixed anxiety states accounted for the remainder of the emotional disorders being treated.

Dosages ranged from 15 to 80 mg. daily, but individual adjustments made weekly in accord with need and therapeutic response brought the average dose to approximately 10 mg. t.i.d.

Criteria for the evaluation of drug response were three: symptomatic relief, the degree and quality of the patient's readjustments and readaptations to his situational stresses (as disclosed through therapy and observed by family and associates), and the extent and depth of progress apparent in daily analysis or in weekly psychotherapy sessions.

RESULTS

Of the 57 patients, 28 achieved complete remission of symptoms and made highly satisfactory readjustments; another 26 (still continuing with combined therapy) are making excellent progress in psychotherapy, with prognoses of early recovery. The 3 remaining patients, while showing benefit, are still far from their goals of emotional stability and good functional readjustment.

The drug was well tolerated and enthusiastically accepted by the group; few failed to comment upon the "lift" and "ease of mind" not previously experienced with

¹ Formerly Senior Psychiatrist, New Hampshire State Hospital. Currently in private neuropsychiatric practice, Concord, N. H.

² Librium® was provided by Hoffmann-La Roche Inc., Nutley, N. J.

other tranquilizing agents. No side effects were noted.

DISCUSSION

From the outset (prior to chlordiazepoxide therapy) these patients had offered considerable, though unconscious, resistance to therapy—from self-imposed mental blocks to such evasions as stem from a reluctance to relinquish their defenses; part of the obstructing force appeared to be anxiety, or the threat of it. For example, a number of patients would become charged with *extreme* anxiety when sensitive areas of experiential recall were being examined; others found self-scrutiny too painful, and visible anxiety would block further analysis.

Communication was often troublesome; verbalization was halting and conscious concern over it would prove disruptive to further exploration, whereas still others had difficulty in grasping the significance of revealed material, thus rendering insight into their conflicts slow and tedious.

CONCLUSION

Psychotherapy was facilitated in two significant regards: 1) through the alleviation of anxiety, and relaxation without over-

sedation, chlordiazepoxide markedly augmented patient-therapist communication, thereby promoting better insight, making constructive therapy possible; 2) through its psychological protection against the threat of anxiety, the patient was fortified against stress-provoking situations encountered between office visits.

In none of this group would it have been possible for chlordiazepoxide or psychotherapy alone to effect as promptly the degree of benefit that their combination achieved. As an adjunct to psychotherapy this agent fulfills a long-recognized need.

A COMPARISON OF TWO PHENOTHIAZINES IN THE TREATMENT OF SCHIZOPHRENICS

M. DIERKS, M.D.¹

Following the introduction of the phenothiazines, and for some time thereafter, it was suggested that their tranquilizing activity was directly related to their capacity to cause extrapyramidal stimulation. This hypothesis was attended by a paradox, the widespread use of anti-parkinsonian drugs to control the extrapyramidal symptoms induced by these very drugs. However, this theory became untenable with increasing evidence² that one phenothiazine, thioridazine (Mellaril), exhibits potent antipsychotic effects with little or no extrapyramidal

stimulation. An opportunity to explore this relationship presented itself at Danvers State Hospital by determining the effect of thioridazine in a series of patients previously treated with trifluoperazine (Stelazine), a phenothiazine whose tranquilizing activity is accompanied by extrapyramidal symptoms.

This series consisted of 109 female patients ranging in age from 23 to 60 years and domiciled in 5 parole and 2 closed wards. Duration of hospitalization ranged from 12 to 18 months, with schizophrenic reactions, involutional psychoses and manic-depressive reactions, manic type, predominating as the diagnoses. Optimum clinical effect had been established in 26 patients

¹ Danvers, Mass.

² Cole, J. O., *et al.*: *Drug Therapy. In Progress in Neurology and Psychiatry*. New York: Grune & Stratton, 1960.

with trifluoperazine alone. However, in 83 patients benztropine (Cogentin) had to be added to control the parkinsonian phenomena induced by trifluoperazine, *viz.*, restlessness, stiffness, shuffling gait, mask-like facies and cogwheel phenomena. The dose of benztropine varied from 0.5 to 8 mg. daily.

These drugs were discontinued and replaced by thioridazine as follows: 1) 25 mg. thioridazine was given t.i.d. for 3 days, followed by increased increments until the dose providing optimum effect was established; 2) an arbitrarily selected equivalent dose of thioridazine was immediately substituted for trifluoperazine, the ratios initially being 20:1 and adjusted thereafter according to response and toleration. No benztropine was permitted in order to determine precisely the parkinsonism potential for thioridazine.

RESULTS

Method 1 provided a smoother transition than did method 2 which elicited fatigue and lethargy in several cases and postural hypotension in 3 patients. These subsided within one to two weeks with dosage adjustment. In 104 of these patients (25 had received trifluoperazine alone and 79 had received trifluoperazine plus benztropine), the effect obtained with thioridazine alone over periods ranging from 45 days to 9 months was rated equal to that obtained before, permitting the patients in parole wards to continue with helpful chores in kitchen, cafeteria and laundry and able to leave the hospital for periods ranging from 3 to 14 days. Range of daily dosage was 4 to 40 mg. for trifluoperazine and 50 to 800 mg. for thioridazine, with 10 mg. for trifluo-

perazine and 200 mg. for thioridazine predominating as equivalent daily doses. Blurred vision due to the anticholinergic effect of benztropine disappeared in 3 patients when they were switched to thioridazine.

One patient responded inadequately to both drugs. Reduction of dosage in 3 patients exhibiting lethargy to thioridazine was followed by hallucinations and led to their return to trifluoperazine with benztropine.

During the time the 109 patients received thioridazine, only one exhibited any signs of parkinsonism. This was a 64-year-old paranoid schizophrenic who had been refractory to a number of drugs but responded dramatically to 200 mg. thioridazine daily. This evoked rigidity which responded to benztropine.

SUMMARY AND CONCLUSIONS

Consecutive evaluations of trifluoperazine and thioridazine were performed in 109 hospitalized schizophrenics. The same degree of tranquilizing effect was obtained with both drugs in 104 patients. Extrapyramidal symptoms were induced by thioridazine in 1 patient and by trifluoperazine in 79 patients and were controlled by the addition of benztropine.

This study has demonstrated that thioridazine is an affective agent relatively free of extrapyramidal symptoms and that the latter are not required for a drug to be an efficient tranquilizer. In addition, treatment with thioridazine alone required fewer tablets per day and resulted in greater economy as well as increased assurance of drug intake and patient cooperation.

A NEW PIPERIDINE PHENOTHIAZINE (PEPERACETAZINE)¹ IN CHRONIC PSYCHOTIC PATIENTS

K. H. TUTUNJIAN, M.D., AND J. A. GUIDO, M.D.²

This report represents a 4-month clinical

¹ Peperacetazine (Quide) supplied by Pitman-Moore Co.

² Respectively, Staff Psychiatrist, Asst. Superintendent, Metropolitan State Hospital, Norwalk, Calif.

investigation of the psychotropic potentialities of a new phenothiazine in facilitating the rehabilitation of chronic back ward patients. Milligram potency ratio with chlorpromazine, 20:1.

METHOD

A sample of 20 psychotic female patients, 20-64 years of age, was randomly selected from a "maximum security ward." Periods of hospitalization ranged from 5-17 years. They had received the gamut of chemotherapy, paramedical therapies and innumerable ECTs; 2 patients were lobotomized. In 70% of the group, the conspicuous target-symptom-complex consisted of gross delusional ideas with combative acting out behavior. The patients were used as their own controls so that improvement could be compared or contrasted with their background of historical and clinical information. Diagnoses: 17 schizophrenic reactions, (9 chronic undifferentiated, 3 hebephrenic, 2 catatonic, 2 schizo-affective, 1 paranoid), 3 chronic brain syndrome, convulsive disorder with psychosis.

All were combative to a varying degree and manifested a few or more of the following: grossly delusional ideas of a persecutory nature; overt sexual seductiveness toward the doctors, nurses or other patients; denudativeness; overt auditory and/or visual hallucinations; unpredictable episodes of excitement with destructive behavior (destroying furniture, seclusion doors), "intentional" incontinence.

Control of situational variables was attempted by avoiding any change in the psychiatric and nursing staff, ward milieu, doctors' and nursing rounds. Each patient received a complete physical and neurological examination, routine hemogram, urinalysis, chest x-ray, and liver function tests. The clinical status was evaluated weekly and combined, for more detailed compilation, with nurses' notes, family observations, and ancillary therapists' reports.

The initial dose was 10 mgm. t.i.d. in the elixir group of 50% of the patients, and 25

mgm. b.i.d. of the oral tablet to the remaining 50%. The dose was increased up to a maximum of 125 mgm. daily in 75% of the patients. Reduction of dosage was not necessary below 40 mgm. daily. Maintenance dose of 75 mgm. was determined on a clinical basis as well as individual tolerance without undesirable side effects. Smaller dosages seemed to be more easily tolerated by patients 45-64 years of age, and/or with a chronic brain syndrome.

RESULTS

After 3-4 days, 50% manifested improvement by qualitative and quantitative abatement of the above-described symptomatology. The most conspicuous result was the marked remission of hyperactive, combative behavior. Fifty percent responded dramatically in this manner, 15% moderately, 35% not at all. Improvement was also evaluated on the basis of the patient's adjustment in the paramedical therapies, number of home visits, and restoration of the eating and sleep cycle. Relatives began attending the family therapy sessions more frequently. For the first time, in some instances, we had an opportunity to evaluate the family situation. One patient with a "high record" of shattering seclusion doors and breaking furniture has remained out of the hospital for prolonged periods with a sustained remission to this date.

Duration of treatment was 4 months. Follow-up evaluations cover a 6-month period. The optimal or maintenance dose of 75 mgm. was sustained in 90% of the patients. Undesirable side reactions were rare and consisted of status epilepticus and autonomic effects (nausea, emesis and bradycardia) which disappeared with reduction of dosage in 2 patients. It was not necessary to use antiparkinson medication.

BENZQUINAMIDE : A PRELIMINARY REPORT

ANTHONY SAINZ, M.D.¹

Benzquinamide, dimethyl-12-ketoamino-methyl-13-acetylquinoline, is a quinoline derivative that has the unique property,

possibly solely among its congeners, of not releasing serotonin or the group of the catecholamines intracerebrally, or, for that matter, peripherally. It is rather remarkable, therefore, that the drug is able to produce

¹ Director, Division of Research, Marcy State Hospital, Marcy, N. Y.

sedation or tranquilization in mice and monkeys. Prolonged animal studies have shown an also remarkable freedom from side effects and toxicity.

A preliminary program was established in September 1961 to determine the phrenopraxic range(1) of the drug. Following the demonstration of lack of toxicity in volunteers, 51 patients, determined through proper screening to be placebo non-reactors (2), were administered the drug according to our triple-blind technique.² This group was controlled with another comprising 16 subjects receiving identical placebos and having a similar human composition. The study sample was composed of 7 manic-depressive, manics; 12 hyperkinetic schizophrenics; 8 diffuse organic brain syndromes with severe agitation; 5 anxiety states; 14 simple stress reactions manifesting severe agitation; and 5 endogenous depressions.

The manics received an "average therapeutic dose" (ATD) of 400 mgs. for about 6 weeks before being placed on the "average maintenance dose" (AMD), which was 100 mgs. The "minimum effective dose" (MED) was 100 mgs. in this group and the "maximum useful dose" (MUD) was 1200 mgs. Four of the 7 patients in this group went into full remission and one, a very chronic case, showed substantial improvement. The remaining two did not respond at all.

Six of the 12 hyperkinetic schizophrenics showed reduced overactivity, but without any primary or secondary changes in their psychosis. Six were unaffected. ATD in this group was 300 mgs., given daily for 6 months. The AMD in those who became less agitated averaged 150 mgs. MED was 150 mgs. and MUD was 600 mgs.

In the organic brain syndromes ATD was 100 mgs., MED 50 mgs. and MUD 300 mgs. The AMD was equal to the ATD. Only two of the patients showed relief from agitation, and these two were subsequently found to be of non-parenchymatous cerebral dysfunction type. The remainder showed inconclusive and ungradable response and 3 of them appeared even to be slightly over-

stimulated. This particular manifestation is now the subject of further study.

The ATD in the anxiety neurotics was 200 mgs., the drug being given for 3 months. No particular effectiveness was found in this group, outside of being the one where the only side effects were reported, namely drowsiness (mild and of short duration) which appeared at doses of 100 mgs. about 15 to 30 minutes after ingestion. Because of its ineffectiveness in this group, other dosage factors were not determined.

The ATD in the simple stress reactions was 100 mgs. and was required for an average of only 2 weeks. AMD was found to be 25 mgs., which was equal to the MED. MUD was 300 mgs. Thirteen of the 14 patients in this group had complete relief from their apprehension and agitation. One failed to respond even at doses of 600 mgs.; he subsequently improved with thioridazine.

The ATD in the endogenous depressions was 400 mgs. without any effect, for which reason other dose factors could not be determined.

Clinically observed and objectively evaluable side effects were 2 cases of drowsiness, found among the anxiety neurotics, and 1 case of gastritis. Laboratory studies, consisting of FBS, NPN, SGOT, SGPT, CHOL, alkaline and acid phosphatase, and Van den Bergh, were done every 2 weeks; complete hematology and urinalysis were done twice a week: excretion studies of 5-HIAA, DOPamine and catecholamines were done weekly. No variations from the normal range were observed.

It appears from our data that benzquinamide is a good, probably superior, tranquilizer, indicated for simple stress reactions. It has a phrenopraxic range similar to the barbiturates and meprobamates, but owing to its freedom from side effects and toxicity, and its clean laboratory record, it seems far better. It has no antipsychotic nor antidepressant activity, and it is not an anagolytic.

A NEW METHOD OF DRUG THERAPY¹JOHN KINROSS-WRIGHT, M. D., ALFRED H. VOGT, M.D., AND
K. D. CHARALAMPOUS, M.D.²

Fluphenazine enanthate (SQ 16,144) is the heptanoic acid ester of fluphenazine (Prolixin[®]). Dissolved in sesame oil and injected subcutaneously into adipose tissue, it slowly releases fluphenazine over a period of two weeks. Burke, *et al.*³, have shown that a single dose of this substance will inhibit the conditioned avoidance response in rats for 12-15 days while an injection of ordinary fluphenazine inhibits for only 24-48 hours. Inhibition of apomorphine-induced vomiting in dogs is prolonged for as long as 4 weeks. Toxicity and pharmacological effects of the enanthate are essentially comparable to those of fluphenazine itself.

Our preliminary observations in monkeys and human volunteers indicated a similarly prolonged effect in man.

A double-blind control study (reported elsewhere) showed that twice monthly subcutaneous injections of 25 mg. of fluphenazine enanthate were therapeutically equivalent to daily 5 mg. doses of ordinary fluphenazine by mouth. In addition, in any 2-week period, the total dose of fluphenazine necessary for equivalent therapeutic effect was three times that of the enanthate.

We have treated 147 patients with fluphenazine enanthate in 3 hospital services. With the exception of one manic patient, all had schizophrenia. The majority fell into the undifferentiated or paranoid categories; 127 were chronic cases. The average duration of illness for all patients was 6.14 years. Sex: 109 male, 38 female.

The drug was given at fixed intervals of 14 days by subcutaneous injection either into the buttock or abdominal wall. The former appeared to be the site of preference, though in either case local irritation was uncommon. The majority of the injections were in 25 mg. amounts. However,

12.5-100 mg. were tried without significantly better effect. Duration of treatment ranged from 2 weeks to 6 months.

Clinical effects were in every way comparable to those of fluphenazine itself, though onset of action is delayed typically for 24 hours. Persistence of tranquillizing effect was consistently noted for 10-20 days with a mean of 13 days.

As was predicted with a piperazine-substituted phenothiazine extrapyramidal effects were obtrusive, occurring in slightly over half the cases. In the main, these were of the episodic dystonic variety. Other side effects were rare. Dizziness, insomnia, dryness of mouth and disturbance of visual accommodation were noted. Extrapyramidal effects were typically maximal on the 2nd-4th day after injection and decreased thereafter. In every case they responded well to anticholinergic medication.

Therapeutic results were better, as might be expected, in the acute rather than the chronic patients. However, of the total number, 17 were unimproved or worse, 40 showed relief of some major symptom though they were still psychotic, 68 showed relief of many symptoms and made a good adaptation to the hospital situation, and 22 achieved remission of their illness and were discharged.

It is possible therefore to conclude that fluphenazine enanthate injected in doses of 25 mg. twice a month is essentially equivalent to standard daily dosage with oral phenothiazines.

A number of authors have pointed out that quality and duration of remission in schizophrenic patients are related to adequate maintenance medication following discharge from the hospital.

Lack of insight or cooperation on the part of the patient or his family more often than not leads to rejection of medication. Cost of drugs, lack of follow-up facilities are additional factors. In general psychiatrists have, through experience, become resigned to a high relapse rate in schizophrenic

patients who have responded to drugs while in the hospital.

A slow-release preparation of an effective phenothiazine which can be given at long intervals would solve much of the problem. Responsibility for daily medication would

be removed from the patient and would be reduced to scheduled visits to the office or clinic. Fluphenazine enanthate is such a preparation though it has the disadvantage of producing a high incidence of extrapyramidal reactions.

TRIFLUOPERAZINE COMBINED WITH AMITRIPTYLINE IN PARANOID PSYCHOSIS¹

SYLVIA F. CHENG, M.D., AND ERNEST J. FOGEL, M. D.²

One hundred female schizophrenic patients in acute intensive treatment service were selected and given the drug combination of trifluoperazine (Stelazine) and amitriptyline (Elavil)(1-5) during the period from Sept. 1961 to July 1962. They were all newly admitted or readmitted, acutely psychotic with paranoid features but showed little evidence of deterioration. Seventeen patients had a history of mental illness less than one month; 21, 1-6 months; 26, 6 months-2 years; 18, 2-10 years and 15 over 10 years. The majority had received private psychiatric treatments prior to admission, 58 were hospitalized previously at private psychiatric hospitals or this hospital. Their ages ranged from 16 to 68 with the average age 34. The criteria for selection were based on target symptoms: paranoid ideation, paranoid attitude, hostility, anxiety, endogenous depression, somatization and hallucination(2-4, 6).

Medication consisted of trifluoperazine 5 to 10 mg. b.i.d. or t.i.d. with amitriptyline 25 mg. or occasionally 50 mg. t.i.d., and chlorpromazine, thioridazine, chlorprothixene or chlordiazepoxide were given in the beginning to control severe motor disturbance. Amitriptyline 20 mg. I.M. were given PRN for acute anxiety and severe depression. Seventy-three patients showed remarkable improvement, 22 showed improvement in area of paranoid component and 5 were unchanged due to disorganization

of thinking and depersonalization. They blamed everybody unjustly on admission but in two weeks they became friendly, warm and gained insight believing that they were helped here. They participated in psychotherapy, group activities and industrial therapy within a very short period of time. Their personal hygiene and interpersonal relationship were greatly improved; many families commented that "they were better than they had ever been for years."

Because of the extraordinarily good result obtained on schizophrenic reaction, paranoid type, we selected another 25 female patients who suffered from paranoid psychosis associated with mental disorders other than schizophrenia. They were 5 involuntal, 5 arteriosclerotic, 5 senile, 3 Huntington's chorea, 2 C.B.S. a/w intracranial infection, 2 epileptic, 2 alcoholic and 1 paranoid state. We found that as far as relieving of paranoid psychosis is concerned such drug combination did equally well.

The usual extrapyramidal symptoms, dyskinetic and vagotonic reactions apparently caused by trifluoperazine are believably minimized by amitriptyline. Amitriptyline in the dosage of 25 mg. t.i.d. merely causes a slight dryness of the mouth in about 50% of the cases and constipation in about 30%. Dosage up to 50 mg. t.i.d. occasionally causes dizziness, drowsiness and blurring of vision. It counteracts digitalis effect slightly(4, 5, 7).

COMMENT

By adding amitriptyline to trifluoperazine the antipsychotic effect of trifluoperazine

¹ Trifluoperazine (Stelazine) and amitriptyline (Elavil) are manufactured by SK & F and Merck Sharp & Dohme, respectively.

² Respectively, Acting Chief, AIT Service, and Superintendent, Logansport State Hospital, Logansport, Indiana.

zine is believed greatly enhanced, with improvement of paranoid psychosis observed in 95% of the cases whereas trifluoperazine given alone would relieve psychosis up to 75%(3) and amitriptyline per se would relieve depression up to 79% of the cases(4). The usual period required to obtain maximum benefit is reduced from 4 to 2 weeks. The patients have appeared normal and experienced a sense of well being; thus it makes drug therapy more acceptable. The rapid clearing of paranoid delusion especially calls for further study of amitriptyline given in combination with trifluoperazine and other phenothiazines.

It appears to us that each 25 mg. of amitriptyline would eliminate parkinsonism induced by 5 mg. of trifluoperazine; 2.5 mg. of fluphenazine; 8 mg. of perphenazine; 10 mg. of prochlorperazine and 100 mg. of chlorpromazine whereas trifluoperazine given alone would cause parkinsonism in 41% of the cases, fluphenazine, 31%, perphenazine, 20%, prochlorperazine, 15%, and chlorpromazine, 10% according to a review of 178 clinical series of 10 phenothiazine

derivates by Anderson which seems parallel to our observation(7, 8).

SUMMARY

One hundred schizophrenics and 25 others with paranoid psychosis received trifluoperazine and amitriptyline in combination. The results were unusually gratifying and side effects reduced.

ECG CHANGES DURING AMITRIPTYLINE TREATMENT

E. BOJE RASMUSSEN, M.D., AND P. KRISTJANSEN, M.D.¹

Amitriptyline has to a certain extent replaced imipramine in the treatment of depressions and is by some investigators found to have fewer side effects. V. Lunn and E. S. Kristiansen² have described cardiac complications under imipramine, appearing in the ECG as isoelectric or negative T₁ or T₂. According to our experience so far amitriptyline may produce similar ECG changes.

On 33 male and 32 female patients ECG was controlled at least once during amitriptyline treatment and compared to ECG from periods without administration of thymoleptic drugs.

Amitriptyline was given perorally in a dosage varying from 75 to 225 mg. daily, and treatment was continued for at least

3 weeks. The average age in the group was 60 years.

In the male group evident ECG changes were found in 3 patients, less certain changes in 13, and no changes in 17 patients. In the female group the corresponding figures were 9, 8 and 15. Evident changes include isoelectric T₁ or T₂ or both, depression of the S-T interval, frequently appearing ventricular extrasystoles; in 1 case right ventricular preponderance was accompanied by stenocardiac complaints.

As less certain ECG changes we have regarded flattening of T-waves in first and second lead, although still positive, tachycardia, inversion of T-waves in third lead, and finally solitary ventricular extrasystoles. In this group as well we have included 3 male patients suffering from cardiac disease and deteriorating during amitriptyline treatment :

¹ Sct. Hans Mental Hospital, Roskilde, Denmark.

² *Wien. Med. Wschr.*, 110 : 754, 1960.

1. A male patient, age 67, suffering from cardiac disease with perpetual arrhythmia, developed a fatal cardiac insufficiency under 50 mg. of amitriptyline daily. During treatment diphasic T_1 and T_2 were registered. 2. A male patient, age 66, suffering during several years from stenocardia, developed an apparent coronary thrombosis with subsequent interventricular heart-block after 3 months under amitriptyline up to 150 mg. daily. 3. A male patient, age 47, suffered from hypertensive cardiac disease. Under previous imipramine treatment negative T_1 and T_2 was transitorily registered. Under amitriptyline 75 mg. daily isoelectric or diphasic T_1 and T_2 reappeared.

Finally some patients showing positive ECG changes under amitriptyline are registered in the second group under "uncertain changes" because the control ECG's were not considered comparable.

Four elderly female patients with cardiac debilitation had to discontinue amitriptyline treatment at an early stage. One of them, aged 75, who had suffered from a coronary attack 16 days before treatment, was severely dyspneic after the second 25 mg. dose of amitriptyline. Three female patients aged 82, 66 and 64, respectively, showed hypotension, tachycardia, and dizziness after 1-2 weeks under amitriptyline, the oldest of them having ECG signs of coronary thrombosis 3 days after discontinuation. The other 2 patients were relieved from their symptoms soon after

treatment was stopped.

A female patient, age 49, with no previous history of cardiac disease developed under 100 mg. daily of amitriptyline ECG changes in the shape of isoelectric T_2 . When after 60 days of treatment the patient wanted discharge for private reasons, amitriptyline was replaced by imipramine in the same dosage. Two days later she stopped taking the tablets due to dizziness, dyspnea, and tachycardia. After a fainting attack she was readmitted to hospital with clinical and ECG signs of myocardial infarction, which gradually disappeared.

Based on the present preliminary impressions it is considered advisable to initiate all amitriptyline treatments by ECG examinations and to use a cautious dosage in elderly patients, *i.e.*, above 65 years. If the preliminary ECG is found abnormal, treatment must be carefully considered and supervised, according to the actual changes. An isolated appearance of isoelectric or diphasic T_1 and T_2 during amitriptyline administration is probably of minor importance.

After termination of the present study two female patients under amitriptyline developed left interventricular heartblock, disappearing completely after discontinuation.

A NOTE ON THE SCHIZOPHRENIC COLLEGE STUDENT

EDWARD PODOLSKY, M.D.¹

There are more than 3,000,000 students currently enrolled in the nation's 1,900 colleges and universities. The frequency of schizophrenia in college students has been estimated at 24.6% by Melvin L. Selzer.² This is an increase of 8% previously established. It is Selzer's belief that the apparent increase is probably due to changing diagnostic criteria. The diagnosis of schizophrenia is no longer reserved solely for persons having definite disorders of thought and perception. The diagnosis can be made, or at least, suspected, on the basis of severe affective disturbance, inability to establish meaningful object relationships, conceptual difficulties, and behavioral aberration.

Most schizophrenic college students are able to cope with the scholastic demands; many are capable of receiving undergraduate and advanced degrees. However, they expend more time and energy in attaining their goals.

The present author has been treating a number of schizophrenic college students through the years. He has been made aware of certain characteristics in them which are quite common. The following characteristics apply generally to the schizophrenic student:

1. He is not quite goal-directed as to his life's vocation, but has vague ideas of what he might want to be, usually some occupation beyond his capabilities—an indication of a loose contact with reality.

¹ 1049 E. 18th Street, Brooklyn, N. Y.

² A.M.A. Arch. Gen. Psychiat., 2 : 133, 1960.

2. His methods of studying are bizarre. He devotes a great deal of time to studying, but is not able to concentrate effectively on his tasks ; he is easily distracted by extraneous factors during his study period. He does copious underlining of passages in his textbooks, makes marginal notes, makes summaries on cards, but is actually not too aware of what he underlines or summarizes. Usually these are mechanical procedures. There are periods of intense study activity followed by periods of little or no study at all.

3. He always aims for an A in all his subjects, but manages at best a B, most often a C. Though always aiming high, he inwardly knows that he will never be able to attain an A, and is therefore quite happy to obtain any passing grade.

4. He is not able to discuss any topic for any length of time. He is easily distracted, and wanders from subject to subject illogically.

5. He has a tendency to make himself conspicuous in his class. He joins classroom discussions, although he is not prepared to contribute anything to the discussion. Afterwards he realizes that he has made a fool of himself and resolves thereafter to refrain from classroom discussions ; but the very next time repeats this sorry performance. In time he begins to feel that his classmates as well as his instructors regard him as an oddball.

6. He is not able to form close interpersonal relationships. He feels threatened and suspicious of his classmates. The friend-

ships he forms are for selfish purposes, to learn about previous examination questions, to obtain free tutoring, *etc.*

7. He seeks special attention from his instructors, ingratiating himself by doing favors for them. He also hands in over-elaborate assignments. He endeavors to get himself noticed and liked by his instructors. He seldom succeeds in getting favorable attention ; most often his instructors regard him as queer.

8. He has the feeling that the administrative staff is composed of spies, that his class advisor is trying to "get something on him." For this reason, he consults with him on as few occasions as possible.

9. He never seems confident enough to take a final examination although he has made elaborate preparations for it. He finds some excuse so that he will be permitted to take a make-up examination. These make-up examinations tend to complicate an already over-complicated program.

10. He takes the easiest subjects early in his college career, leaving the more difficult ones for his junior and senior years. Most often he is required to take summer courses and more than 4 years to complete his college work.

For some strange reason most schizophrenic students are able to complete their college work with a fair to good average. Quite a few of them look forward to graduate work or professional school. A few even succeed in getting admitted to medical school.

CASE REPORTS

THE RESPONSE OF AN ADRENALECTOMISED PATIENT TO ECT

A. H. CRISP, M.B., M.R.C.P.(E), AND F. J. ROBERTS, M.B.

This memorandum records the successful treatment with ECT of a depressive illness in a totally adrenalectomised patient.

ECT has come to be regarded as being most beneficial in depressive states. Many authorities believe that it is the "endogenous depression" which responds best to this therapy(1-3). It is generally agreed that it does no more than interrupt the current illness.

In 1948 Gordon(4) collected some 50 theories regarding the mode of action of ECT. The psychodynamic theories are difficult to substantiate(5). The possible reactions and experiences of fear and punishment engendered by the ECT have been found to be unrelated to improvement during treatment(6-10). Ottoson(11) has shown that the essential therapeutic factor is the fit and that the memory disturbance, held by some as important for recovery(12), may develop equally with subconvulsive electrical stimulation. Others have shown that stimulation of the diencephalon, recordable on EEG, is an important factor in recovery(3-13); the patient begins to experience consciously acceptable reality once more, perhaps because anxiety is being engendered and repression consequently facilitated(14). Fleming(15), reviewing current theories on the action of ECT, points out that it has been claimed that the response depends upon an increased resistance to stress following the stimulation of the pituitary adrenal axis with a consequent increased secretion of steroid hormones(16, 17). This theory was refuted in 1956 when a case was carefully described of a depressed but adrenalectomised patient

who responded well and promptly to ECT(18). We have recorded a similar and second case since the theory is still propounded(19).

The patient, a 55-year-old spinster, is suffering from a fairly widespread breast carcinoma. Despite this, she is still subjectively physically fit. In 1956, she underwent a radical mastectomy which was followed by local radiotherapy. She was subsequently maintained on oestrogens and was given further radiotherapy to the superficial secondary deposits. Spread to the opposite breast was noticed, and adrenalectomy was advised. In March 1961 she underwent a bilateral oophoro-adrenalectomy in a two-stage procedure. Within a few hours of losing all her adrenal tissue she became agitated, importunate and depressed. She complained of lack of energy, difficulties in concentrating, and an overwhelming fear and belief that she was going to die from a stroke. She was resistant to the idea of further treatment, and suspicious of our intentions to a delusional degree. She was found to be denying the sinister nature of her real physical illness and any contemplation of this worsened her agitation and depression. Initially, our attention was directed towards the hormonal upset as a possible cause of her depression. Depression, however, is not a common sequel to adrenalectomy, although it is sometimes associated with hypercorticism, endogenous or iatrogenic, especially if there is a pre-existing manic-depressive diathesis in the personality. The steroid replacement therapy was therefore tentatively reduced in amount for a few days but without effect on the mental state, so that the dosage was thereafter restored to that of the normal post-operative regime.

We then concluded that she was suffering from a depressive illness which had been precipitated by the implication and unexpected extent of the recent operations but which was independent of hormonal disturbance. This view was consistent with the history of a depressive illness of similar nature 19 years previously which had responded to ECT. After 2 weeks' treatment with antidepressive

¹ Respectively, Lecturer in Psychiatry, Middlesex Hospital Medical School, Senior Registrar, Dept. of Psychological Medicine, King's College Hospital, London, England.

We would like to thank Dr. D. W. Liddell, Consultant Psychiatrist to King's College Hospital, for his permission to publish this case, and his advice.

drugs and a minimum of psychotherapy, during which there was no change in the patient's state, we decided to supplement her treatment with ECT. She responded appropriately and was quite recovered after 9 treatments, saying she had not felt so well for many months. During the treatment period she was receiving tranylcyromine (Parnate) 10 mgms. t.d., trifluoperazine (Stelazine) 5 mgms. b.i.d., cortisone 25 mgms. q.i.d. and 9-alpha-fluorohydrocortisone 0.1 mg. daily. She was discharged and returned to work. During the last 15 months she has continued at work and has been substantially well. There have been 2 fairly acute relapses despite the fact that in the first instance she was still taking tranylcyromine. These illnesses were treated successfully, on an outpatient basis, with a further 7 and 5 ECTs respectively.

The impression from this case has been one of repeated recovery from depression in response to ECT in the absence of the patient's adrenal cortices.

FURTHER DATA TO THE CLINICAL EFFECTS OF NIALAMIDE

EVAN J. HALAS, M.D.¹

Nialamide was instituted in massive doses in a case of longstanding depression, treated before unsuccessfully with various anti-depressant agents.

The patient is a 36-year-old male of average weight and build showing the classical clinical picture of depression. This condition had lasted for more than 4 years, with ups and downs and increasingly shorter remissions. There were two previous depressive episodes, one 19 and the other 13 years ago. He also had eczema of 7 years' duration and colitis of more than 20 years. Both conditions were static.

We started with the initial doses of 300 mg. Nialamide a day, as suggested by N. S. Kline

(1). Between the 10th and 15th day, first the feeling of depersonalization disappeared, then gradually the emotional tone changed, soon to reach levels of euphoria and a kind of hypomanic over-activity.

The pattern of sleep changed also, requiring less sleep yet awakening refreshed. Interestingly the nightmarish content of the dreams did not change for a considerable time.

Between the second and third week the eczema spontaneously disappeared and the colitis changed to constipation, then to normal stools. About the same time the patient, who never cared before for sweets, developed a voracious appetite, particularly for sweets, consuming an incredible amount of pies and candies. Although the increase of appetite was amazing, the gain in weight was still not in

¹ Chief of Service, Columbus State Hospital.

proportion, since the patient gained more than 20 pounds in less than 10 days. He noticed that his output of urine diminished considerably, suggesting a parallel retention of water. Liver function tests made at this time showed: direct Van den Bergh 0.0, total bilirubin 0.2, serum transaminase /SGPT/ 8 units, showing reactions within the normal range, and alkaline phosphatase 0.23 Bodansky units, which is considerably lower than the normal range.

Between the 7th and 8th week of treatment, the patient experienced an excruciating headache with sudden onset, starting at the nuchal area, spreading forward to the frontal area, diminishing somewhat when standing upright and increasing when sitting or lying. The pulse rate decreased to 40/min. and the blood-pressure showed a sudden rise, above 190 mm. systolic pressure.

In about 25 minutes the headache disappeared as suddenly as it started, the pulse rate returned to normal and so did the blood-pressure, returning to 108/65 mm. which was his normal rate. Assuming that the fluid retention was related to this attack, diuretics were administered and the dose of Nialamide was decreased, first to 200 mg. then to 150 mg. a day. In spite of the reduction two more similar attacks occurred, however of far less severity.

Although the emotional response to this drug was remarkable, in view of these side effects the treatment was discontinued. A few weeks later the eczema reappeared and so did the colitis.

Reviewing the literature dealing with the effects of Nialamide, we found one article where E. Beresford Davies(2) described quite similar attacks with sudden increase of systolic blood-pressure, associated with typical headaches, and slowing of pulse rate; he too attributed these manifestations to fluid retention.

In conclusion, if we consider the definite changes in patient's appetite, sleep pattern, water metabolism, carbohydrate metabolism and the imbalance of the vaso-motor system, all these seem to confirm previous reports that the site of action of this agent is the diencephalic area. The definite changes in the alkaline phosphatase rate matches with the results of R. Naranjo(3), who found in approximately half of his cases treated with Nialamide decreased alkaline phosphatase rates. The changes observed regarding patient's eczema and colitis leave us open to speculation as to the etiology of these somatic manifestations and their response to this agent.

TRANSIENT NEUROLOGICAL SYMPTOMS ACCOMPANYING ECT

FRANCIS J. KANE, JR., M.D.¹

Neurological symptoms are a feared but fortunately rare complication of ECT(1). This case is unusual because of the necessity to persist with ECT after the neurological symptoms abated.

A 56-year-old married housewife was admitted to the North Carolina Memorial Hospital on 7/8/61, with a 7-month history of affect depression, severe anorexia, some weight loss, loss of interest in her usual surroundings, agitation, and insomnia with early morning awakening. There was also severe somatic concern focused around her heart. She pre-

sented a depressed apathetic appearance, with worried facial expression, moderate psychomotor retardation, and considerable hypochondriacal concern without delusion, associated with a dry mouth. Sleep and appetite were poor, and periods of agitation were seen.

Physical examination was notable for a hypertension of 200/100, and there was a suspicion of angina pectoris. EST was deferred for a time because of the fear of cardiac complications, but she deteriorated rapidly. After 2 weeks in the hospital, she was started on EST modified with Anectine and Pentothal. On 7/28/61, after her third treatment, she manifested considerable confusion, and in the afternoon began to complain alternately of

¹ Dept. of Psychiatry, University of North Carolina.

chest pain and numbness in her body without any specific focus. However, on the following day when she seemed less confused, she complained of parasthesias of the left arm and leg, with weakness of the left arm. Repeated neurological examinations showed initially lower left facial weakness and weakness of the left arm and weakened dorsiflexion of the left foot, with slightly hyperactive DTR's on the left. There was a transient Babinski on the first and second days of examination. The sensory complaints were not confirmed. Gait was disturbed with associated arm and leg movements being less coordinated on the left. The neurologist felt she had a transient ischemic cerebral episode, and ECT was withheld. Imipramine, 150-200 mg. daily, was given, but the patient regressed markedly, becoming ceaselessly agitated, sleepless in spite of large doses of sedatives, and anorexic to the point of necessitating tube feeding. She sat ceaselessly picking at her hands, fingernails, and clothes, and had many delusions concerning her guilt. Because of the marked deterioration of her condition, she was reconsidered for ECT. The neurologists felt that all but the slight weakness in her left leg had cleared. The family was apprised of the serious risk in treating her, and with their agreement she received 11 additional ECT's between 9/7 and 9/29/61. During the first week she received daily ECT because of her marked regression, weight loss, and the difficulty of maintaining hydration. Following treatment, she was forgetful and confused, but easily managed by ward personnel. She was discharged on 10/13/61, much improved with only the aforementioned weakness of the left leg which did

not seem to impair her to any obvious degree. Recent follow-up showed no recurrence of her illness nearly a year later, and no progression of her neurological symptoms.

This is the second reported case with hemiparetic symptoms, the other being reported by Olsen(2). Vascular and cellular changes are reported in experimental animals, and in deaths occurring in connection with ECT(3). Madow believes most of these changes are reversible(3), which seems to be borne out by the experience with this patient. This case also confirms Kalinowsky's assertion that previous cerebrovascular disease is not an absolute contraindication to treatment(1).

SUMMARY

A case is reported of a 56-year-old psychotically depressed woman with severe vascular disease who suffered a transient hemiparesis after her third ECT. Her neurological picture cleared almost completely, and she later received 11 further ECT's with a good remission of her psychosis. No further neurological sequelae were noted, and she is well 9 months after discharge.

TRANQUILIZERS AND PSYCHOSOMATIC ILLNESS

WERNER TUTEUR, M.D.¹

The following case histories illustrate the beneficial effect of tranquilizers on psychosomatic illness. Controlled studies on such patients and syndromes are difficult to obtain. Neither their degree of illness nor society demand their confinement.

Case 1. White male, aged 33, married. Diagnosis: globus hystericus. A traveling salesman, father of one child, whose history was replete with emotional instability. His wife gave birth

to only one child. Salpingectomy following tubal pregnancy prevented further pregnancies. His symptoms were most acute during emotional excitement. The condition had existed on and off for years. When first seen on Mar. 9, 1962, he was placed on chlorpromazine spansules, 75 mg. t.i.d. On his second visit on Mar. 13 he reported considerable improvement, and by Mar. 16 he was free of complaints. There are periods when he gets along with one or two 75 mg. spansules a day. At this writing, Aug. 9, 1962, the patient is able to control his disturbance pharmaceutically.

¹ Elgin State Hospital, Elgin, Ill.

Case 2. White female, aged 35, married. Diagnosis : globus hystericus. A mother of 5 children, the youngest 3 months old. When first seen on July 21, 1962, she was wearing a wet towel around her neck, complaining bitterly of "stiffness outside and inside her neck," conforming with other classical complaints of globus hystericus. The patient stated that after each delivery she had been depressed and anxiety ridden. She was reassured and placed on chlorpromazine spansules, 75 mg. t.i.d. Four days later globus symptomatology had considerably abated. Two weeks after initiation of pharmacotherapy all globus symptomatology had disappeared. Her personality remains that of an emotionally unstable person, well expressed in the past by her psycho-obstetrical history.

Case 3. White male, aged 33, single. Diagnosis : cardiovascular neurosis ("heart flutter"). A television technician. His parents divorced when he was six. After living with father and stepmother while 7 years of age, conditions were so intolerable that his mother called for him and raised him. When first seen on May 8, 1962, he gave a history of many years of a "fluttering heart, which beats very fast at times, hurts him and scares him to the degree he thinks he is going to die." This started at age 10. There had been numerous ECGs and even EEGs, all with normal results. He functioned when first seen with a blood pressure of 120/82 and a pulse rate of 90, which was regular. Initially placed on chlorpromazine,

75 mg. spansules, t.i.d., this was changed 4 days later to 150 mg. at hour of sleep, since he complained of a feeling of being "keyed up all day," although there had been no "heart flutter and pain." On this dosage he has avoided this symptomatology since treatment began and recently completed a 2-week traveling vacation without incident.

There appears to be a possibility of giving relatively fast relief to a specific psychosomatic symptom, such as globus hystericus and cardiac discomfort, with pharmaceutical means. The three patients experienced reoccurrence of symptoms when temporarily discontinued from medication, but reinstitution of medication brought prompt relief. No placebos were used. We are aware of the unorthodox use of sustained release capsules. Rather than giving three of them at one time in the morning, or any time of the 24-hour period, they were given like ordinary tablets, t.i.d. Experience has shown that they are better tolerated than tablets. Whether or not it is a certain overlapping effect which occurs from such technique must remain subject to further investigation. Further reports on tranquilizers and psychosomatics along with investigative work regarding their functioning in this field are indicated and encouraged.

ELECTROSHOCK THERAPY OF A DEPRESSED PATIENT WITH COMPLETE HEART BLOCK

LORAN F. PILLING, M.D., MAURICE J. BARRY, JR., M.D., AND
THOMAS W. PARKIN, M.D.¹

We wish to report on a patient with complete atrioventricular heart block who had a course of EST for mental depression. A brief period of ventricular tachycardia and ventricular standstill occurred but the patient recovered.

A review of the literature revealed no report of a patient with complete heart block having received EST. However, we found reports of one instance of transient complete heart block and 11 instances of lesser forms of atrioventricular block oc-

curing after such therapy (5, 8, 9, 14, 17). It is of interest that, after such treatment, there have occurred a few instances of shortened PR interval with QRS prolongation simulating the Wolff-Parkinson-White syndrome (anomalous atrioventricular excitation) (12).

Several review articles indicate cardiovascular contraindications to and complications of EST (1-4, 6, 7, 10, 11, 13, 15, 19-23). An excellent recent monograph on the cardiovascular aspects of EST is that by Perrin (16).

¹ Mayo Clinic and Mayo Foundation, Rochester, Minn.

This 56-year-old man was first seen at the Mayo Clinic in Aug. 1961. His chief complaint was of a "nervous breakdown" which he said began in July 1959. At that time he had insomnia with early morning awakening and difficulty with memory and concentration. At the same time he began to have episodes of weeping, feelings of sadness and pessimism for the future, a decrease in sexual potency, and occasional persistent thoughts of suicide. All of these symptoms began within a few days and continued unchanged for 6 months. Then he began to feel guilty and to worry about recurring dreams which featured obscene expressions and phrases. Next he began to have persistent obsessional waking thoughts of the same type, such as fantasies about the appearance of the genitals of others. His appetite declined and he lost 40 pounds.

The patient sought help in his home community and was referred to a local psychiatrist who recommended private hospital treatment. Because physical examination revealed "athlete's heart," the patient was not given EST as had been planned. Instead, he was treated

with subcoma doses of insulin and orally administered tranquilizers and antidepressants. On this regimen he improved slightly and was discharged. The slight improvement was short lived, and he came to the Mayo Clinic on Aug. 8, 1961, where a diagnosis of involuntional reaction, depressive type was made.

There was no history of syncope, angina, dyspnea, or digitalis therapy. The ventricular rate ranged from 40 to 50 per minute and did not increase after exercise. The blood pressure was normal. The first heart sound varied in intensity, and a grade-1 systolic murmur was audible at the apex. His initial ECG revealed complete atrioventricular block (Fig. 1), and the cardiac silhouette was slightly enlarged on a roentgenogram of the chest.

The patient was admitted to the psychiatric unit for further psychiatric and cardiac evaluation. It seemed initially that this patient should not be treated with EST because of his cardiac disorder; therefore, a program combining psychotherapy and increasing doses of a MAO inhibitor was undertaken. It soon became evident that the patient's depression was so deep and inhibiting and his basic personality so rigidly defended that he was unable to communicate anything other than depressive and guilty material. He revealed an unusually rigid and unforgiving superego and much obsessional guilty preoccupation with ambivalent feelings about his parents and siblings. He was unavailable to any specific psychotherapeutic approach.

When his deep depression continued unchanged after this therapeutic trial, a conference was held. It was agreed that: 1. The patient could not function outside an institution if his depression continued unchecked. 2. Drug therapy and psychotherapy had little effect. 3. EST was the treatment of choice if the patient's heart could withstand it.

The situation was discussed thoroughly with the patient and his wife—the possible risks and complications of EST were explained. The patient and his wife requested EST, and treatment was begun on the 11th day of hospitalization.

The patient received 11 convulsive treatments in the next 26 days using a Medcraft Electroconvulsive unit. Atropine, grains 1/150 (0.43 mg.) was administered 30 minutes before each treatment. Anesthesia and muscle relaxation were achieved by administering 5 ml. of a 2.5% solution of sodium pentothal and 30 mg. of succinylcholine chloride (Anectine) intravenously. Oxygen, 100%, was administered by mask for several minutes before and after each treatment. A combination cardiac pace-

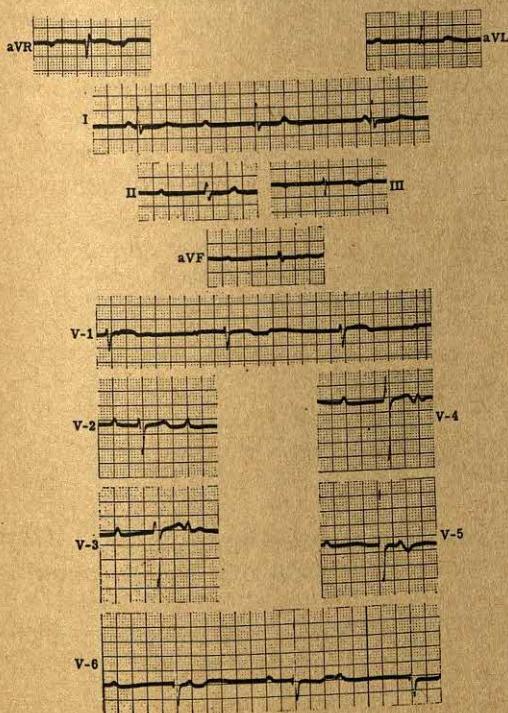

FIGURE 1

Electrocardiogram before EST shows complete atrioventricular block. Ventricular pacemaker seems to be located between AV node and origin of right and left bundle branches. AQRS (means manifest QRS axis) = +100. QRS interval = 0.10 sec. QRS voltage in precordial leads is suggestive of left ventricular hypertrophy.

maker-monitor and external electric counter-shock instrument was available in the treatment room. In addition, a surgeon was present to perform thoracotomy and cardiac massage if necessary.

ECGs were taken several times during the treatment. Significant ECG abnormalities appeared on one occasion immediately after the tonic convulsion: they consisted of ventricular

of complete heart block.

The patient experienced no syncope, angina or heart failure during EST and his blood pressure remained normal. Specific drug therapy for the heart block was not instituted, because the patient remained asymptomatic.

The patient's depression responded favorably to the shock therapy, and he was discharged Sept. 22 to the care of his family physician.

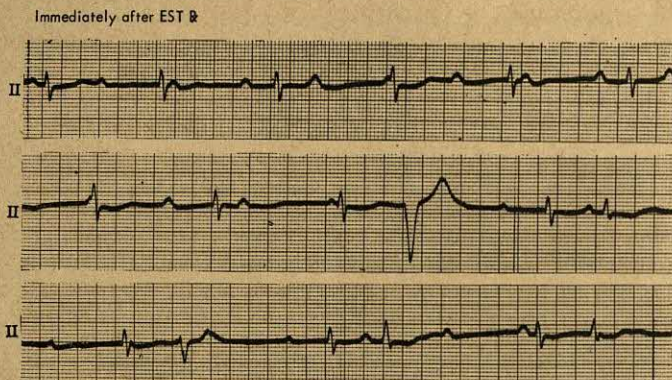

FIGURE 2

Lead II Immediately After EST. Fourth QRS Complex In Middle Tracing Shows Premature Ventricular Beat. In Lower Tracing Ventricular Bigeminy is Present Due To Multifocal Ventricular Beats.

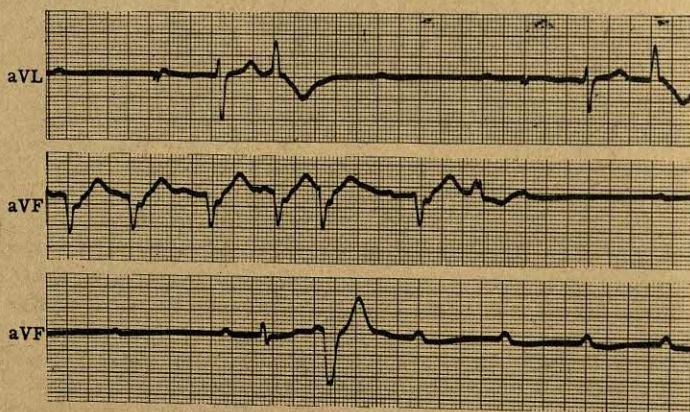

FIGURE 3

Note Leads Are Different From Those of Figure 2. Ventricular Premature Beats Produce Bigeminy In Upper Tracing. Middle Strip Reveals Ventricular Tachycardia, Terminal QRS Complex of Different Origin Than Preceding Complexes, and Ventricular Standstill. Lower Tracing, A Continuation of Middle One, Shows Return of Ventricular Activity For 2 Beats and Then Ventricular Standstill. P Waves Increase In Amplitude and Duration, Perhaps Because of Transient Atrial Enlargement Due To Increased Intra-atrial Venous Pressure. As Noted In Text, Electrocardiogram Subsequently Revealed Return To Pretreatment Status.

premature beats, occurring within 12 seconds, and of subsequent multifocal ventricular premature beats producing a ventricular bigeminy followed by a ventricular tachycardia lasting 6 seconds. Ventricular asystole then appeared and lasted about 8 seconds (Fig. 2, 3). The ECG then returned to the pretreatment pattern

Because of the apparent risk of ventricular standstill, fibrillation, or tachycardia in such a patient as ours, one should have readily available methods of applying electric currents externally: a cardiac pacemaker-monitor to apply electric stimula-

tion for ventricular standstill and an electric countershock instrument to interrupt ventricular fibrillation(24). If intrinsic pace-making activity does not resume after use of the designated instruments, intravenous administration of certain drugs, such as epinephrine and isoproterenol (Isuprel), may be required. In the presence of complete heart block, treatment of ventricular tachycardia with quinidine or procaine amide (Pronestyl) is contraindicated. In these cases, isoproterenol, ephedrine, or epinephrine should be used(18).

SUMMARY

A psychiatrically depressed patient with complete heart block received a course of electroshock therapy. On one occasion ventricular tachycardia and ventricular arrest occurred, but the patient recovered without cardiac therapy.

The potential aggravation of a pre-existing, serious arrhythmia should be considered carefully before the institution of EST, but the reported case illustrates that it can be used successfully in such circumstances. If necessary precautions are taken, such therapy may be appropriate when other treatment has failed.

THE PRESIDENT'S PAGE

In a short time you will be receiving mail ballots on the adoption of the new constitution. The changes proposed are urgently needed. Our present constitution is essentially a document adopted forty years ago and it has been amended almost every year; as a result, it is a thing of shreds and patches with numerous internal inconsistencies.

These have resulted in some confusion about membership categories and eligibility, the functions of Council and even the geographic jurisdiction of the Association itself. The processing of membership through the appropriate district branch has been arranged in such a way that the Association gains from the intimate knowledge which the district branches have of potential members. The procedure, in turn, considerably clarifies the relationship between the district branches and the Association itself.

An important aspect of the new constitution is that it recognizes the Assembly of District Branches and makes the Speaker a voting member of the Council which is precisely the role he should play.

The new constitution, like all works of

man, is imperfect. However, it is the result of three years of labor. Every phrase of it has been run through the Constitution Committee, the Council, the Assembly of District Branches, the Long Term Policies Commission and the Policy Committee. As a result of all this clash of mind on mind, the document has been polished. It has been molded to meet objections raised at various stages by each member of the reviewing bodies.

We hope you will vote "Yes" on this new constitution and by-laws. If it is not adopted we shall have to get along with our jerry-built, patched-up old document. If it is not adopted the Policy Committee will have no recognition, the Speaker will have no vote on the Council and the awkward and ill-defined relationship between the district branches and the central office will continue.

We urge the support of the proposed constitution, not because so many have sweated so long to prepare it, but because it provides our growing organization with a new, necessary, and smoothly purring governmental machine.

C. H. HARDIN BRANCH, M.D.,
President.

COMMENT

NARCOTIC DRUG ADDICTION

Recent advances in the understanding and handling of problems in narcotic drug addiction have been carefully studied in many medical, legal and research areas. Dale C. Cameron, M.D. is Chairman of the Committee on Narcotic Addiction of the Council on Mental Health of the American Medical Association. He and the members of his Committee have furnished the following report for publication in the Journal.

L. H. S.

Because of widespread misunderstanding on the part of the public and various professional and other groups and individuals about the problems associated with narcotic addiction in the United States, the American Medical Association and the National Research Council recently issued a joint statement designed to clarify some of the issues involved. The Federal Bureau of Narcotics, in commenting on the joint statement, expressed "its complete approval of the views" contained. The entire statement follows :

The American Medical Association and the National Research Council for many years have been concerned about and have studied the narcotic drug addiction problem. To assist in carrying out its studies, the American Medical Association collaborated with the American Bar Association in establishing a Joint Committee which made an Interim Report to the two organizations in 1958, and a Final Report in 1959.

It is concluded that there is widespread public and professional misunderstanding about this subject, specifically (1) that the Federal Bureau of Narcotics believes drug addiction to be a crime : a belief that is contrary to the Federal law and its application by the Bureau, and (2) that the American Medical Association proposes the establishment of community ambulatory clinics for the withdrawal of narcotics from addicts or for the continuing maintenance of addicts on narcotics ; a belief that is contrary to the official position of the American Medical Association.

Historically society has found it necessary to employ legal controls to prevent the spread of certain types of illness that constitute a hazard to the public health. Drug addiction is such a hazard.

The successful and humane withdrawal of individuals addicted to narcotics in the United States necessitates constant control, under

conditions affording a drug-free environment, and always requires close medical supervision.

The successful treatment of narcotic addicts in the United States requires extensive post-withdrawal rehabilitation and other therapeutic services.

The maintenance of stable dosage levels in individuals addicted to narcotics is generally inadequate and medically unsound and ambulatory clinic plans for the withdrawal of narcotics from addicts are likewise generally inadequate and medically unsound.

As a result of these conclusions the American Medical Association and the National Research Council oppose on the basis of present knowledge such ambulatory treatment plans.

These two organizations support (1) after complete withdrawal, follow-up treatment for addicts, including that available at rehabilitation centers, (2) measures designed to permit the compulsory civil commitment of drug addicts for treatment in a drug-free environment, (3) the advancement of methods and measures towards rehabilitation of the addict under continuing civil commitment, (4) the development of research designed to gain new knowledge about the prevention of drug addiction and the treatment of addicted persons, and (5) the dissemination of factual information on narcotic addiction.

Narcotic drug addiction in the United States is a serious problem in some of the larger cities. Although the rate of known addiction for the general population has decreased in recent years, the rate is high for some minority groups. The essential elements for the production of narcotic drug addiction are (1) susceptible unstable persons, (2) available narcotic drugs, and (3) the means for bringing the susceptible person and the drugs together. Psychiatrists have principal roles in mental health activities that will contribute to prevention by decreasing the number of susceptibles and

in programs for the treatment and rehabilitation of addicted persons. Since susceptible persons are very frequently introduced to narcotic drugs by someone who is already addicted, the treatment of the addicted person will benefit the individual and will decrease the spread of addiction. The treatment of narcotic drug addicts is a medical problem. The control of the availability of drugs is a problem that includes international restrictions of production to medical requirements and enforcement of narcotic drug controls at the international, national, state, and local levels. Although the control of the availability of narcotic drugs is largely a nonmedical problem, it is of direct interest to the psychiatrist because of its role in prevention.

Narcotic drug addiction among persons in the United States, aside from those with chronic terminal or extremely painful conditions necessitating medical addiction, is, in the vast majority of cases, a symptom of an underlying personality or emotional problem. This "symptom" itself leads to further psychological, physiological, and pathological changes. Long-term maintenance of a patient in an addicted state when there is no indication for the administration of narcotics other than to maintain the addic-

tion is not fulfilling the obligation of a physician, and is contrary to Federal law. It is not an effort to restore the health of the patient, but an attempt to give "relief" on rather dubious grounds, since it continues the very condition for which relief is needed. There may be occasional cases in which it would be medically unsafe to attempt withdrawal, but such situations are indeed rare.

The physician who endeavors to withdraw narcotic drugs from an addict in other than a drug-free environment should do so only with the full recognition that he has undertaken a most difficult procedure. Most addicts will endeavor to augment their supply of drugs through other sources. Withdrawal in a nondrug-free environment should be undertaken only as research in attempting to develop new treatment methods, and then only with adequate consultation.

The American Medical Association and the National Research Council are opposed "on the basis of present knowledge" to ambulatory treatment plans as a generally applied routine method, but encourage research directed to improved methods of treatment, as well as prevention.

DALE C. CAMERON, M.D.

POLITICAL POWER

At last I perceived that the continuation of all existing states is bad and their institutions all but past remedy without a combination of radical measures and fortunate circumstances; and I was driven to affirm, in praise of true philosophy, that only from the standpoint of such philosophy was it possible to take a correct view of public and private right, and that accordingly the human race would never see the end of trouble until true lovers of wisdom should come to hold political power, or the holders of political power should, by some divine appointment, become lovers of wisdom.

—PLATO

CORRESPONDENCE

PSYCHIATRISTS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR: Most APA members are now in private practice. This gives them so good an income, that they are unable to devote time to unpaid, or modestly paid community services in clinics, public hospitals, guidance centers and the like. Most psychiatrists received part or all of their graduate education with an assist from the community in the form of in-service training in public or community-financed facilities. There is, one would think, something owed to the community in return for this.

Almost every public hospital, community clinic, or similar installation is desperately understaffed. Most of them cannot afford fees that compete with private practice. Not enough private practitioners recognize the moral obligation to serve the community that has been so good to them. If they work for \$10 an hour in a community clinic or public hospital, they are—in effect—donating \$15 of their valuable time for each such hour, since they can earn that much more in private practice.

But where does the average (\$80 a week) American get psychiatric care? He can hardly pay \$50 a week for private psychiatric attention. In other branches of medicine, Blue Shield or another insurance might pay the bills; or he can go to a public clinic. But Blue Shield does not, as a rule, pay standard psychiatric fees; and the community clinic is no solution if the better-trained psychiatrists turn up their noses at serving in them.

And what happens to the doctor-patient relationship if the private psychiatrist commits his patient to a public hospital? Will the private psychiatrist visit the institution, see the patient, attend staff meetings about him, make therapeutic suggestions, and show any interest in his previously paying patient? No—he cannot afford the time.

The private practitioner will not serve Americans in public hospitals or community

clinics; but he will fight vigorously against other therapists who *are* willing to render this service: psychologists, clergymen, psychiatric social workers, and so on.

Somehow, some one must be bold enough to call attention to the need for psychiatric manpower in community clinics and public hospitals. Perhaps the Examining Boards of the APA might do something along the lines of the plans developed by county medical societies for providing round-the-clock medical care. Specifically, the Boards might require (as a condition of retaining the diploma) and the APA might require, as a condition of continued membership, that the unretired psychiatrist devote a small, but specific proportion of his time to unpaid or modestly-paid community service. It is unlikely that any practitioner's living standard will be seriously lowered by such service. Organized psychiatry must somehow come to grips with this problem or shrug its shoulders and (to mix my metaphors badly) say: "Let them eat cake."

Only a small proportion of psychiatrists are now in community clinics and public hospitals. Those who cannot afford private care are piled on to the shoulders of the few doctors willing to work in such installations—and their loads are increasing to the point where they cannot give first grade service; or where they too, no matter what their ideals, are being driven out of this into greener-backed pastures of private practice—thus making the problem even more desperate.

The solution of this lies in the hands of our organized profession. We cannot forever accept a two-class society in terms of psychiatric care. Having private practitioners contribute some of their time to community enterprises is one possible way out. And surely the soaring mind of man is capable of thinking of other solutions.

Henry A. Davidson, M.D.,
Essex County Overbrook Hospital,
Cedar Grove, N. J.

PSYCHIATRY IN ARMENIA

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR: On September 22, 1962, being in Armenia at the invitation of the Armenian Academy of Science, I had occasion to visit the psychiatric institute in Yerevan the capitol of that country. I was very much astonished to find practically a miniature copy of our Illinois State Psychiatric Institute. The building was new, sturdily built, clean and well arranged. It had 160 beds divided into four services, one on each patient floor, each service having a chief psychiatrist and an assistant. One of these chief psychiatrists turned out to be Dr. Yasmadjian who was in St. Anne's Hospital in Paris at the time I studied there in 1925. The Institute has one psychiatrist for every 10 patients. It was interesting to find that the optimal patient load for a psychiatrist was the same in Yerevan as in

Chicago. The Institute had adequate laboratories—physiological, chemical and electronic, occupational therapy, activities therapy, group therapy, sleep therapy and psychotherapy of the behaviorist type. There were a number of medical students since this is the main psychiatric teaching hospital of the Yerevan Medical Institute. There was adequate nursing staff, aides, social workers and psychologists.

I was very much impressed with this institute and so was the Danish psychiatrist from Copenhagen, who was visiting there at the same time. I had no opportunity to visit the other mental institutions of the country but I was told that there was one trained psychiatrist to every 25 patients in those institutions.

Percival Bailey, M.D.,
Illinois State Psychiatric Institute,
Chicago, Ill.

PHENOTHIAZINES AND CARDIAC ARREST AFTER ECT

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR: In the August 1962 issue of the *American Journal of Psychiatry* on page 178 there is an interesting case report by Sune Nystroem, M.L., about cardiac arrest after ECT.

I agree with Dr. Nystroem's concluding remark that closed heart massage may be life saving in such cases which, fortunately, are very rare.

I would like to draw attention to the following: phenothiazines are slowly excreted. A single dose can be found in the urine many days after the medication was given to a patient, as shown by Fred M. Forrest, *et al.* (*Am. J. Psychiat.*, 114: 932,

1958).

The autonomic nervous system effects of 25 mg. levomepromazine given at bed time to the 62-year-old patient, weighing only 47 kg, as reported, may have been potentiated by 250 mg. Evipan—Natrium I.V. and complicated by the stress of ECT the following morning.

In my opinion it is safer to discontinue phenothiazine at least two to four days (depending on the dose and the patient's condition), reserpine at least one week prior to administration of ECT.

Manfred Braun, M.D.,
VA Hospital (NP Service),
Bronx 68, N. Y.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR: The etiological aspects of cardiac arrest after ECT deserve attention because so much still remains obscure in that field. This is also valid for the importance of

phenothiazines as a causative factor. Therefore, when acceding to D. Braun's opinion, it is necessary to take some facts into consideration.

Conclusive proof of the significance of the phenothiazines in this respect would be

present if a higher mortality rate after electroplexy could be demonstrated in a patient group treated with phenothiazines than in a non-treated group. Such an investigation would not be too difficult, especially since some hospitals consistently avoid the combined treatment and consequently might supply the control group. However, it has not been possible to find a report of that kind.

The principle of own-control has been made use of by Kalinowsky (*Am. J. Psychiat.*, 112: 745, 1956), when finding that the number of deaths in connection with ECT rose after the introduction of the phenothiazines. A numerical record of this is, though, for natural reasons difficult to produce.

Another possibility of solving the problem set forth lies in an analysis of the limited number of published cases of death after electroplexy in patients receiving phenothiazines. Special characteristics might be found, indicating that the drugs in question have a particular effect in this context. The article of Barker and Baker (*J. Ment.*

Sci., 105: 339, 1959) is relevant here. Of 5 cases of ECT-death where the patient had not received phenothiazines 1 was considered to have died from left ventricular failure, 1 from myocardial syncope, coronary artery disease and emphysema, and 3 in other diseases. The 4 fatal cases that had got phenothiazines all died in cardiac failure (incl. shock). The material does not permit any conclusions but gives a hint of the possibility that the drugs used are prone to produce cardiac failure. Furthermore, we know from the pioneer report by Weiss (*Am. J. Psychiat.*, 111: 617, 1955) that chlorpromazine in combination with ECT gives a particularly strong fall in the blood pressure.

The examples just mentioned might serve as a support of the view that there are rational reasons for avoiding, as far as possible, the combination of ECT and phenothiazines.

Göteborg SV, Sweden.

THERAPEUTIC ABORTIONS

Three communications, two from New York and one from California, protested some points in the article "The Psychiatrist's Role in Therapeutic Abortion: The Unwitting Accomplice" by Dr. Sidney Bolter in the October issue of this *Journal*. The following Letter to the Editor is representative of the three:

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: I feel that the article by Dr. Sidney Bolter on therapeutic abortions should not go unanswered. No one can disagree with Dr. Bolter when he insists that psychiatrists should not break the law and that they should not be put in the position of stretching the letter and spirit of the law in recommending therapeutic abortions. Moreover, I find no point of disagreement in his interpretation of the proper recommendation in the two cases presented. However, when he jumps from these points to the conclusion "that with only a few exceptions, actually there is good biological,

psychological, and moral justification for the law as it stands," strong and insistent objections must be expressed.

A letter such as this is not the proper place to discuss the specific issues involved, but I feel that it should be unequivocally stated that there is no biological, psychological, or moral justification why a prospective mother's life need be endangered before the pregnancy can be legally terminated. In fact, considerable question can be raised as to the moral propriety of the state forcing a pregnant woman to continue with a pregnancy that may seriously endanger her health, that may be expected to result in an abnormal or deformed child, or that is even the result of rape.

Furthermore, there is no moral justification why the religious and moral views of any portion of the population should be imposed on the entire population unless the decency of society as a whole is threatened. The view that literally equates abortion

with murder is ludicrous, to say the least, when it is viewed with such seriousness that it should be imposed on all, as the law of the state. Such a viewpoint warrants due respect only if it is considered as the per-

sonal conviction and belief of an individual or group rather than as an established fact.

Robert L. Marcus, M.D.,
50 W. 96th St.,
New York, N. Y.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Time and space make it impossible for me to answer the various comments which I have received, either directly or through your office, concerning my article on therapeutic abortion. There were many points which I made in this presentation and each could be the subject of long and interesting debate.

It appears to me, however, that the basic issue involves the need on the part of so many psychiatrists to play a part in changing the world. Psychiatry, although a long practiced art, is still an infant science, and I feel very strongly that we are in no position at our present stage of development to contribute significantly to the development of our legal institutions and to any changes in the laws of our country. As individual citizens, we can speak and make whatever contributions we feel are in keeping with our background, training, opinion, and personal desire, but I do not feel that we

have any right to stump the country, using poorly supported psychiatric concepts and get the public to believe that we are acting as a single body. The profession of psychiatry must concern itself, mainly, with the care of sick people and if individuals within the profession want to go further, that is entirely up to them.

Despite the very interesting and constructive comments concerning my paper, I still hold to the opinion that the psychiatrist has no special place in the making or changing of laws concerning therapeutic abortion. I still feel, too, that abortion is a form of murder but want to emphasize that this is not based on some religious teaching.

I am in the process of preparing a paper on the subject of sterilization and will try to combine this with answers to some of the arguments presented by my critics of the abortion paper.

Sidney Bolter, M.D.,
West End Clinic,
Detroit, Mich.

NEWS AND NOTES

DR. BARTON APPOINTED MEDICAL DIRECTOR OF THE AMERICAN PSYCHIATRIC ASSOCIATION.—President C. H. Hardin Branch has announced the appointment of Dr. Walter E. Barton to the position of Medical Director of the American Psychiatric Association. This appointment will take effect April 1, 1963.

Dr. Barton's previous experience especially qualifies him for this office. As Superintendent since 1945 of the Boston State Hospital and Associate Professor of Psychiatry at Boston University since 1952, as member of Council, for 4 years a member of the MHS Board of Consultants, and finally as President of the American Psychiatric Association 1961-62, he is familiar with the tasks that will await him in Washington. It is gratifying to know that he will be looking after the interests of the Association in this office.

AMERICAN ORTHOPSYCHIATRIC ASSOCIATION.—The 40th annual meeting of this Association will be held at the Shoreham and Sheraton Park Hotels, Washington, D. C., Mar. 6-9, 1963. This will be the Association's first meeting in the nation's capitol.

Thirty-five major sessions, 16 panels, and 33 workshops will be held during the meeting covering a wide variety of topics relating to mental health.

For information, write to: Dr. Marion F. Langer, American Orthopsychiatric Association, 1790 Broadway, Room 1313, New York 19, N. Y.

THE DELAWARE VALLEY PSYCHIATRIC RESIDENTS ASSOCIATION.—This Association, the first regional organization of psychiatric residents, was founded at The Institute of the Pennsylvania Hospital in May 1962.

In the Delaware Valley, there are 23 psychiatric training centers with openings for 300 residents; at present, there are approximately 150 residents in training, and all are eligible for membership in the Association.

The purpose of the Association is to improve communication and to facilitate the interchange of ideas among psychiatry residents in the Delaware Valley. To do this, the Association plans to 1) try to establish an information center to assemble and distribute information about events in psychiatry and related fields in the Philadelphia area; 2) afford opportunities for residents to meet one another, professionally and socially; 3) arrange lectures, panels, or paper presentations by known authorities or by the residents themselves; 4) serve as a liaison between the residents and other psychiatric organizations.

A *Calendar* of events is published monthly containing news items in psychiatry, psychology, sociology, anthropology, neurology, psychosomatic medicine, child and adolescent psychiatry.

The officers of the Association are a chairman, vice-chairman, and secretary-treasurer. An executive committee, composed of one representative from each training center, appointed by the residents at each center, assists the officers.

The initial meeting was held on Nov. 20, 1962 at The Institute of the Pennsylvania Hospital, when Dr. Kenneth Appel, Professor of Psychiatry at the University of Pennsylvania, addressed the Association.

Robert E. Jones, M.D.

DR. STUNKARD HEADS DEPT. OF PSYCHIATRY, UNIVERSITY OF PENNSYLVANIA.—Dr. Samuel Gurin, Dean of the School of Medicine, University of Pennsylvania, has announced the appointment of Dr. Albert J. Stunkard as Chairman of the Dept. of Psychiatry, succeeding Dr. Kenneth E. Appel who has retired. Dr. Stunkard has been a member of the faculty since 1957. He is a graduate of Yale University and the Columbia University College of Physicians and Surgeons, and has served as assistant professor of medicine at Cornell University Medical College. In 1960 he won the Hofheimer Prize awarded annually by the APA for research.

ANALYTICAL PSYCHOLOGY FOR CLINICIANS.

—University of California Extension announces its third residential workshop on "Introduction to Analytical Psychology for Clinicians," July 7-19, 1963. Applicants are required to have an M.D., Ph.D. or the equivalent.

The staff consists of Bruno Klopfer, Ph.D. (Coordinator), John Perry, M.D., Marvin Spiegelman, Ph.D., and Max Zeller, D.Jur.

The fee is \$75.00. A few tuition scholarships of \$30.00 are available. For information write to: Dept. of Social Sciences, University Extension, Univ. of California, Los Angeles 24, Calif. Applications must be received by May 15, 1963.

THE HOMEWOOD SANITARIUM, GUELPH, ONT.—Dr. A. L. MacKinnon, medical superintendent of Homewood Sanitarium in Guelph since 1951, retired Oct. 1, 1962

after 37 years' service to the institution. Dr. Glenn S. Burton, assistant medical superintendent since 1951, succeeds Dr. MacKinnon, while Dr. Merville O. Vincent, who joined the medical staff two years ago, has been appointed assistant medical superintendent.

FIFTEENTH ANNUAL INSTITUTE OF PSYCHIATRY AND NEUROLOGY.—The Institute

will be presented Feb. 28-Mar. 1, 1963, at the North Little Rock Division of the V. A. Hospital, Little Rock, Arkansas. Workshops in psychology, social work, and nursing will be conducted Feb. 27, 1963. Participants will be: Dr. Silvano Arieti; Dr. C. H. Hardin Branch; Dr. Hans S. Falck; Dr. Ian Gregory; Dr. James A. Knight; Dr. Hugh Mullan; Dr. Victor C. Raimy; Dr. Howard P. Rome; Dr. A. L. Sahs; and Miss Jane Schmahl.

BOOK REVIEWS

TEACHING OF PSYCHIATRY AND MENTAL HEALTH. (Geneva: World Health Organization, 1961, pp. 186. \$2.00.)

The introduction states "A WHO Expert Committee on Mental Health met in Geneva in May 1960 to discuss the undergraduate teaching of psychiatry and mental health promotion." This book represents some of the revised papers read at the meeting.

In the opening chapter Dr. E. E. Krapf, Chief Medical Officer, Mental Health, WHO, makes some interesting comments as to how the teaching of psychiatry has developed, but without linking up the development to any particular country.

Dr. Eugene S. Turrell, Professor of Psychiatry, Marquette University, Milwaukee, Wis., in a chapter "On Becoming A Physician," makes three fundamental theses: 1. The teaching of dynamic and psychotherapeutic psychiatry requires exploration of the unconscious mind, which will, in turn, result in self-evaluation by the student. 2. Such self-evaluation may be a painful process, because it requires scrutiny not only of affects and conflicts associated with becoming a physician but also of unconscious factors of motivation in the wish to study medicine. 3. Resistances to learning dynamic psychiatry may develop as a defense against undergoing this painful self-evaluation. These difficulties may in part be due to the fundamental reactions associated with the process of becoming a physician. With a rather broad list of references, it is of interest that the author omits any reference to Jung's work on the unconscious.

The third chapter, "Perspectives in the Teaching of Psychiatry," by Dr. Tsung-yi Lin, Professor of Psychiatry, National Taiwan University, Taipei, is much the longest chapter (33 pages). It is a most excellent and extremely broad discussion of the subject. Dr. Lin quotes from authorities all over the world and gives examples of the way the teaching of psychiatry has developed in a number of medical schools.

Dr. Ignacio Matte-Blanco, Professor of Psychiatry, University of Chile, discusses the important relationships in personality development and many of the tragic results that follow from some of the severe mistakes of our most advanced medical centers in handling medical and surgical patients. He quotes one pathetic example of small children ad-

mitted for operation, "left in a waiting room, separated from their mothers or any mother image, immersed in deep sorrow and anxiety, crying for their mothers, unheeded and alone. And how frequently is such a procedure justified by saying that children soon 'get adapted,' when in reality, as any psychiatrist can see, what really happens is that their distress reaches the point at which they are no longer able to express it audibly. This can fairly frequently be observed in centres where the 'physical' standards are extremely high, and it obviously is the result of an appalling lack of psychiatric education. For this reason it seems of high importance to formulate clearly the type of psychiatric and psychological training needed by the general physician."

Dr. T. Ferguson Rodger, Professor of Psychological Medicine, University of Glasgow, in "The Place of Psychiatry in the Medical Curriculum: A British Viewpoint," points out that medicine in Britain emphasises a personal and humanistic point of view, so much so that this has led to criticism that British medical education turns out good practitioners but poor scientists. He feels that this has caused the Scottish physician to assume the role played in America by the psychiatrist, such as discussing with patients why they are reluctant to undergo operations. He then speaks of what is and what should be taught as psychiatry, indicating that Scotland has already developed physicians in all branches of medicine who look upon the patient as an individual and who have acquired some of the knowledge which the American psychiatrist is trying to instill in the American physician.

The chapter, "The Role of Neurologic Studies in the Teaching of Psychiatry" is written by Mortimer Ostow, M.D., Associate in Psychiatry, Montefiore Hospital, New York City. He believes that comparative neurology is an important study for the psychiatrist in order for him to understand comparative behavior. He discusses certain changes that occur with specific brain lesions, *e.g.*, a feeling of depersonalization accompanying a temporal lobe seizure; a special type of visual hallucination occurring in a toxic delirium. He points out that "some of the behavioral consequences of organic brain lesions represent, not the direct consequences of neural dysfunction but rather defensive manoeuvres of the primitive nucleus of the ego." He warns against the tendency to overinterpret neurological data.

A chapter, "The Teaching of Medical Psychology and Sociology," by Dr. S. Lebovici, consultant physician to the hospitals of Paris, contains an interesting discussion as to how much and what type of psychology should be taught to medical students. He speaks of both social psychology and cultural anthropology and quotes opinions of a number of writers from different countries.

Jean Stoetzel, Professor of Social Psychology at the Sorbonne, offers "Observations on the Social Character of Mental Disorder." He discusses the social nature of mental diseases, the social status of mental patients, and the social character of psychiatric treatment. He ends with a carefully worked out annex, "proposed programme for the teaching of social psychology to students of psychiatry" to be given to all 4-year medical schools.

"An International Survey of the Teaching of Psychiatry and Mental Health," prepared by the Mental Health Unit, WHO, is a tabulation of the responses to a questionnaire sent to a large number of medical schools all over the world. It contains considerable valuable statistical material.

In the chapter on "The Teaching of Psychiatry in the USSR," Dr. O. V. Kerbikov, Head of the Department of Psychiatry of the Second Moscow Medical Institute, pays tribute to Pavlov's teachings, and attempts to outline some essential and fruitful tasks connected with the teaching of psychiatry: 1. So to organize the teaching that when the general practitioner graduates from the medical faculty he is not only acquainted with the main lines of major psychiatry but can also find his bearings in the complex subject of minor psychiatry. 2. To give students not only knowledge of the foundations of clinical observation and treatment of mental patients but also an acquaintance with the main aspects of modern laboratory and experimental methods of examining patients and the more important methods of scientific research (electroencephalography, conditioned reflex methods, and biochemical and psychological techniques). 3. So to organize the teaching of psychiatry that the student surmounts the obstacle of the fragmentation of medical knowledge due to the narrow specialization of the clinical disciplines in such a way that psychiatry takes on for him the importance of widening his general medical outlook and in the full sense of the word crowns his education as a physician.

A chapter on "The Teaching of Psychiatry in Africa," is by Dr. T. Adeoye Lambo, M.R.C.P. (Ed.), D.P.M., Psychiatric Special-

ist Western Region Government, Nigeria. Dr. Lambo goes into a fairly specific discussion not only as to how psychiatry is being taught in Africa, but how he feels it should be done ideally. In general, he tries to draw from European and American experience, but feels that the cultural factors in Nigeria may cause some difference in the method of teaching.

The last chapter, "The Teaching of Psychiatry: A Swiss Viewpoint," is written by Dr. M. Bleuler, Professor of Psychiatry, University of Zurich. This chapter is a very careful discussion of the historical development of psychiatry at the University of Zurich and of the present method of instruction. One gets from this chapter a good deal of Bleuler's personal feelings and attitudes toward the teaching of psychiatry, which makes it most excellent reading.

Since the chapters vary so greatly in what aspects of psychiatric teaching are discussed, it is impossible to compare the contributions. All are interesting and valuable and the reviewer recommends the book to all those who are interested in increasing and broadening their knowledge of the teaching of psychiatry throughout the world.

K. M. B.

PROGRAMME DEVELOPMENT IN THE MENTAL HEALTH FIELD. Tenth Report of the Expert Committee on Mental Health, World Health Organization Technical Report Series Number 223. (Geneva, Switzerland: World Health Organization, 1961, pp. 55. \$60.)

This Tenth Report of the Expert Committee on Mental Health is made 12 years after the first which appeared in 1949. Its preparation followed a not unusual pattern in the World Health Organization, that of requesting a series of working papers from authorities in one or another facet of the problem being studied, the distribution of these to and their study by the members of the Expert Committee who then met for some days of discussion and for the formulation of the report itself. The Committee had nine members and was chaired by Dr. Robert Felix, of the United States of America. Dr. A. V. Snezhnevsky of the Union of Soviet Socialist Republics was the vice-chairman. All members were selected as individuals rather than representatives of countries, but their origins are of interest; Switzerland, United Kingdom, Australia, Germany, South Africa, Costa Rica, and Egypt were the countries in addition to those of the chairmen. All members of the group were psychiatrists except a nurse-

matron of a hospital, a professor of hygiene and social hygiene, and a public health administrator.

As might be expected, reports prepared in this manner have the character of a declaration: "These truths we hold to be self-evident." Their purpose is education and stimulation, the codification of what is known and stimulation to recognize areas where work needs to be done. Thus this Tenth Report contains the germs of most of the ideas needed to teach a course in the administration of mental health programs, including most of the many unresolved problems in that field. The outline for much of what has become known as social psychiatry is clearly here as is a pertinent and well-organized discussion of the research needs and opportunities in the mental health field. It is very doubtful that these aspects are presented anywhere as completely as they are in this 55-page pamphlet. If it filled no other purpose, it would be a very effective teaching aid for courses in community psychiatry.

In contrast to the report of the United States Joint Commission of Health and Mental Health, this document takes the position that mental illnesses are illnesses to be dealt with as are other diseases. Recognizing that this philosophy underlines programs for mental health in most of the world, the document is often concerned with the administration of total health programs and the relations of the various phases of such programs, including mental health, maternal and child health, communicable diseases, *etc.*, to each other.

The report begins with a review of trends in mental health from 1949 to 1960. In 1949, the group concluded that the task of achieving a reasonable level of treatment of psychiatric patients in the world was impossible and that hope would perforce have to be placed in preventive efforts and the acceptance of responsibility by public health authorities for mental health work. This is still an active goal and some progress is seen in the training of health workers for the expanded task. The need for specialized mental health workers has been given extensive attention by the World Health Organization with three reports and a number of conferences having been devoted to various aspects of training. Considerable expansion of research is noted in the 12 years but the subject is again heavily stressed in the 1961 report.

The hard decision that many presently neglected patients will have to remain neglected in favor of more active treatment of fresh cases is reluctantly reached. New organizational methods are needed, with a central leader-

ship for planning and operation being given high priority, though training programs must come first in order to have staff available for the planning.

The administrative organization should have as its aim the whole gamut of needed services, preventive-educational to the general public, outpatient care opportunities, general hospital care of the psychiatrically ill, part-time hospitalization and full psychiatric hospital care as well as follow-up services. The "mental health unit" combining staffs for all these types of services at relatively local levels is proposed. Such units will make for efficiency in the use of personnel in service and for training of medical and non-medical specialists, and to expand the scope of personnel who are not specialists so that mental health objectives can be included in their work. The mobilization of community "caretakers" and "gate keepers" is carefully considered; of the latter group, employers and union leaders are given most important place.

The operation of a system of services with 24-hour-a-day hospitalization, a relatively small part of the total mental health program, is envisaged as requiring the collaboration of a team of workers. These will vary in the proportion of time devoted to or available for mental health concerns. Since such a group will require effective leadership to accomplish the work planned for it, the report considers at some length the qualities and training necessary in the leader and in those who are to follow his leadership in the planning and operation of the program. Universally recognized as an obligatory requirement for any complex program operation, few papers face the issue as squarely as is done here.

The final expository section is on research. It is a competent and comprehensive review, stressing ecological and epidemiological methodologies as is appropriate to the philosophy of the report. The possible roles of the World Health Organization in the promotion of mental health programs is discussed in the closing pages.

This is a document of high quality. For many it will expand the horizons of what psychiatry in the service of a total population is likely to become. Those familiar with social psychiatry will find it a very convenient presentation of the concepts in the field, useful as a guide in planning anywhere in the world, and a convenient guide for teaching.

EARLY VICTORIAN PSYCHIATRY, 1805-1905. By C. R. D. Brothers, M.D. (Melbourne : Government Publication, 1962, pp. 254, illus.)

Dr. Brothers is Chairman, Mental Hygiene Authority, State of Victoria, Australia. After completing his Beattie-Smith Lectures on the history of Victorian psychiatry in 1957 he was requested by his colleagues to elaborate at book length this vast material that he had given in abbreviated form in his lectures. This book is the result and constitutes the first detailed account between two covers of the management of mental cases from the early days of the colony to the close of the 19th century. As in pioneer times elsewhere, there was no provision of any kind for mental cases except in jails or lock-ups as they were called. Prisoners were detailed to care for the patients and for this service were given time off from their sentences.

In 1840 when "the first real gaol was erected" some distinction was made between criminals and the insane, a small "lunacy ward" being provided for the latter. The violent cases had to be sent to Sidney, Tasmania, for care. The institution here and the Tasmanian asylum at New Norfolk were the only asylums for insane in the continent of Australia.

From here on Dr. Brothers gives a detailed account of the succession of institutions and other services developed in the State of Victoria, together with a roster of institution physicians and some account of their lives and work.

A special feature of this book is the rich collection of illustrations, some 75, including photographs of the medical officers during the period covered, maps, views of buildings, plans and interiors, grounds and activities, and copies of documents. The extraordinary amount of data here gathered together will make this volume especially valuable for reference.

In order that the modern period may not be overlooked the author has provided an addendum (9 pages) containing a concise chronological summary of developments from 1905 to 1952.

C. B. F.

MENTAL HEALTH TEACHING IN SCHOOLS OF PUBLIC HEALTH. Edited by Elaine Cohen. (New York : Columbia University, School of Public Health and Administrative Medicine).

This report is based on the work of six pre-Conference Committees and a National Conference held in 1959, sponsored by the Association of Schools of Public Health and

financed by a Grant (2M 9141) from the National Institute of Mental Health.

From the prefatory statement that "This overall review came about because it seemed timely to provide the school faculties, curriculum committees and administrators with an updated base from which to make judgments as to necessary changes in faculty, curriculum content and time, teaching opportunities and methods," one might infer that the objective was to obtain uniformity—however stultifying to both life and learning—of both content and method. Indeed, content and method, including audio-visual helps, and times allocated and academic credits, are set out in detail. Hazards to which students are subjected by the courses are also mentioned. But in the last chapter we come back to something seemingly more reasonable: "There are relatively few firm guide lines to enable an assessment of the general state of development of community mental health work. The entire field is in a state of flux in all of its aspects. However, despite the many seeming 'irreconcilables' and 'insolubles,' considerable headway was made by the conferees toward clarification; it was possible to achieve some consensus in terms of functions and training objectives, teaching methods, and general curriculum content, as well as to identify areas of major dissent." The headway is not apparent to this reviewer. All he can say is that, in his opinion, if anyone engaged in public health instruction can derive any help or guidance from this volume, apart from the opening chapter, that person must be so sorely in need of help that it would be well, for the sake of the public health, to change his vocation.

But the first chapter, "Public Health and Mental Health: Converging Trends and Emerging Issues," by Dr. George Rosen, is a masterly review and analysis which should be available to, and read by, all students and staff in all schools of public health.

Cherry Hill, N. J.

DER VERLAUF DER SCHIZOPHRENEN UND DER SCHIZOPHRENIFORMEN PSYCHOSEN (The Course of Schizophrenic and Schizophreniform Psychoses). By K. A. Achté. (*Acta Psychiatrica et Neurologica Scandinavica*, Supplementum 155, Vol. 36, 1961. Copenhagen : Ejnar Munksgaard, 1961, pp. 273.)

The author worked three years on this monograph which he undertook on the request and under the continuous encouragement of his chief, Professor Kaila, the director of the Psychiatric University Clinic in Helsinki, Finland. The monograph like several others in this series is written in German. However, an English summary of 26 pages makes it accessible to every interested Anglo-American reader.

Dr. Achté worked on two groups of patients: one admitted to Prof. Kaila's Clinic 1933-35, and another one admitted there 1953-55. He studied the case records, examined a great number of patients personally and presents follow-ups of at least 4 years, some of some 20 years. The materials were divided into "typical schizophrenias" and "schizophreniform psychoses." There was a small "intermediate group" which may be disregarded here as well as a few "mixed cases."

In the schizophrenia group, the earlier patients (1933-35) appear in general to have been more severely ill than the more recent ones (1953-55). Catatonic symptoms seem to "have become less frequent," while the "hebephrenic type . . . has shown a certain increase." A number of patients diagnosed as schizophreniform "developed typical schizophrenia over a follow-up of 4 years." This happened considerably less frequently in the more recent than in the earlier group.

The author found that "changes in clinical type were . . . relatively infrequent." He emphasizes the almost ubiquitous appearance of paranoid ideas, especially ideas of reference, "in the initial stage of the psychosis regardless of the later development of the clinical picture."

The author relates that in 1939 and 1959, respectively, 24% of the earlier, and 39% of the more recent patients "were fully recovered." That means a remarkable change of the prognosis which seems most unfavorable in the hebephrenics. (The author includes the simplex patients in the hebephrenics.) The "catatonic patients either recovered fully or did not recover at all." The prognosis of the paranoids "was not essentially different."

Dr. Achté is cautiously discussing many factors which took the former curse off schizophrenia. The hospital is more "cosy"; the

patients are no longer afraid of mental hospitals nor of psychiatrists; the human relations between physician and patient have undergone incisive alterations; early treatment—including the treatment of per se benign cases—plays its role. Despite his predominantly optimistic attitude referring to "the patients who had displayed a typically schizophrenic disease when in hospital," the author avers that "no more than one-tenth of them made full recovery." He goes on to say: "It can accordingly be concluded that typical schizophrenia is rarely cured even by the methods which are in use in our clinic today."

This is a very good, thoroughly solid piece of work for which the author and his chief, Professor Kaila, must be commended and congratulated. The monograph demonstrates that clinical psychiatry is alive and dynamic in its own right.

CHILDHOOD SCHIZOPHRENIA. By William Goldfarb, M.D. (The Commonwealth Fund. Cambridge, Mass.: Harvard University Press, 1961, pp. 216. \$4.50.)

This eagerly awaited report by William Goldfarb, M.D., from the Henry Ittleson Center for Child Research comes to us in the form of a beautifully compact biometric study. It is a five-year accumulation of physical, behavioral and familial data on 26 disturbed children, 6-11 years old, rejected from normal schooling and compared with 26 matched normal children from a public school.

There is a foreword by Herschel Alt and an introduction by David M. Levy, M.D. There is also a chapter on The Schizophrenic Subclusters: Factors Approach, by Irving Lorge, Ph.D.

The summary and concluding chapter is concerned with two schizophrenic subgroups in childhood, an organic and a non-organic. The sicker non-organic subgroup is said to be produced by an abnormal condition in the rearing environment, characterized by parental perplexity. The "organic" children were noted to have neurophysiological deficits. However, the etiology of the organic factors in these children or of the perplexity in their parents is not defined.

From the extensive battery of tests and appraisals it is suggested that only "receptor intolerance" is fairly typical of schizophrenia. The schizophrenic children show a tendency to exclude distance receptor stimuli, that is, the visual and auditory, while accepting prox-

imal sensory or touch experiences, and this contributes to the confusion regarding time, space, person and body image. This reviewer finds that this, indeed, is an original contribution. It may still be necessary to make comparable studies on other non-schizophrenic brain-damaged children to determine the specificity of this response in schizophrenia. Even if this mode of behavior is observable in other children with developmental problems, these observations are an important scientific contribution.

Schizophrenia is described as "merely a label indicating that the child deviates dramatically from the normal in ego functioning . . ." Furthermore, this group of 26 children was selected not because of any definable schizophrenic features but because of certain social factors (too disturbed for regular public school, belonging to a certain family structure, *etc.*) and the absence of gross bodily defects. Consequently the conclusion that the term schizophrenia in childhood is only an umbrella under which multiple disorders are being lumped has to be questioned.

CURRENT PSYCHIATRIC THERAPIES. VOL. 1. Ed. by Jules H. Masserman. (New York: Grune & Stratton, 1961, pp. 246.)

This is the first volume of a series which aims to cover annual summaries of current advances in therapy, special articles on particular therapies, condensations of papers from professional meetings and editorial reviews of special advances. The 40 contributors to this maiden collection are all from the U. S. A., except for 2 from Austria and 3 from Montreal, Canada.

Part I, Preventive Psychiatry, describes campus psychiatry at Cleveland, a suicide prevention centre at Los Angeles and the community extension service at the Massachusetts Mental Health Center in Boston. Part II, Child and Adolescent Psychiatry, contains a review of the present status of child psychiatry, notes on the management of acute conversion reactions and scrupulosity, and a description of an adolescent treatment centre in Utah. Part III, Psychophysical Methods, has a review of the chemical and electrical therapies, the Montreal treatment by verbal repetitive signalling, and a note on the clinical management of depression. Part IV, Psychoanalysis, presents two papers on medical education and psychiatric practice. Part V, Couples and Groups, discusses simultaneous psychotherapy of mar-

ried couples, also the integration of group therapy with individual psychoanalysis. Advances in group therapy and military psychiatry are noted. Part VI, Clinic, Institution and Community, includes descriptions of dynamic psychotherapy in the Massachusetts General Hospital Psychiatric Clinic, intensive therapy of psychoses in the Vienna University Hospital, and feigned insanity by prisoners. Modern concepts of hospital therapy are outlined and Maxwell Jones discusses community aspects of hospital treatment. In Part VII, Aftercare Programmes, family care and community aftercare services are described. In Part VIII the editor reviews anxiety and the art of healing, pointing us to the ideal of a holy physician.

It probably is too early to judge the usefulness of this series as an addition to existing annuals. My impression of a scrappy unevenness and extended diversity will remain until the next volume shows its wares.

ALLAN WALTERS, M.D.,
University of Toronto.

AN APPROACH TO EDUCATION OF PSYCHIATRIC NURSING PERSONNEL. By Garland K. Lewis, Marguerite J. Holmes, and Fred E. Katz. (1961, pp. 124. \$2.00.)

The authors have presented a report of the seminar project for teachers of psychiatric aides which was conducted as a pilot project in four Southern states from April 1958 to September 1960. The overall purposes of this project were the improvement of the care of the mentally ill and the investigation and demonstration of a method of short term clinically-centred seminars for improving competency of nurses responsible for supervision and inservice education of psychiatric aides.

The National League for Nursing and the American Psychiatric Association sponsored the project and the funds were provided by the Community Services Branch, National Institute of Mental Health, U. S. Department of Health, Education and Welfare. All psychiatric hospitals and general hospitals with psychiatric units in these states were invited to participate. Twenty-five institutions responded and planned for 168 of their professional nurses to attend the seminars; an additional 7 nurses from institutions or organizations attended as students. Eighteen 10-day seminars were held: 3 in Arkansas, 9 in North Carolina, 4 in South Carolina and 2 in Louisiana. In the 25 institutions participating over 32,000 patients were being cared for by 5,366 nursing personnel. The 10 state hospitals selected had a patient

population of 26,000, with nursing staff of approximately 300 professional nurses and 3,400 practical nurses and aides. The aim was directed to the care of the 32,000 patients through the 175 seminar students and indirectly through the 5,000 nurses and aides. Particularly within the state hospitals taking part in the project, the impact of this programme would be very great—a method of dissemination of knowledge to a large group of personnel, and the continuing effect of the students putting into practice the principles of psychiatric nursing as taught to them.

The well-developed plan for this project, the philosophy, the purposes, the objectives, and the methods devised to carry it out are indications of how the director of the project and her staff were able to bring it to successful conclusion.

The plan as originally set up, 18 seminars of 2-week duration, enabled over one-fourth of the registered nurses in the participating hospitals to attend. This in itself merits the attention of all those responsible for care of the mentally ill, with the hope that they will have a similar project in their district. The value of this type of teaching could not be adjudged immediately but could help us to attain far-reaching goals. The outcome of this project has demonstrated that it was a successful method, irrespective of the diversity of the group of students in each seminar group as to positions held and the variation of preparations of the individual student. The nursing care of mentally ill patients, the main theme of the seminars, was the central concern of each student.

This excellent report is well presented, and the detail given takes the reader through the project with clarifying descriptions of the learning experiences as planned and the outcome as the student progresses. These learning experiences were the care of one patient, interaction notes, individual conferences, group conferences, assigned reading and a film. The 35 hours of the student's time with one patient was the central learning experience through which she had an opportunity to develop her observation, communication and nurse-patient interaction, assisted by the individual supervision of a skilled instructor. How this was accomplished is discussed objectively and with great clarity in the report.

A follow-up study was done during the final year of the seminar project by a sociologist. This report includes considerable data regarding procedure used as well as some information garnered from the extensive inter-

views conducted during the follow-up study.

This report will be stimulating reading for both nursing educators and nursing service personnel of all psychiatric facilities. To my knowledge, it is the first time that an attempt has been made to improve the nursing care of the mentally ill so extensively. As the material is presented, it can be used as a guide to conduct other similar seminar projects.

University of Toronto.

THE UNCONSCIOUS BEFORE FREUD. By Lancelot Law Whyte. (New York: Basic Books, 1960, XII + pp. 219. \$4.50.)

A Frenchman is said to have said that there is much that is new in psychoanalysis and much that is good; but the good is not new and the new is not good. The story of the unconscious component of that peculiar function that, as Ring Lardner put it, "we laughingly call our mind" was not a new one when Freud took it up.

The author of this book has been pondering this subject for quite a long time, at least back to the years following World War I, "when psychoanalysis was a novelty and I innocently imagined that Freud had just discovered the unconscious mind." Over the years the author's perspective changed as he considered the course of European thought during 200 years before Freud. Hence this book. It is simply a striking confirmation of what is, or ought to be, a truism: "Historical understanding can throw light on current problems." What's past is prologue. Mr. Whyte surveys a considerable range of thought and speculation about conscious, unconscious, and self awareness from ancient times on and quotes appreciatively from Margetts: "Almost since the dawn of civilization man has had an inkling of understanding that mind activity outside of our waking consciousness does exist."¹

From the 13th century a quotation from Thomas Aquinas is apposite: "I do not observe my soul apart from its acts. There are thus processes in the soul of which we are not immediately aware." The author cites references from writers down the centuries, philosophers, theologians, dramatists, physicians, *et al.*, enough to convince any unbeliever that the mind has its sub basements like a skyscraper, but it remained for Freud to supply the social register of the creatures that inhabit there.

IN MEMORIAM

HARRY A. STECKEL, M.D. (1886-1962)

Doctor Harry A. Steckel died suddenly on the morning of July 13, 1962. He was shaving in preparation for a full day of appointments. That probably would have been the way Harry would have wished it. He often said he never would retire. That was the pattern of his interest which prevailed throughout his 52-year service in psychiatry.

He was born December 13, 1886 in Catasauqua, Pennsylvania. His parents were Jacob Harry Steckel and Martha Bartholomew Steckel.

Harry Steckel was earnest, honest, ambitious, driving, in the cause he always held close to him, the welfare of the mentally ill. He worked, he wrote, he taught in their behalf. This was expressed in a life full of accomplishment in this field.

He was graduated from the University of Pennsylvania Medical School with an M.D. degree in 1910. After a general hospital internship and residencies in state hospitals in New Jersey and Iowa, he entered the New York State service at Kings Park State Hospital in 1912. From thence he continued through the grades to the superintendency of the Newark State School. Within a year he was called to the professorship of psychiatry at Syracuse University Medical School and to become the first director of the then Syracuse Psychopathic Hospital in 1930.

His civil career was interrupted by an interval in the military service in World War I. In February 1918 he opened the first ward for psychiatric patients for U. S. troops in France at Neuchateau. Subsequently he was made Division Psychiatrist of the 26th Division and remained in that post through all the engagements of the division to return with it to the U. S. In

May 1919 he left the service to return to his work in the state hospitals of New York. He continued in the army reserve and retired in 1935 as a full Colonel. He received the Congressional Medal of Merit in 1944.

In his psychiatric views which he expressed forcefully he was conservative and eclectic. He could be cryptical and sharp but not unkind. His qualities for leadership were evinced by the many presidencies he held. Besides teaching medical students and residents he lectured at Elmira College and Syracuse University. His published papers were numerous in the fields of mental hygiene, psychiatry and in national defense. He co-authored Chapter II, Volume X of *The Medical Department of the United States Army* published by the War Department.

In 1922 Dr. Steckel conducted a survey of prison populations in New York State for the National Committee for Mental Hygiene.

In 1929 he had served as Superintendent of the State School for Mental Defectives at Newark, New York.

In spite of an active public life his chief joy was his family. He married Carolyn E. Moon in 1919 and they saw their two children Elizabeth Ann and William Henry grow to maturity and marry. His family life was close and warm. After his daughter married and gave them grandchildren, it was his custom to drop in for a few moments call upon them each morning on his way to his office.

To his friends he was warm and likeable. To his subordinates he was firm, strict, but always loyal to their interests.

All in all he lived with high credit a full Christian life.

Eugene N. Boudreau, M.D.

PSYCHIATRY IN INDONESIA

NATHAN S. KLINE, M.D.¹

Indonesia is a country of 97,000,000 people with a total of 32 trained³ psychiatrists. Since the population of Indonesia is about half that of the United States a comparable figure for us would be 64 boarded psychiatrists in the entire country. There are an additional 10 psychiatrists practicing in the mental hospitals who are not regularly qualified and 8 residents in training at the University of Indonesia Department of Psychiatry.

All physicians are obligated by law to work for the government from 7 a.m. to 2 p.m. at the university or polyclinics but are free the rest of the time to conduct private practice. The only persons allowed full time private practice are those who have passed the retirement age for government service. The average monthly salary⁴ for psychiatrists is between 2000 and 3500 rupiah, which amounts to between \$22 and \$39 per month at the official tourist rate of exchange or roughly \$7 to \$13 per month on a free market basis. The superintendent of a hospital earns 4000 rupiah a month. The

monthly average income from private practice in Djakarta is approximately 15,000 rupiah (\$167 at the official tourist rate), so that it is economically mandatory that all physicians have a private practice. This system of working part of the day for the government and subsequently working for one's self can be designated as "2 p.m. Socialism." The 7 a.m. to 2 p.m. time spent at the polyclinics is usually shaded slightly at both ends and private practice starts as a rule about 4:30 p.m. and continues until 8 or 9 at night.

Despite the great paucity of psychiatrists the demand is even less so that most of those who are qualified as psychiatrists do general medicine in their private practice and only 3 or 4 physicians specialize primarily in psychiatry during their free hours.

*University of Indonesia.*⁵ At the University Psychiatric Clinic there are 64 beds for inpatients with a staff of 10 psychiatrists, 8 residents who serve for a 2-year period, 8 senior clerks, each rotating for 1 to 2 months, and 12 junior clerks rotating on the same basis.

Much of this excellent system was built up during the 5-year affiliation (which expired in 1961) with the California University Medical Center. The inpatients are all psychotics, and in this group somatic therapy is almost always used, although not exclusively. During the past 7 years the number of admissions ranged from 443 to 752 and discharges from 391 to 694, depending to a large extent on how much chlorpromazine and reserpine were available.

There was a drop in patients admitted and discharged in 1960 due to a sharp decrease in the availability of pharmaceuticals for treatment purposes. Most of the patients not discharged to the community either died or were passed on to the mental hospital at Grogol.

⁵ The buildings which house the major part of the school were originally an opium factory.

¹ Rockland State Hospital, Orangeburg, N. Y.

² Appreciation is expressed to Professor Slamet Iman Santoso, Dr. Kusumanto Setyonegoro and especially Dr. Kho Tjok Khing of the University of Indonesia for their warm hospitality.

Gratitude is also due to Dr. Salekan, Director of the Division of Mental Hygiene, Brigadier Satryo, Minister of Health, Mrs. Dr. Soebandrio and Professor Soedjorno D. Toestonegoro, President of the University, since without their sponsorship this report would not have been possible. The invariable courtesy and assistance make me regard many others, not individually named, as also among my friends.

³ Three years of specialization plus the writing of a thesis qualifies a physician for certification in psychiatry by the Board of Psychiatry, Neurology and Neurosurgery.

⁴ There is a cost-of-living bonus which presently amounts to approximately 100% of the salary.

A rupiah is worth about one cent at the official tourist rate. Attendants earn \$3 to \$6 a month. The illegal "free market" value of the rupiah is a third of the tourist rate, i.e., the attendant's salary is \$1 to \$3 a month.

An average of 40 (1000 per month) patients are seen per day at the university outpatient clinic during a 6-day working week. Of these approximately 10 each day are new patients.

About three-fourths of the psychotic patients seen at the outpatient clinic are not admitted either to the University Clinic or to the local mental hospital because both are already filled to capacity. When electroshock equipment and drugs are available patients are given ECT and psychopharmaceuticals. At times such patients are kept in the hospital from 7 in the morning until 6 at night, thus constituting a day hospital program out of necessity.

As a rule patients are seen about every 2 weeks over an average of 1 to 2 years. These figures do not include epileptics who are referred to the neurology clinic nor mentally deficient patients who, once diagnosed, are kept at home. The arteriosclerotics constitute about one-fiftieth of the admissions and organic psychotics in general are rare. There are some character disorders, usually 1 or 2 neurasthenics, 1 or 2 obsessive compulsives, 1 or 2 anxiety states, and the same number of involutional depressions in each 25 admissions. Two or 3 of the 10 new patients each week are schizophrenic. Pre-war about 25% of new patients were general paretics, but it is now hard to find any of the classical type of luetics in the new admissions.

In the mental hospitals and the clinics the number of Chinese, whether foreign or Indonesian born, is disproportionately great; the Chinese are more health conscious whereas the Indonesians tend to "protect their family name" and "explain away" illnesses or other disorders. Thus 40% of the inpatients at the clinic and 30% of the outpatients are Chinese in origin although the Chinese comprise only about 10% of the 3,500,000 persons in Djakarta.

Military Hospital. The Military Hospital has an inpatient facility of 60 beds and a twice-a-week outpatient clinic handling 20 patients each working day.

Division of Mental Hygiene. There are 7400 patients in 25 mental hospitals throughout the country staffed by a total of 32 psychiatrists (of whom 22 are qualified). The Department of Mental Hygiene does

not have outpatient facilities. Treatment is almost entirely custodial with less than 5% of all patients on active somatic treatment or psychotherapy.⁶

I was able to visit five major mental hospitals in Indonesia: 1. Sumber Porong which is at Lawang and has 2000 patients (pre-war 4000 patients); 2. Bogor which is located outside of Bogor and has a capacity of 1200 patients (pre-war 3000 patients); 3. Kranat which is at Magelang with 1100 patients (pre-war 2000 patients); 4. Grogol at the outskirts of Djakarta with a capacity of 400 patients; and 5. Bangli which is on Bali with a capacity of 150 patients plus an additional 100 beds under construction. The drop in patient population from pre-war was necessitated in part by the reduction in professional personnel, since of the 18 Dutch psychiatrists who were evicted at the time of independence 12 had been working in the mental hospitals. Another factor is that the mental hospitals were greatly overcrowded and since their reorganization they have not taken more patients than they could adequately handle. The most important factor, however, is probably budgetary limitations since some of the hospitals have empty beds, but no way of providing food and services for patients who could be admitted.

Grogol Hospital. Grogol Hospital, named for the river that passes in front of it, is located some 10 kl. from the center of Djakarta. Of the 400 beds only 300 are presently in use; 200 for males and 100 for females. The hospital occupancy is 25% below capacity because money is not available for food, clothing, drugs, water, electricity, transportation and other upkeep. The admission rate is 100 patients per year with approximately the same discharge rate. The total yearly hospital budget exclusive of salaries is 1.4 million rupiah (\$14,000 at the official tourist rate and roughly \$5000 at the free rate). The staff consists of a director and 4 physicians, all of whom are general practitioners. There are 30 nurses plus 70 other personnel including attendants. In the past year 7 patients had been given insulin and 14 patients a combina-

⁶ The total budget for the management of mental hospitals is 50 million rupiah a year.

tion of chlorpromazine and reserpine (with drugs supplied by the family). Eighty percent of the patients are schizophrenic and another 10% are epileptic. About 50 patients are given ECT 3 times a week. Since there are no electroshock machines, convulsions are produced by placing electrodes on either side of the head and then plugging into a wall circuit and pulling out again. According to the director the biggest problem is the lack of aftercare which results in an extremely high relapse rate. Since the family of the patient must provide his medications which are quite expensive they are almost invariably discontinued when the patient leaves the hospital. Also pre-war there was some system of paying the family to help take care of the patient if he was well enough to leave the hospital although not well enough to work, but since this is no longer done the families are not anxious to have patients return home, and they tend to become stockpiled at the hospital. Approximately 20% of the families do pay toward the cost of the patient care but this averages 17½ rupiah (20¢) per day.

Bogor Hospital. Bogor Hospital, built in 1882, now has a capacity of 1200 with 580 male and 550 female patients in residence. There are an average of 400 yearly admissions and discharges. The staff consists of 5 doctors (of whom 3 are psychiatrists), 250 male nurses and 250 female nurses. There are different classes of patients in the hospital and 10% pay something toward their upkeep. Fourth class patients when they can afford it are supposed to pay 12½ rupiah per day and first class patients 37 rupiah. The actual cost is 10 rupiah per day for food and 30 rupiah per day for total maintenance exclusive of the medical care. Occupational therapy is the main type of treatment. EST is given twice a week to 37 of the 550 female patients and 3 times a week to 30 of the 580 male patients (the difference is due to the decision of the doctor running the service). Occasionally Cardiazol is used, but insulin is too expensive. Chlorpromazine is used at times when it can be supplied by the family since the hospital cannot afford to provide it. The cost is 2.75 rupiah for a 25 mg. tablet and occasionally 10 tablets will be given 6 times a day (*i.e.*, 1500 mg.), but such dosage

which costs the family \$1.83 per day extra is extremely rare. As will be noted later the only size chlorpromazine tablet available in all of Indonesia is the 25 mg. size. In view of the cost the family frequently tries to bargain with the hospital physician, urging him to use as few tablets as possible. The hospital is completely "open" with patients free to come and go as they choose and without locked wards. An average of perhaps one per month leaves the hospital but invariably returns. The departure from the hospital is usually the result of getting lost rather than an attempt at escape. Of the 1350 patients already in residence or admitted during 1960 there were 958 hebephrenic schizophrenics, 125 catatonic schizophrenics and 135 paranoid schizophrenics.

The attitude of the community toward mental illness according to the director of the hospital is usually quite open, and there is no feeling of either fear or dislike of psychiatric patients. This is in some contrast to Djakarta where there is a certain amount of shame regarding disease in general, but interestingly enough primarily centered on leprosy and tuberculosis rather than psychiatric disorders. Occasionally a major social problem is created by a patient (a father, say) being accepted back into the family if the daughters are about to be married since the father may become an economic burden. There is a great tendency to forget about relatives who are hospitalized and particularly in those groups which do regard mental disease as a disgrace. Because of the extended family system a peripheral relative is just as great a source of embarrassment as a father or son.

There is invariably a long waiting list for admission but in cases of extreme urgency the staff can accept a patient immediately. All patients admitted to the hospital require certification. The family applies for admission and the patient is then certified by a psychiatrist and placed at the bottom of the waiting list. The notice of certification is sent to the Department of Justice for filing in case anyone wishes to contend the action.

Of the patients discharged from Bogor an average of about 1 per day can be seen at the outpatient polyclinic in town. At the Bogor Mental Hospital which is several

miles outside of town there are extensive follow-up facilities available, but they are rarely if ever used because of the transportation problem. It would cost 20 or 25 rupiah at the very least for the patient to get to the hospital, and in most cases it would be closer to several hundred rupiah which is completely prohibitive.

Bangli Hospital on Bali. The Bangli Hospital, formerly a military barrack, was built in 1920 and became a 150-bed mental hospital in 1930. Two new 50-bed wards for males are to be added in 1962. On the island of Bali there are also three 40-bed general hospitals.

There are 18 polyclinics on the island with a limited number of physicians who are in attendance on different days. The visit to the mental hospital is routinely made on Monday and probably does not occupy more than an hour of the time of the general practitioner. There are no resident physicians at the hospital and there are no psychiatrists on the island of Bali. The number of patients at the hospital (circa 1961) is the same as when the Dutch were there. A definite shortage of supplies exists, including penicillin and even materials for work therapy, so that there are looms and other equipment which stand idle. In 1961 there were 90 male patients, 60 female patients and a waiting list of 131 men and 20 women. Thus the waiting list was larger than the number of hospitalized patients. Patients are given a month's clinical trial at home before they are formally discharged from the hospital. The hospital averages about 15 male and 10 female admissions *per year*.

The diagnoses of the patients of the hospital in 1960 are shown in Table 1.

The facilities for laboratory examinations are also extremely limited, and during the entire year 1960 there were only 13 blood tests for syphilis (4 were positive), no sputum tests, no vaginal smears, 122 urine and fecal examinations (diarrhea and particularly amebic dysentery are common).

In conjunction with the mental hospital at Bangli, but several miles away at Klungkung, there is a colonia(1) of 59 patients managed by 8 employees. This is a type of rural farm residence for long term patients who cannot adjust in society but ap-

Paranoia	3	1	4

parently do extremely well under supervision. The government pays 2 rupiah per day toward the patient's upkeep if the family cannot afford this. The colonia is largely self-supporting since it sells the agricultural produce it grows.

Porong Hospital in Lawang. Built in 1902 the full name of this hospital is Rumah Sakit Djiwa Sumber Porong. Formerly there were 4000 beds, but now the theoretical capacity is 2000 patients with three unused wards, because the buildings have been condemned. The actual capacity is therefore 1800 and the actual occupancy is 1774 patients plus 110 patients on parole. The hospital is extremely clean throughout, although there is open ditch sewerage as in most of Southeast Asia. There is an acute shortage of journals and current psychiatric books. A colonia for 1100 patients was totally destroyed during the war for independence and the patients sent home.

Treatment consists primarily of ECT with patients given a course of 12 treatments. Drugs are used only when the family can afford to buy them and in the course of the past 4 years there have been less than 100 such patients. Chlorpromazine is usually given in top doses of 150 mg. a day or reserpine is used, 12 tablets of the 0.25 mg. size (*i.e.*, 3 mg. per day). Another form of treatment is occupational therapy, but only 6 of the 50 looms have sufficient thread for patients to be working on them.

Magelang Hospital. This hospital, built in 1920, formerly was overcrowded with 2000 beds in contrast to the 1100 now in use. Ad-

missions and discharges total about 300 a year. The director is a German physician who has been there for 6 years. In addition on the staff are 3 or 4 local physicians not trained in psychiatry. Approximately 50 patients pay up to 50 rupiah and another 50 patients pay less than 50 rupiah whereas the other 1000 pay nothing. Treatment consists of scopolamine, morphine, and ECT for sedation. Psychopharmaceuticals are not available.

ECT, used only in cases of excitement, is given 3 times a week for up to 10 weeks. For the past year patients have been kept outdoors most of the day, and there is very little disturbed behavior. The remaining closed wards in the hospital are having the bars removed since all of the patients are outdoors at least in the afternoon.

Occupational therapy consists largely of mat weaving with a substantial amount of Batik work which seems most relaxing for schizophrenic patients with a proclivity to stereotypy or automatisms.

Attitudes Towards Mental Illness. As a rule there is less fear of psychiatric patients in Indonesia than in many other cultures, and certainly leprosy and tuberculosis are regarded as having a greater stigma attached to them than mental disorders. One possible explanation is that in accord with Javanese religious practices there is appeasement of the "black gods and spirits" as well as worship of the good ones so that people are not afraid of becoming contaminated by the evil spirits in the mentally ill since these spirits have been propitiated.

As is obvious, only a small proportion of the mentally ill are admitted to the hospitals and the majority are given "native treatment," particularly in east and in central Java. Such practices are more frequent in the villages than in the cities and generally consist of "washing a patient's soul in the river" which is not without its hazards as sometimes the patients drown. There is also treatment with incense, holy water and amulets. A large number of the patients who cannot be admitted to the mental hospitals because of the space limitations become tramps and wanderers. Senile patients and mental defectives, on the other hand, are kept at home.

Javanese families are very patient, and

this is especially helpful in the treatment of ambulatory patients. If, for instance, they are asked to feed a withdrawn or depressed patient they will continue offering him food perhaps 100 times whereas the average European or American family would give up in disgust after 3 or 4 attempts.

Differences in Types of Mental Disorders. The hospitalized patients are usually schizophrenic with an even higher proportion than in the United States. There do exist some subtle differences which may well be related to culture. One of the most interesting of these is that the paranoid patients do not have nearly so systematized delusions as do paranoids in the Western world and even when they have hallucinations, rather than trying to find out how they are produced, who is causing them, and why, the patients simply accept them. Abusive voices, visions of people far distant or long dead and the other common hallucinations and delusions are not particularly disturbing to the Indonesian patient. In part this may be because such phenomena are not regarded as so unnatural as in our culture, and in part there is a general acceptance of things without the need to inquire into causes (which is so typical of Western civilization).

In none of the hospitals which I visited was there any record of a native Indonesian ever having committed suicide, and even among Indonesians of Chinese origin suicidal attempts are extremely rare. As far as could be gathered from the statistics the occurrence of manic states was more frequent than depressions.

Among the more unusual forms of psychiatric disorder is *latah*. This appears to occur in a hysterical type personality and may be a type of conditioned reflex. It is usually an elderly Indonesian servant who becomes *latah* with attacks being precipitated by sudden or unexpected events, sounds or occurrences. The most striking symptom is repetition, but it is quite distinct from echolalia. The person becoming *latah* usually shouts such phrases as "horse penis," "cow vagina" or other phrases with similar sexual content. An attack can be deliberately provoked by shouting, for instance, "don't do that!" with the victim then repeating "don't do that" or, if a dirty word is

shouted, the patient will repeat it or add one or two of her own. This can be transferred into the sphere of action, e.g., a servant enters carrying a bowl and if someone shouts "drop it" the servant will drop it and then repeat whatever is said. The attacks last only as long as the person is being teased. Subjects are almost always conscious of what they are doing and do set limits to their action: for instance, if a female is told to pull up her sarong she will not do so. Someone could shout "kiss him" and the person in *latah* might do this but later become angry about what she had been tricked into doing. If the teasing continues long enough the subject may make an effort to discontinue the odd behavior and terminate the attack.

In summary, *latah* appears to be a type of hyper-suggestibility induced by shock, command, noise or physical trauma such as stumbling or being pinched. Almost all the patients are females.

Another much discussed condition is *amok* which is probably an indiscriminate acting out of acute aggressiveness without specific motive or selectivity as to the person or thing being attacked. If nothing else is available such patients will sometimes attack their own body. It is unusual to be able to examine such patients since the attack almost always ends in the death of the patient who is shot by the police or military to prevent further mayhem or homicide. The disorder usually occurs in young or middle aged males who are quite responsible individuals up to the time of running *amok*. It is possible that these attacks are induced by shame with an inner need for revenge. The person appears to accept an insult or a shameful situation quite calmly without saying anything and quite possibly without conscious awareness of his deep emotional reaction only later to become *amok*. The few patients examined have all had complete amnesia for the episodes and are definitely not schizoid types of individuals but appear to be the more emotionally hyper-reactive. It may be that they experience an hallucinatory state with a feeling of being pursued by devils which is necessary for them to slay. Incidentally, there is no record of a patient who became *latah* later running *amok*. Unlike *latah*,

the incidence is as high in individuals of Chinese origin as among the Indonesians.

Another practice which falls into this general group is *diguna-guna* which is probably a type of anxiety pseudo-psychosis. By way of background: 1) a man is in love with a woman who dislikes him and he then seeks some device to make her love him; 2) a man feels he has been insulted and wishes an evil spell cast to make his enemy ill. Both of these can be theoretically achieved by taking some belonging of the person on whom the spell is to be cast (such as nail parings or hair) and bringing this to the *dukun* who (in addition to being the local medicine man) is a medium and capable of inducing (or removing) trances. The person on whom the spell is cast cannot resist: the woman falls in love with the man; the enemy becomes psychotic in which case "black magic," *dibikin*, has been invoked. The victim is not always directly informed that he or she is being "bewitched," and it is a question as to whether he learns of this from secondary clues or in some other way. It is possible to influence the patient out of this pseudo-psychotic state. There does not appear to be an easy explanation for some of these cases. There are some intriguing similarities to Haitian beliefs(2).

Mandi-Minjak-Mendidi (which means "bathing in boiling oil") and *djalan diatas api bara* ("walking on blazing charcoal") are both Chinese religious ceremonies which occur yearly (if the government permits) when a particular statue is taken out and carried through the streets. The devotees transform themselves into the "God of Fire" with the help of Chinese priests and in this trance state they demonstrate the might of the god since they can perform feats that would not otherwise be possible.

Koro is the Chinese belief that under certain circumstances the penis may recede into the abdomen and occasional cases are found where a stick has been bound tightly to the organ to prevent this disaster.

Kesuruban is like a seance in the United States or Western Europe. One who believes intensely goes into a trance and is then possessed (usually by a good spirit). One occasion for *kesuruban* is if a physi-

cian tells a patient that there is nothing more that he, the physician, can do to help. The patient with some fellow believers may go to a local temple. This is true of both the Chinese who pray to the God of Medicine and the Javanese who, despite the fact that they are nominally Islamic, will never pray directly to Mohammed to ask a favor but always request such help from the Hindu Gods who are also members of the Javanese pantheon. When the medium goes into trance he speaks with a different articulation and intonation and sometimes uses a foreign dialect. If the god predicts the patient will get well he or his friends later return for a second ceremony to determine the medication, the dosage, and the method of treatment including incantations, *etc.* Frequently the second visit is unnecessary because the medication itself appears in a trance or a dream and the believer then proceeds to a Chinese or other dispensary to have the medication prepared according to the recommendations. Sometimes this consists merely of writing certain formulae on paper and after burning and mixing, the ashes are swallowed. In *kesuruban* a skilled medium can also go into a trance under his own power without a seance and transform himself into an "ideal" personage. Under these circumstances there is frequently identification with the characters of the Indonesian shadow plays (*wajang*).

Another peculiar phenomena is *kuda-kepeng* (kuda=horse and kepeng=matting or bamboo). The resultant performance, usually done for payment, consists of a boy and a girl who spin about on their

feet for three to five hours to very monotonous music with the "master" snapping a horse whip. At the end of this time they appear completely entranced and will eat raw rice including the stems, leaves and husk and also will chew up electric light bulbs (spitting them out) without apparent injury to the mucosa of the mouth.

Discussion on the Future of Psychiatry in Indonesia. It is palpably impossible to furnish an adequate number of psychiatrists or hospital beds for Indonesia in the immediately foreseeable future. The responsibility for patient care therefore devolves directly upon the general practitioner, and a plan is being developed both to provide such training and to evaluate its effectiveness. Some of the general factors that must be considered have been discussed elsewhere (3-6).

PSYCHIATRY IN IRELAND

IVOR W. BROWNE, D.P.M.¹

Since my arrival in the United States, it has been said to me on many occasions: "So you are a psychiatrist from Ireland. Surely they don't need psychiatrists over there. I thought that life in Ireland was so easy going they wouldn't have any worries about mental health." And yet, when one begins to look more closely at the situation, it is found that approximately 7 persons per 1000 of the population in the Republic of Ireland² are currently hospitalised for mental illness(2). This is more than twice as high as the corresponding figure for the United States of 3.61 per 1000(4), and is probably the highest figure in the world. An even more startling percentage is to be found in one county in the West of Ireland where 12.3 persons per 1000 are in mental hospitals; that is more than 1% of the total inhabitants in that area. In a country with a predominantly rural society where toleration of disturbed behaviour is probably high rather than low such facts as these hardly suggest that the problem of mental illness is a negligible one or that there is much room for complacency.

Ireland is a small island, the western outpost of Europe—some 300 miles from north to south, nearly 200 miles from east to west. It is a country with an ancient civilisation presenting many contrasts between the old and the new, ranging from the inhabitants of a modern European city like Dublin to the nomadic "travelling" people who roam all over the country and whose way of life has probably changed little for over a thousand years. In little more than a century the population of Ireland has fallen from over eight million to approximately half that number. Although for hundreds of years there has been some emigration the more recent excessive trend was largely set in motion by the great famine of 1845-47, when in barely four years nearly a million people per-

ished from starvation and an even larger number were forced to leave the country. The present population of the Republic of Ireland is just under three million.³

A high rate of emigration alone is not sufficient to explain this marked reduction in population. Another factor is probably the annual marriage rate of 5.3 per 1000, one of the lowest in the world. Contributing to this is the fact that one quarter of the population do not marry at all and the average age of those who do is one of the world's highest—33 years for men and 28 years for women. These characteristics too are probably partly a result of the great famine when the Irish people seem to have suffered a profound loss of confidence in the future. Prior to that period they had married at an early age.

In recent years there has been increasing evidence that the tide is turning against such all-pervading pessimism. Under the impetus of a rapidly growing industrialisation and an improving economic position an atmosphere of buoyant optimism is fast replacing the former cynical apathy. Already people are beginning to marry earlier in urban areas, the rate of emigration has fallen markedly in the past two years and a growing number of those who had left the country are returning home. Ireland is now about to enter the European Common Market and this will undoubtedly lead to widespread economic and social upheaval. These signs would seem to indicate that the country is approaching a period of rapid social change. This is already being mirrored by an increasing interest in mental health and a feeling that something must be done to provide more adequate psychiatric care. It seems therefore an appropriate time to review the current position of mental health services in Ireland.

Historical Background of Health Services. Considerable progress has been made in the past quarter century in Ireland towards the provision of adequate health services and

¹ Research Fellow in Mental Health, Harvard University, School of Public Health.

² For the purposes of this paper the six northern counties will be excluded.

³ The population of the six northern counties is approximately 1,390,000.

the achievement of reasonable standards of general health. During this same period, however, there has not been a corresponding activity in the sphere of mental health. Since the end of World War II when for the first time the Department of Health became a separate entity (1947), a number of urgent health problems have been tackled with considerable success(1), notably the control of communicable diseases and the development of adequate maternal and child health services. In more recent years the main emphasis has been placed on a campaign for the eradication of tuberculosis. Large regional sanatoria were erected in addition to many smaller facilities. While this programme was still being carried out, new powerful anti-tuberculous drugs were introduced with the result that a number of the newer sanatoria have never been fully occupied at any time since they were built. This lesson should serve as a warning to those who would suggest the construction of large new mental hospitals, for such structures are already contra-indicated by present knowledge of the nature of mental illness, and are likely to become even more incongruous in the face of future therapeutic advances.

During the same period there was an energetic hospital construction programme as a result of which modern medical and surgical hospitals were erected all over the country. Ireland is now more adequately supplied with general hospitals than almost any other country in Europe. In contrast to this the mental hospitals are almost without exception old and dilapidated. Although there should not be any shortage of accommodation (7 beds per 1000 population), these institutions are in fact filled to capacity and in many cases grossly overcrowded.

Perhaps at this point it is interesting to speculate as to why Ireland should have such a uniquely high mental hospital population. The reason which first suggests itself is that this is due, in large part, to long continued emigration of the more virile, healthy elements of the population. It seems to me, however, that a more likely explanation lies in the fact that the majority of the mental hospitals were built early in the last century when the population was roughly twice as large as it is today. This then would

provide an instance of what has often been noted by others that the more psychiatric facilities there are available the greater the number of patients who will be found to utilise them. In this way the existence of a large number of mental hospital beds in a country may have an adverse rather than a positive effect upon mental health. If, as in many countries, an acutely disturbed psychotic can only find accommodation in the local jail, he is likely, as soon as the acute episode subsides, to be returned to the community from which he came. Should there be a place for him in the mental hospital, however, he might well (until recently) remain there languishing on a back ward for many years.

Although there was considerable scope for development under the Irish Mental Health Act, 1945, not a great deal has in fact been accomplished to date(1). Until recently there was not much active treatment carried out in the mental hospitals and even now in a number of areas patients are given little more than custodial care. Up to 1945, nineteenth century definitions, law, and procedures still governed the care of the mentally ill. Patients were "committed" to mental hospitals on warrants signed by peace commissioners, and there was provision for nothing between detention on such warrants and complete freedom. There was a system of "trial discharge," but this did not work well in practice. The Mental Health Act, 1945 (Amend. 1953), was for its time a progressive piece of legislation which made medical personnel responsible for certification of mental patients without resort to judicial process. It is worth noting here that in Britain the Irish Act of 1945 was severely criticised, mainly on the grounds that compulsory detention was effected on medical recommendation alone. It was only some thirteen years later in 1959 that England and Wales adopted similar measures. The United States has not yet done so.

Present Position of Mental Health Services. In 1959, the total number of patients resident in mental institutions in Ireland was 20,609; of these 19,590 were under care in the district (state) mental hospitals and 1,019 were resident in private, private charitable, authorised and approved institutions

(3). During the year 1959, 8,569 patients were admitted to the district mental hospitals and of these 1,666 were over 65 years of age. Any attempt at a breakdown into diagnostic categories must necessarily be somewhat inaccurate due to lack of uniform diagnostic criteria being applied in different hospitals. Figures are only available for the district mental hospitals, but these are interesting in that they show such a high preponderance of psychotic disorders. It seems that in Ireland mental illness is not likely to come to public attention until it has reached psychotic intensity. Broken down into broad categories these percentages are :

TABLE 1
Diagnostic Categories of Patients in Mental Hospitals

DIAGNOSTIC CATEGORY	% OF PATIENTS UNDER CARE ON 31ST. DEC. 1958	% OF PATIENTS ADM. DURING YEAR ENDED 31ST. DEC. 1958
Schizophrenic Disorders, Paranoid and Puerperal Psychoses	53.73	31.18
Manic-Depressive and Involuntional Disorders	15.53	33.78
Mental Deficiency	10.61	3.45
Senile, Presenile Psychoses, Organic & Epileptic Conditions	15.82	14.56
Neurotic Disorders	2.21	9.76
Pathological and Immature Personality, Character Disorders	1.48	2.00
Alcoholism	0.48	4.99
Drug Addiction	0.04	0.24

The average cost of maintaining a patient in a mental hospital per year (estimated for the year ending March 31st, 1959) is approximately \$600, that is less than \$2.00 a day. The cost of a more adequate service would undoubtedly be higher if measured in this way over a given time. Of course this would not necessarily be true if the cost of each patient's illness were measured as a whole, for with more active treatment the duration of complete financial dependence might not be so prolonged. In all events, the present maintenance per patient is extremely low and covers a bare subsistence level. In many instances the actual living conditions for the patient are literally wretched.

Most of the mental hospitals are overcrowded and the number of well trained psychiatrists is inadequate although increasing. Other personnel such as psychologists, psychiatric social workers and occupational therapists are almost nonexistent. Psychiatric nurses are also in short supply

and are, for the most part, inadequately trained. In the field of child psychiatry, there is only one child guidance clinic which is working to full capacity. This is run by a religious order. Another guidance clinic is being organised at a children's hospital in Dublin but is not yet functioning on a full scale. It should be remarked in passing that these clinics follow the traditional pattern for a child guidance clinic in the United States. To my mind, this conception is outmoded, inappropriate, and becomes ludicrously expensive when applied to a country such as Ireland.

Preventive psychiatry is almost com-

pletely undeveloped. There is little activity going on in the community, and not much work is being done in the area of mental health education. Although a few of the Dublin voluntary hospitals have psychiatric beds, there is no properly developed psychiatric department in a general hospital. An aftercare service has been started in connection with only one mental hospital.

The position with regard to mental retardation is little better. It is estimated that there are at least 2,000 persons in the mental hospitals who are there primarily because of mental retardation (5). In addition, there are approximately 25,000 mentally handicapped persons in the community of whom about 7,000 probably require institutional care. To deal with this problem, there are 14 residential centres which provide accommodation for only 2,620 persons. With one exception, all these institutions are managed by religious communities. The government has no direct programme in this field.

There are only three active geriatric units in the whole country. Most old people are cared for in the county homes, or in mental hospitals, often under miserable conditions. Otherwise they have to be looked after at home. Efforts are being made at present to improve the county homes but little evidence of this can be seen as yet. There has been some development in the sphere of domiciliary psychiatry. In a number of districts patients are now seen in their own homes by the psychiatrist or specially selected members of the nursing staff. This is particularly aimed at the geriatric patients who at present occupy a large number of beds in mental hospitals.

In spite of this on the whole rather gloomy picture, there have been a number of more positive developments in recent years. There are two private mental hospitals in Dublin which have now achieved a high standard, comparing favourably with better psychiatric hospitals in Britain and the U.S.A. The staffs of these hospitals carry on active teaching and training programmes. Even in the district mental hospitals there has been a gradual change towards more active treatment. The number of patients admitted on a voluntary basis is increasing; during the year 1959, as many as 58.5% were voluntary(3). The number of psychiatric outpatient clinics, most of which are conducted by the mental hospitals, has grown rapidly during the past few years. At the end of 1959 there were 92 clinics in operation. Plans are now in progress for the opening of two day hospitals with a third to follow.

During the past year the mental health services were discussed openly in the Dail (parliament) for the first time. As a result of this a Commission of Enquiry has been set up to examine thoroughly the whole problem. A similar commission has already been formed to investigate fully the allied question of mental retardation.

These sporadic but nevertheless quite definite evidences of progress would seem to indicate that the country is approaching a period of more active development in the sphere of mental health. As things stand at present, however, the mental health services in Ireland are in roughly the position of equivalent services in Britain and the

United States in the period prior to the second world war, when psychiatric outpatient treatment was rapidly developing and the whole child guidance movement was taking shape. There is the important difference, however, that since then knowledge and understanding of the human personality and mental illness generally, as well as methods of treatment, have advanced considerably. A country such as Ireland is now in a position to draw on such experience and, hopefully, to avoid some of the mistakes which have been made by other countries during the past thirty years.

From the evidence produced by the tuberculosis programme in Ireland it can be learned that the Department of Health is capable of making a concerted drive and investing sufficient capital to bring about significant changes in a particular sector of health. It would seem a pity if, when making efforts to raise the standards of mental health, Ireland were merely to follow slavishly the painful step by step progress already gone through by other countries more developed in this field, rather than make a radical departure from traditional facilities and procedures. Perhaps it is possible for a small country, in a relatively short time, to carry out successfully a plan of major development and reorganization within a limited field of health throughout the entire country. In a nation as large as the United States, on the other hand, it takes many years for a major change in the organization of a health service, however desirable, to gather momentum.

CYTOGENETIC AND PSYCHOSEXUAL INCONGRUITIES WITH A NOTE ON SPACE-FORM BLINDNESS¹

JOHN MONEY, Ph.D.²

Congenital Sex-Organ Deformities (5, 7-11). Genital deformities, as in the various syndromes of hermaphroditism and in the syndrome of penile agenesis, provide the next best alternative to actual experimentation with human psychosexual development relative to chromosomal status. As a result of genital deformities, some individuals with the XY chromosome constitution get assigned to be raised and live as females, and some, with the XX, as males. Examples representing two syndromes are shown in Figures 1 and 2.

For psychosexual research, it is particularly fortunate that, as sometimes occurs, individuals raised in one sex are matched by those of identical diagnosis raised in the other. These parallel pairs serve, in a sense, as experimental controls of one another. The importance of having these controls is this: if the genetic and/or hormonal factors responsible for the genital deformity should conceivably be also responsible for some alteration of psychosexual potential, then both individuals of a parallel pair with identical diagnosis presumably have this alteration.

It turns out, with few exceptions (Figure 3), that each individual of a parallel pair develops psychosexually to have a gender role and identity concordant with assigned sex. The development of one of the pair, therefore, has been able to override any genetically determined tendencies in psychosexual differentiation which would have worked to the advantage of the other member of the pair.

The data on hermaphroditism and related congenital sexual deformity require

one to infer that individuals so affected are born psychosexually neutral or undifferentiated. Psychosexual differentiation then takes place, influenced as language acquisition is influenced, by surroundings and experience. A gender role and identity become established congruously with the sex of assignment. It is a marked, though not obligatory asset, if the genital morphology and the body image it generates agree with, or at least do not grossly contradict the sex of assignment.

There are some logical hazards in generalizing from the pathological example of hermaphroditism to infer that all the human race begins life psychosexually undifferentiated. It could be argued that genetic factors which induce genital deformity also induce an original neutralism of psychosexual potential that most of the remainder of the human race does not possess. Then it could be further argued that in cases of aberrant psychosexual development, like homosexuality and transvestism, there is also an original neutralism, which increases the individual's vulnerability to postnatal developmental experiences and aberrations. Unfortunately for logical neatness, the completely contrary proposition could also be argued, namely that homosexuals and transvestites are unique in alone having at birth a predetermined psychosexual differentiation, but in the wrong direction.

It is not at all necessary, however, to subdivide the human race into those who are psychosexually neutral or undifferentiated at birth and those who are not. It is more reasonable to suppose simply that, like hermaphrodites, all the human race follow the same pattern, namely, of psychosexual undifferentiation at birth. Certainly, an examination of the different syndromes of hermaphroditism and related genital deformities with respect to what is known about the genetics, embryology and endocrinology of their etiology, gives no plausible basis for supposing that these very different clinical conditions all happen to

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

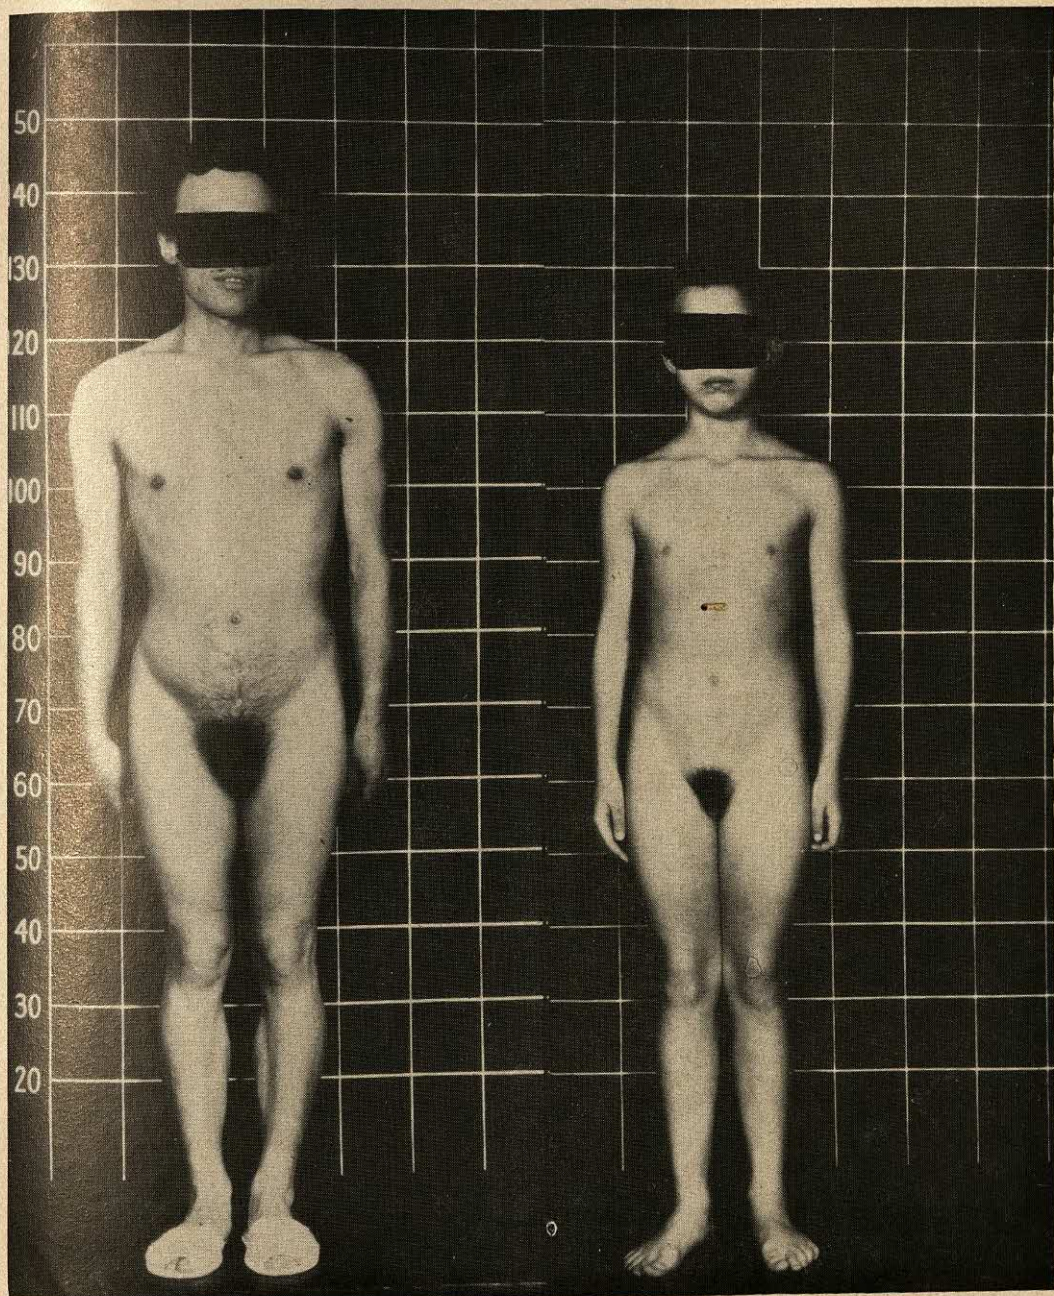

FIGURE 2

Two cases of female (XX) hyperadrenocortical hermaphroditism without cortisone treatment. Left, age 23, raised and living as a girl. Right, age 6 (note precocious adrenal virilism), raised and living as a boy. Nine years later, psychosexual identity in both patients remains fully congruous with continued dichotomy in sex of rearing and correlative surgical and hormonal treatment.

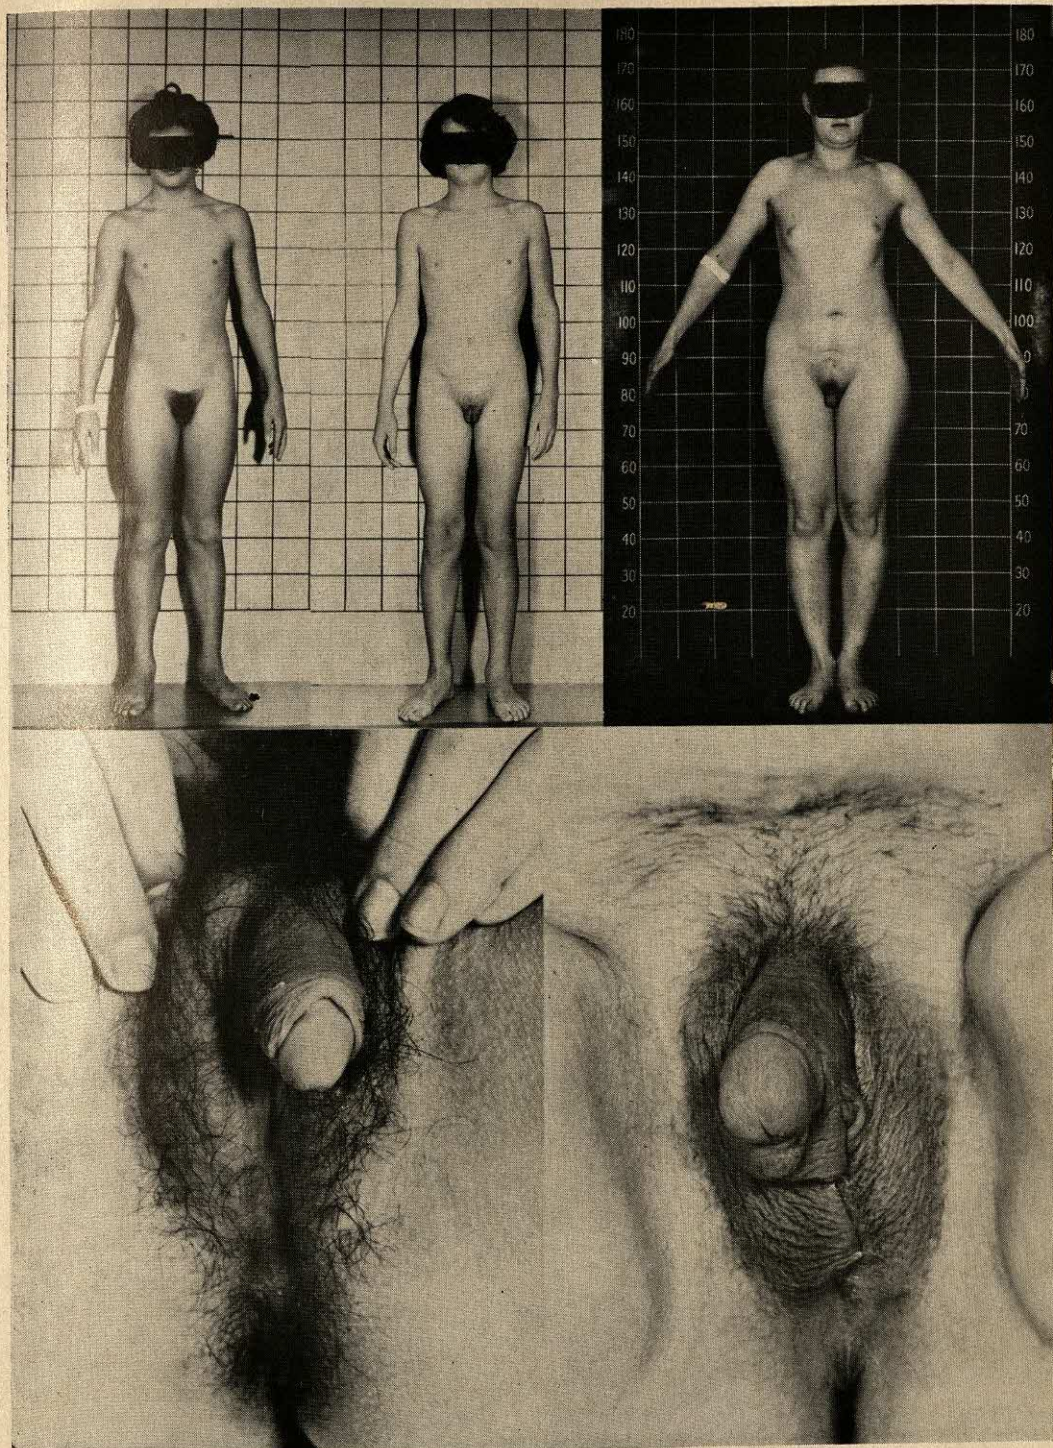

FIGURE 3

Two cases of unfeminized cryptorchid hypospadiac male (XY) hermaphroditism. Left, raised and living as a girl and requesting surgical and hormonal feminization. Right, a rare case of spontaneously requested sex reassignment and surgical masculinization (at age 14) after equivocal rearing as a girl. Psychosexual identity congruous with patients' requests.

share in common a genetic or prenatal factor which predisposes only such a patient to become psychosexually differentiated as either male or female, dependent on rearing.

One is very surprised sometimes not that psychosexual neutrality exists, but that it has not in some cases of hermaphroditism been completely abolished by those same factors that produce the hermaphroditism. To illustrate: hyperadrenocortical virilism in female hermaphrodites (Figure 2) may be so complete as to produce an actual penis in place of a clitoris before birth. Postnatally, virilizing puberty is precocious and intense, producing an exaggeration of masculine physique. Yet, the genetic and hormonal factors responsible for this excessive virilism do not masculinize psychosexual differentiation. In the days before cortisone treatment, some such girls grew up untreated and, even with the hypertrophied clitoris left in place like an hypospadiac penis, established a feminine gender role and identity.

Allow that hermaphrodites share with the rest of the human race the condition of being psychosexually undifferentiated at birth. Nonetheless, they do possess a unique characteristic—excepting those whose hermaphroditism is internal and concealed—not shared by others, namely, that their genitals do not definitively assert that they belong to the one sex or the other. This ambiguity makes it feasible for a child to assimilate the sex of assignment in a way that would be incomparably more difficult for a child with normal-looking external genitals (with or without internal hermaphroditism). In fact, it may even be that the very ambiguity determines, by way of a compensatory, reaction formation, a vigorous assimilation of the assigned sex. On the other hand, it is also the ambiguous external genital appearance, plus equivocal rearing and social experience, that facilitates some few hermaphrodites in the repudiation of their assigned sex.

This influence of the genital morphology is mediated by way of the body image and is not a direct, primal determinant of psychosexual differentiation. The evidence of hermaphroditism, including both assimilation and repudiation of assigned sex, does

not support any simple-minded theory of social environmental determinism in psychosexual development.

Psychosexually undifferentiated organisms are not necessarily identical. They may be dissimilarly equipped to undergo psychosexual differentiation, in rather the same way as some embryos are dissimilar from others and differentiate as hermaphrodites. How organisms differ in their preparedness to undergo psychosexual differentiation after birth can scarcely be guessed at, presently. One must allow the possibility not only of genetic differences but also of those engendered by intrauterine experience. It must surely be assumed that these differences are not specific for psychosexual differentiation, *per se*, though they may be integral to its progress, exerting their influence on the course of learning, assimilation of experience and response to stimuli.

As an example, consider the sense of smell. There is a sex difference in olfactory acuity in adults, positively correlated with the estrogen phase of the female menstrual cycle. Nothing is known about either sex differences or individual differences in the sense of smell in the newborn. It is conceivable that differences do exist. Though it is an unlikely possibility, it is at least possible that boys and girls respond differently to the smell of men and women, and so are differently affected with respect to psychosexual differentiation.

Another provocative speculation is that males may be equipped differently than females in regard to "territory assertion rights," a complex behavioral entity little understood in the human species. Conceivably this entity may manifest itself in the greater incidence among boys than girls of free-ranging locomotor activities and expeditions, greater vulnerability to death by accident, more frequent engagement in physical, body-contact, power struggles for position in the childhood pecking-order, and less sedentary sports and pastimes. The contrary behavioral entity in girls, one may speculate, pertains to what is, in the phylogenetic sense, nest-making and infant-care.

The theoretical model for psychosexual differentiation, as presented up to this point, involves an original state of neutrality plus individual differences that antedate psy-

chosexual differentiation but will affect its course.

Some of these differences may well be genetic traits. It is more likely that such traits are dispersed among the autosomes than that they all happen to be carried on the X or Y chromosome.

Regardless of chromosomal mechanism, such genetic traits as may relate to psychosexual differentiation do not assert themselves, willy nilly, regardless of postnatal experience. The evidence of hermaphroditism is very clear that the genetic predispositions, better called the norms of reaction, toward masculine and feminine are not mutually exclusive in psychosexual differentiation.

Old-fashioned concepts of the autonomy of heredity, to the exclusion of environment, in psychosexual determination need to be revised. The hereditary mechanism is not one that directly determines psychosexual differentiation. Rather, it determines that psychosexual differentiation shall, like native language, be dependent on postnatal experience. As psychosexual identity becomes differentiated it becomes permanently indelible and imprinted, and subsequently as influential as if present at birth. This idea of the indelibility of the products of the interaction of heredity with experience and learning is profoundly important and is prerequisite to an understanding of how a person's gender identity and role can become so fixed as to appear as if innately determined, *in toto*. The evidence from hermaphroditic cases of sex reassignment is that the critical period for gender imprinting is in early childhood, beginning with the onset of mastery of language.

Chromosomal Sex in Homosexuality and Transvestism. In aberrations of psychosexual differentiation, the error which induces aberrancy may be envisioned as having its origins in the genes, in intrauterine experience or—and this is by far the most likely possibility—in the experiences of the early years of life which are the most critical ones for psychosexual differentiation. So far as genetics might be concerned in aberrant psychosexual differentiation, it is not possible to implicate any gross visible anomaly of the sex chromosomes, on the basis of present techniques. Patients with psycho-

sexual aberrations have, as a general rule, the usual XX or XY chromosome complement.

Before the technique of chromosome counting was discovered, nuclear sex chromatin surveys of homosexuals disclosed no discrepancies between them and control groups of men with normal masculine gender identity (2, 14, 16). Barr and Hobbs (1) found typical male chromatin pattern in the cell nuclei of 5 cases of genuine male transvestism.

The converse of the above findings also holds true, namely, that syndromes characterized by chromosomal deviation are not also marked by psychosexual deviation. Thus, abnormalities of the X and Y chromosome complement, as in Klinefelter's and Turner's syndromes, do not correlate, except maybe fortuitously, with psychosexual aberration.

The XXY (Klinefelter) Syndrome. In addition to its pertinence for psychosexual theory, the XXY syndrome is of psychiatric interest in relation to associated sporadic incidence of mental deficiency and of symptoms of psychopathology. In the present context, however, I wish to direct attention only to psychosexual aberration, which is also of sporadic incidence in the syndrome.

Raboch and Nedoma (16) found no homosexuality in 36 men with this syndrome, identified by means of a positive sex chromatin. Conversely, none of 194 homosexuals had a positive chromatin.

In 1957 Pasqualini, *et al.* (15), published a review of 31 Klinefelter cases from Argentina. Seven were rated low in sexual activity and 13 normal, with no data on 11. Homosexual experiences, of occasional incidence, reported by 2 patients, were the only aberrations of sex behavior mentioned.

Mosier, *et al.* (12), found a higher preadmission history of sexual offenses (nature not specified) in a census of 10 XXY cases in a mental deficiency hospital than in a control group ($p=0.0025$).

In another institution, a census of 6 sex offenders with the XXY syndrome was constituted as follows: 3 cases of sexual offence with boys, 1 with a girl, 1 rape with a married woman and 1 attempted mother-rape.

Over the last 5 years I have seen 21 pa-

tients with the XXY syndrome, verified either by a positive sex chromatin finding or by actual chromosome count. The youngest was a prepubertal boy of 12½ years, the oldest a man of 69. The others ranged in age from 14½ to 52 years. The sample was obtained not by random selection from the total United States XXY population, but was biased in favor of psychopathology and low IQ. Six of the patients were institutionalized for mental deficiency, with IQs ranging from 60 to less than 37. Among the remaining 15, 6 were below average in IQ, 7 were average, and 2 were superior (IQ 121 and 132).

All 20 of the postpubertal patients were low-powered in sexual urge and frequency of erection and orgasm. Only three were rated with medium strength of genitopelvic eroticism, their orgasm being reported at a maximum of three times a week. The rest were rated weak, except two who were morbidly weak and apparently had no orgasm at all in the prime of life. A low sexual threshold is a feature of the XXY syndrome frequently remarked on by those familiar with case management.

Sexual activity was distributed among the 21 patients as follows :

None	2—including 12½-year-old
Masturbation	8
Heterosexual	6—all noninstitutionalized
Homosexual	
Female > male	3—including 1 institutionalized boy
Male > female	1—institutionalized opportunistic homosexual
Transvestite	1—claimed no orgasm, no masturbation

Only the transvestite had been married, and for no longer than a few months. He was a fairly typical example of the contrasexist eonist who requests a surgical and hormonal sex reassignment. He was atypical in claiming total impotence and an absence of genitopelvic arousal or interest of any kind.

Other instances of the paired occurrence of transvestism and the XXY syndrome have been reported. Overzier published a case

in 1958(13). The coincidence of the two conditions would appear to be sporadic, however. The same can be said of the coincidence of homosexual behavior and the XXY syndrome. The psychosexual pathology in such cases can best be regarded as yet another manifestation of a more general vulnerability of the XXY constitution to psychopathology of many different varieties.

Though there is no final and conclusive answer, to date, because of sampling bias, the XXY constitution does indeed seem to be fertile soil for a range of psychologic dysfunctions, including simple and episodic schizophrenia, psychopathic delinquency, extreme phobia, mental deficiency, congenital dyslexia, and congenital speech apraxia—to mention the most outstanding dysfunctions represented in my sample of 21 cases.

XXX and XXXY Syndromes. Examination of 5 mentally defective individuals, 3 XXX females and 2 XXXY males revealed no unexpected psychosexual findings, except low-powered eroticism.

The XO and Related Chromosomal Anomalies of Turner's Syndrome. Chromosomal and sex-chromatin data on the 40 patients used in this report are presented in Table 1.

TABLE 1

Nuclear Sex Data * on 40 Cases of Turner's Syndrome	
Chromatin negative	
No count done	24
XO	3
Inconclusive	1
Chromatin positive	
XO/XXX mosaic	1
XO/XX mosaic	2
XO/XX mosaic	2
XO/Xx (deletion) mosaic	1
XX (probable translocation)	1
XO/xX mosaic	2
Chromatin pattern undetermined	3

* The chromosome counts are those reported by Dr. Malcolm Ferguson-Smith, now at the University of Glasgow, whose cooperation is gratefully acknowledged.

Five different people, in the course of personnel changes over the years, were responsible for the tests and interviews. The 40 cases range in age from 11 to 31 years.

They belong to a total sample of 52 cases, of which 2 were too young and 10 were, for various fortuitous reasons, insufficiently studied for psychosexual tabulation. The 52 constitute 85% of the census of Turner's syndrome in the pediatric endocrine clinic for the 10 years 1951 through 1961. Vacations and conflicts of schedule were responsible for failure to see the other 15%. It is not known how representative the sample is of the total United States population of the syndrome. However, the sampling was not biased by referrals for psychologic and psychiatric reasons. The typical presenting complaints were dwarfism plus pubertal failure.

There was no evidence in the present sample of any direct association between the chromosome anomaly and psychopathology. Five of the girls had moderately severe neurotic problems stemming from their dwarfed stature and/or morbid family sociodynamics. Eight others showed some lesser sign of ego defense against dwarfism and hormonal infantilism. None of the 40 patients evinced deviations from the expected female gender role and identity. There was only one instance of reported homoeroticism. It occurred at age 11(6) and was totally without residue when the patient returned with her fiancé 11 years later preparatory to marriage and obviously in love.

Completeness of information on cognitive eroticism, genitopelvic eroticism and sexual experience varied greatly as a function of age, treatment status, availability for interviews, and other clinical exigencies. The general trend, however, was consistent. In childhood, and adolescence, the girls had the romantic, sentimentalized fantasies of courtship and marriage that are typical of girlhood. They did not include genitopelvic eroticism. The incidence of childhood masturbation was variable. Development of teenage dating was heavily influenced by problems of dwarfism (very few patients reached an adult height of 5 feet, and the severely affected were adult at 4½ feet), and by the timing of hormonal substitution treatment to induce puberty.

In adulthood, the women were, like most women, romantically aroused by visual or narrative stimuli, but required tactual stim-

ulation to become aroused to genitopelvic eroticism and copulatory activity. Those two patients who were married reached orgasm, even when they had discontinued estrogen treatment, one of them for 8 years. They had intercourse only once a week or less, and reached orgasm at least every third or fourth occasion. One other patient had orgasm, from infrequent masturbation. One other patient had tried intercourse a few times, perfunctorily, without orgasm.

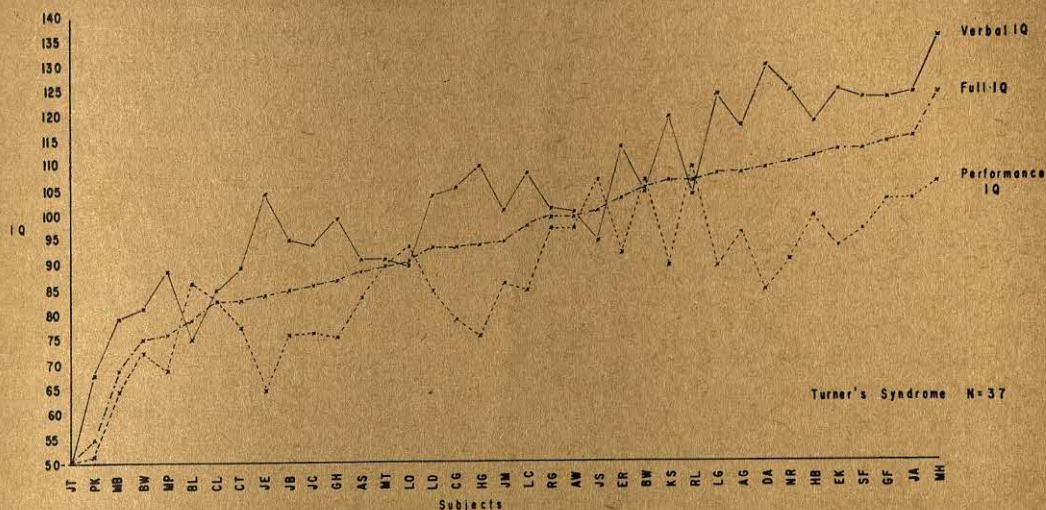

In addition to these 4 patients, there are records from 10 of the remaining 16 older patients with information about genitopelvic eroticism. None had had orgasm. Their reports varied tremendously in degree of arousal experienced, from apathetic unresponsiveness to full-functioning erotic excitement. All in all, it is impossible to associate high-powered erotic functioning with any of the chromosomal anomalies of Turner's syndrome. Some patients may rate as average, but the tendency seems rather to be toward low-powered erotic functioning. Chromosomes cannot be directly implicated, of course, because these patients have, first, the psychosocial handicap of dwarfed stature and, second, the hormonal handicap of congenital absence of the ovaries.

A Note on "Space-Form Blindness" in Turner's Syndrome. Figures 4 and 5 show the IQ distribution of 37 cases of Turner's syndrome. The range is from below 50 to 125, with a Mean of 95 and a S.D. of 17.

Notice, however (Figure 6), the unusual discrepancy between Verbal IQ ($M=103$; $S. D.=19$) and Performance IQ ($M=86$; $S. D.=15$). The difference is significant at beyond the level of 1% ($p<.01$). This difference, as was shown by Shaffer (17) in a study of a subgroup of 16 of the present cases, can be attributed to a specific space-form-perception deficit. The deficit applied equally to chromatin positive and negative cases in Shaffer's sample.

Shaffer's procedure, based on the factorial analysis of Cohen (3, 4), was extended to all patients of the present series, with the modification of including results from the three Wechsler scales, W-B 1, WISC, and WAIS. A score for Perceptual Organization was calculated for each patient, from the Wechsler subtests, Block Design and Ob-

FIGURE 4

Distribution of Verbal and Performance IQs of 37 cases of Turner's syndrome arranged according to ascending order of magnitude of IQ.

ject Assembly. Another score, for Verbal Comprehension, was calculated from the subtests, Information, Comprehension, Similarities and Vocabulary. The results are shown in Figure 7, and as follows:³

³ The calculations are based on 36 cases only, omitting the gross mental defective who made no score on any of the subtests.

Perceptual Organization :

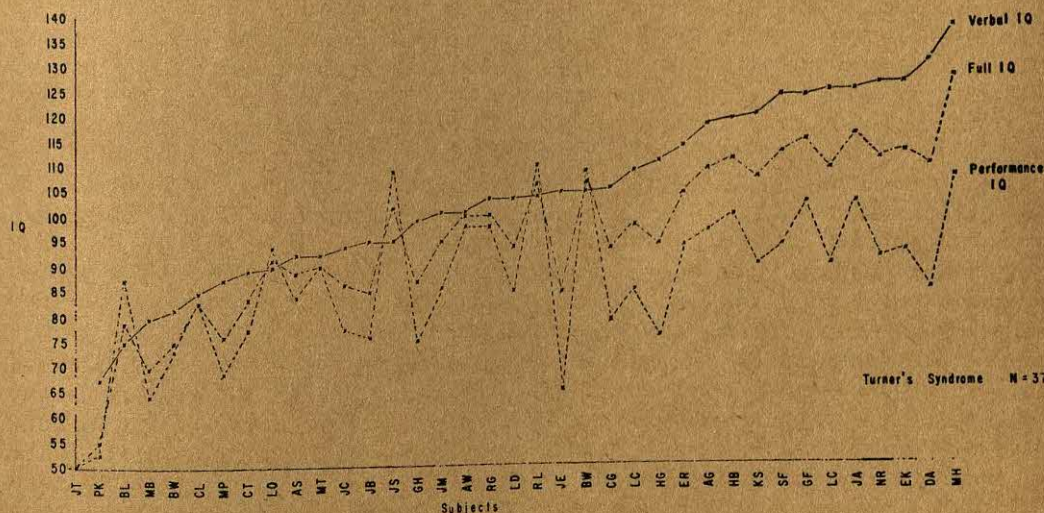

M=77.5 ; S.D.=32

Verbal Comprehension :

M=112 ; S.D.=28

The difference is significant at beyond the level of 1% ($p < .01$). One may speak, therefore, of a degree of "space-form blindness" associated with the X chromosome anomaly of Turner's syndrome. Apart from

FIGURE 5

Distribution of Performance and Full IQs of 37 cases of Turner's syndrome arranged according to ascending order of magnitude of Verbal IQ.

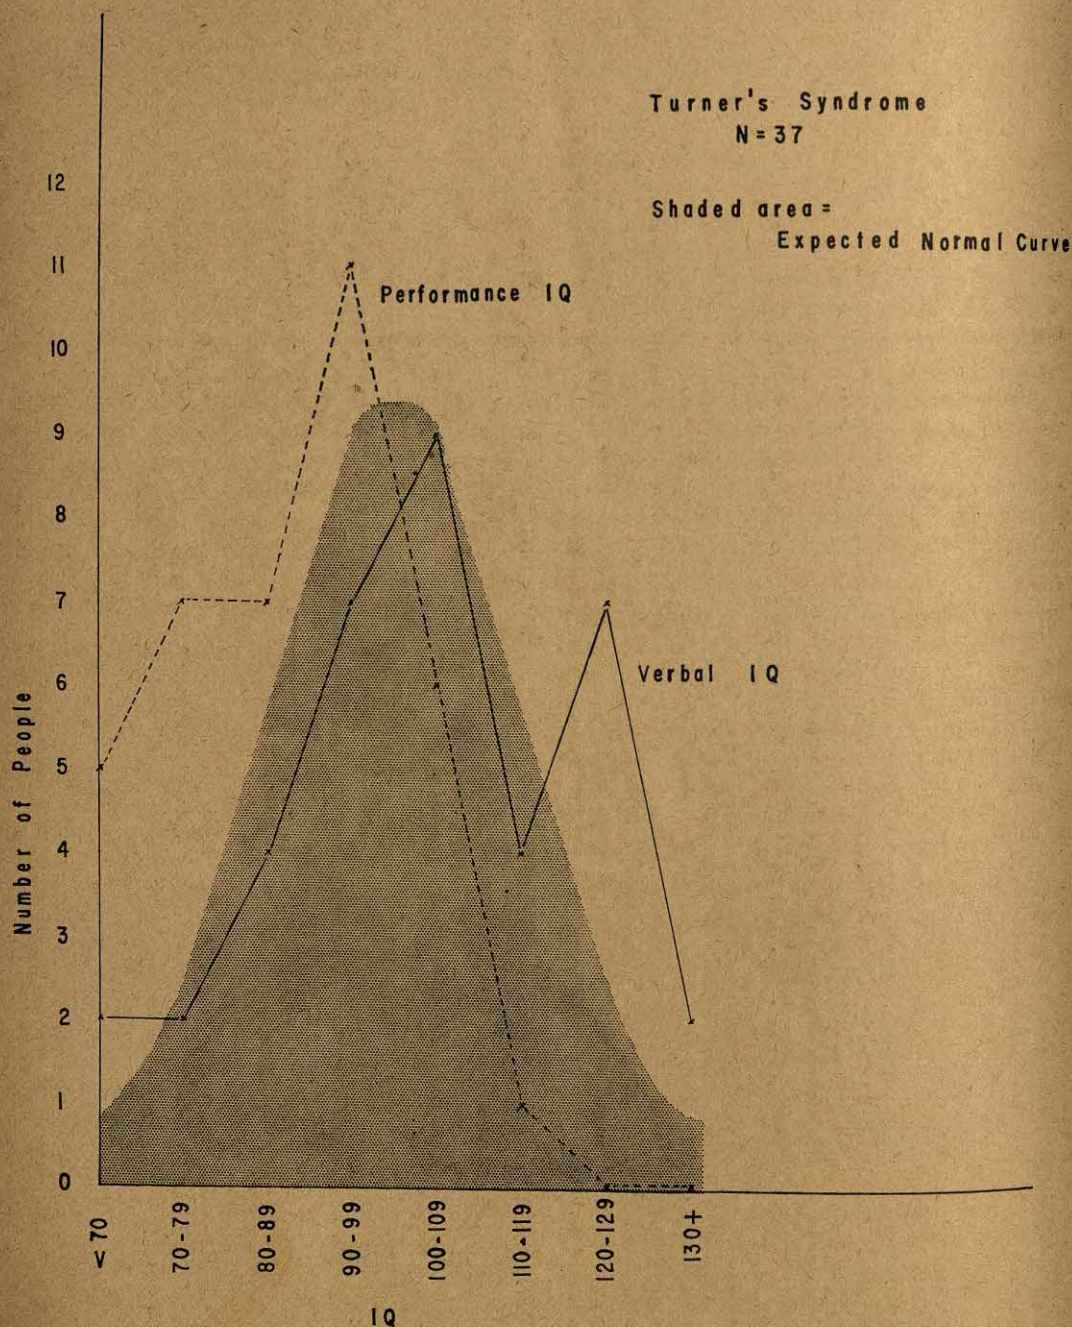

color blindness, which is carried on the X chromosome, I know of no other higher cognitional function which can be attributed to a particular chromosome. If this finding holds up, therefore, in the face of

further investigation, it has considerable potential significance.

GENES AND THE PSYCHE : PERSPECTIVES IN HUMAN DEVELOPMENT AND BEHAVIOR ¹

GEORGE C. HAM, M.D.²

At the beginning of this century, two scientific trends began which were destined to have outstanding effect on man's concept of his own development and adaptation. Each of these discoveries and the associated concepts were destined to have a unifying and clarifying effect on many other disciplines of science considered until that time as distinct, self-contained and relatively unrelated. One of these trends, psychoanalysis, is quite familiar to all of us. The other, genetics, and particularly human genetics, has been little understood, little appreciated, and, like an unwanted relative who must be avowed as a member of the family, has been largely ignored in psychiatry.

It is unnecessary to trace the history and the effects of Freud's discoveries upon our understanding of man and of men. The concepts of instinctual drives, the unconscious, the mechanisms of the ego, the superego and ego ideal, of transference and countertransference, of psychosexual development, and of others too numerous to list here, are now familiar to us all and incorporated as basic unifying principles of modern dynamic psychology. These principles and their development as they permeated through, and into the body of medicine, and particularly into the discipline of psychiatry, have given life and dynamic energy to the understanding of man and his mental aberrations. An active, hopeful attitude has replaced the relatively hopeless and static view of fixed, unmalleable and predetermined man. These principles, in somewhat altered form, and sometimes in altered words, have become incorporated in the thinking and attitude of scientists and scholars in disciplines not directly included in the field of medicine. These include academic psychology, soci-

ology, anthropology, political science, the humanities, religion and many others.

As a consequence of the rapid development of psychodynamics, there have been some extremely interesting, and, in my opinion, unfortunate consequences. Outstanding among these has been the almost exclusive focus on the psychological experiential component of human life with particular emphasis on the first 5 or 6 years of existence. Interestingly enough, these factors are referred to as "genetic" factors, which has created some semantic confusion. There is absolutely no doubt of the validity of the part played by the reaction of the growing individual to his internal and external experiences in the formation of his personality and his adaptive qualities. However, there is evidence that emphasis upon these experiential aspects, mostly in a psychological sense, has excluded other factors which are necessary to more complete understanding of adaptation, development and the human condition. A second consequence of the emphasis on human experiential events as the determinant of operational explanations is the little expressed but somewhat necessary assumption that the human being at birth largely represents a biologically standard product. It is then assumed that on this *tabula rasa* will be written with the pen of life's vicissitudes, the determining factors for future success or failure of this particular individual. Most outstanding has been the de-emphasis of the understanding of biological variation of the human organism as a necessary component of man's growth, development, adaptation and success. Included in this biological inattention has been and is the great binding mordant of all biology—genetics.

The meteoric growth of knowledge in the field of genetics in the past several decades, and in particular, the last 10 years, indicates the burgeoning dynamic and adaptive facts related to our present day genetic knowledge. Over the past several decades, several roads have been followed in the search for

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Professor and Chairman, Psychiatric Research, Training and Treatment Center, University of North Carolina School of Medicine.

genetic truth. Recent events have led these various pathways to a common goal, thriving with movement, activity and understandable interrelationships.

Derived from Mendelian theory and the genetic studies of plants and animals which have made possible our tremendous agricultural and animal husbandry developments, there arose the study of man. By the detection of various structural abnormalities in individuals—phenotypes—and using the principles of Mendelian inheritance as related to dominant and recessive characteristics, it has become possible to trace family pedigrees and demonstrate genetic linkage and genotypes. At the present time the number of known gene linked abnormalities in man is over several hundred. These studies have demonstrated that there are lethal genes in the population, which, if present in both of a pair of chromosomes—the homozygous condition—can lead to death of the individual. If present in only one chromosome—the heterozygous state—they may not be expressed in any demonstrable way. However, they may reveal themselves if particular stress is placed upon the system related to the products of the particular gene or genes, as in primaquine sensitivity or porphyria following administration of barbiturates.

As in plants and animals, it is now known that in-breeding in human beings tends to accumulate lethal genes in the homozygous condition increasing markedly the danger of nonviable or markedly defective progeny. In contrast to this is the knowledge of the effect of out-breeding, which through heterozygosity, reduces visible expression of the lethals in the population, and decreases the chance of appearance of abnormal genetic material in the progeny.

It is of some interest that two of the concepts developed by Freud, although explained on socio-psychodynamic principles, have as their end result the prevention of in-breeding and homozygosity and the increase in out-breeding and heterozygosity. I refer to the Oedipus complex and the taboo against incest described in *Totem and Taboo*.

The obvious difficulty of experimentation with human material in a controlled fashion such as can be done with lower organisms

led to the study of human twins. Knowledge that monozygotic twins each shared similar genetic material, in contrast to dizygotic twins, permitted the study of concordance rates of phenotypic characteristics. Outstanding contributions in this area have been made by Kallmann, Penrose, Slater, Gedda, Böök and others. Although arguments still continue in terms of the exact genetic mechanism involved, *i.e.*, single recessive gene versus many genes, the data available, depending somewhat upon the statistical method used, indicate that there are important genetic factors in such syndromes as schizophrenia, manic-depressive psychoses, homosexuality and intelligence. These studies further indicate that one of the outstanding difficulties in such research is the lack of quantitation at a descriptive and clinical level of these entities, making correlation statistically difficult, and, even more importantly, conceptually confusing. The development of methods of categorization of these illnesses in multiple factors remains an essential component for evaluation of genetic correlation of the future.

Paralleling the development of population genetics has been the field of cytogenetics. Optical and electron microscopy, and x-ray diffraction have produced dramatic morphological information and have made possible discoveries and knowledge at the molecular level. The clear demonstration of the chromosomes and their behavior during the formation of the gametes in meiosis led to the understanding of the way in which genetic material is transmitted from the male and female into the zygote. The principles of segregation, of crossing over between chromosomes, of non-disjunction, and many other phenomena were clarified. The process of mitosis and cell division and embryological differentiation is yielding exciting growth in our knowledge of factors influencing fetal development, and, therefore, of the potential of the postnatal organism. Methods of tissue culture of various body cells, their treatment with colchicine and hypotonic swelling, allowed the study of the number of chromosomes in the human karyotype and have identified the number of autosomal chromosomes and the two sex chromosomes. Interestingly enough, it was only in 1957

that the final number of chromosomes in man was determined. This consists of 22 pairs of autosomal chromosomes, one set from the mother, one set from the father, and two sex chromosomes, either XX or XY, determining femaleness or maleness, respectively. Further study indicated the presence of chromatin material that could be detected by simple microscopic examination of smeared cells from the buccal mucosa and other cells that would indicate the presence of genetic femaleness.

Coincident with these technical and conceptual developments came the demonstration of gene loci carried on the chromosomes. Detailed study of genes in *drosophila*, in phage, in *neurospora*, and in various bacteria such as *e. coli* have allowed exact determination of structure and function of this gene material. Exciting experiments in the manipulation of the genes in their rearrangement on the chromosome and the study of the effects have led to knowledge in terms of transformation of genic material, and on the subsequent products of this altered state in the growth and development and metabolic potential of the progeny.

Paralleling these studies has been the amazing growth of biochemical and molecular genetics. In the early part of the century a man of great insight named Garrod developed a concept and coined the term, "inborn errors of metabolism." He suggested that four metabolic disorders—albinism, alkaptonuria, cystinuria and pentosuria—had certain features in common. First, in all four conditions the onset of the particular abnormality could be dated to the first days or weeks of life, especially when a special effort was made to do so. The second characteristic was their familial occurrence in a considerable number of cases. The third feature was that the conditions were relatively benign and compatible with a normal life expectancy. A fourth feature, noted by other clinicians in his day, was the frequency with which these disorders occurred among the offspring of consanguineous marriages. What was a supposition in Garrod's time regarding the original four inborn errors of metabolism has now become fact. Well over 50 gene determined metabolic abnormalities in man are known.

We know a great deal about how these conditions are transmitted from one generation to another, and also about the varied biochemical processes responsible for these changes. These inborn errors of metabolism have been shown with reasonable certainty to result from mutation of genes. The effects may be present in either an absolute or relative sense. In other words, there may be an absolute absence of a necessary metabolic step, leading to the accumulation of products that otherwise would have been metabolized. This accumulating abnormal metabolic product may be revealed in secondary clinical effects, such as in phenylketonuria. In this condition there is an enzyme missing known as phenylalanine hydroxylase. The clinical symptom is that of mental deficiency. The compound that accumulates is phenylalanine and its derivatives, and the treatment is the removal of phenylalanine from the diet. Or, in the case of diabetes, insulin is the missing protein. The associated clinical symptoms are well known and the treatment is to replace the missing, or defective protein. Here the clinical syndrome occurs in varying degrees and appears at different times in the life cycle in various individuals. Porphyrria may be present in absolute sense or may be shown to be present in a latent sense as evidenced by abnormalities in the quantity of the precursors of this substance in the blood and urine of pedigree relations. This condition in latent or overt form is frequently associated with psychiatric disorders. Other latent or marginal metabolic abnormalities may be detected by loading the organism with substances which reveal gene determined inadequacies in various metabolic pathways.

Most recently has come the exciting discovery of the basic role of the desoxyribonucleic acid (DNA) contained in the genes. Time does not permit more than a cursory discussion of this fundamental discovery. The theory states that the hereditary "blueprints" of cell structure and function are coded within the cell nucleus as long chain molecules of DNA. These plans are transmitted in a series of steps to the cytoplasmic "assembly line," where they direct the synthesis of each cell's characteristic products. All DNA so far examined from bacteria to man have the same general plan;

namely, chains of only 4 nitrogen containing units. These are adenine, guanine, cytosine, and thymine. The specific order of these bases, like the order of letters and words, is meaningful. This hereditary "message" is written in a 4-letter alphabet. DNA can code itself during its replication, thus explaining both the passage of hereditary characteristics from one generation to the next, and the development of multicellular organisms. The DNA in the fertilized human ovum replicates itself thousands of billions of times to form myriad cells of the mature individual. Each cell contains a copy of the special message that makes for human beings, as well as for the uniqueness of the individual. The information contained in the DNA molecules is transferred to ribonucleic acid (RNA) and thence to microsomes in the cytoplasm of the cell. RNA also consists of 4 bases, 3 of them the same as DNA, but instead of thymine, RNA has uracil. Thus, the order of the bases in the DNA determines the order of the bases in the RNA, and this in turn determines the selection and order of amino acid chains in the synthesis of enzymes and other proteins. The properties of proteins are determined by the sequence of their hundreds of thousands of component units, each derived from one of the 20 amino acids. This theory and the technical discoveries associated with it, and its emerging experimental proof, are giving us the answer to the intricate process by which structure and function of living organisms are shaped. We may expect in time to decipher the entire set of instructions by which genetic messengers direct the manufacture of proteins and enzymes, the basic stuff of life.

Although presented in only broad outline form, the evidence before us, and accumulating daily, brings us full circle from the erroneous concept of genetic inheritance as static, fixed and unalterable, to a recognition of a dynamic and adaptive science similar to that outlined earlier in terms of psychodynamics and experiential factors. Let us approach this from a somewhat different viewpoint. We know that the total functioning of the human organism is dependent upon the many billions of highly different cells organized into organs and

systems. These are made of protein and other compounds. These organs and systems and the cells they contain depend upon enzymes numbered in the hundreds for maintenance, for cell reproduction and for integration of the entire organism. We have seen that these enzymes and proteins are manufactured in the cytoplasm of the dividing cell under the influence of RNA. This RNA pattern, determining the order of polypeptides into chains of proteins, is dependent upon the availability of the necessary substances in the substrate, the cytoplasm, such as amino acids. The RNA code in turn is determined by the DNA from the nucleus of the cell and specifically, from the particular gene controlling that particular synthetic process. Alterations in the final product, the enzyme or the protein, can result from vicissitudes related to the disturbances in substrate available for coding by RNA with consequent minimal defects and deficiencies or gross abnormalities. Likewise, through the inheritance of mutant genes, or lethal genes, the DNA signal produces defective RNA and consequent defective gene products. Some of the factors that may be involved in these processes have been alluded to earlier. The end result, however, is that either at the chromosomal level, carrying one or many defective genes, or at the developmental level in cell division following fertilization, or during embryologic development, or postnatal replacement of enzymes, proteins and cells, there may be disturbances in substrate environment for synthesis. The end result may be widely varying, qualitative, and possibly quantitative protein and enzyme structure. Enzymes may be produced which, with minimal stress on the system, are sufficient to carry out their necessary function, as in sub-clinical diabetes. Under specific stress, however, the system may fail and the organism will reveal a secondary metabolic abnormality and its consequences to the total organism. Thus we are *not* a standard, fixed product in terms of enzyme systems and metabolic responses. This fact has been demonstrated by the biochemist Williams and his co-workers in Texas. They have been able to demonstrate that when many systems are measured, there is biochemical individuality rather than sameness. Thus we

may actually vary in many ways and yet be considered phenotypically normal.

Since all processes in human life, including psychological and behavioral activity, are mediated by structures made of protein and related compounds, and directed and controlled by other proteins as enzymes, these factors take on significance in understanding any aspect of man. Continuing this line of thought, one can then postulate that those aspects of man viewed through the psychological objective of our investigating microscope or those behavioral characteristics revealed by a sociological or anthropological examination are mediated through, and in part determined by, these basic protein and enzyme systems. We know that replication of specific protein molecules occurs in the day to day death and replacement of cells and is controlled by DNA, RNA and polypeptides systems. This process is a dynamic reaction between genetic message, substrate and local controlling factors. Can this knowledge add to our understanding of their composite resultant; namely, psychological mechanisms, personality aggregates and social behavior?

Perhaps a piece of evidence indicating genetic control of instinctual behavior in African parrots (1, 2) related to cross-breeding of two variants within the same species will indicate to us the potentialities of such basic mechanisms and the promise for extended understanding of instinctual behavior of man. One variant of parrot, in the adult stage at nesting time, instinctively tucks nest material in the feathers of the lower back or rump in carrying it to the nest. Another variant instinctively carries such material, one piece at a time, in the bill. Inter-breeding between these two variants produces in most of the hybrid females a bird who shows what may be termed "instinct confusion." The F_1 hybrid females almost always attempt to tuck nesting material in the feathers but are never successful in carrying it this way for several reasons (2):

- (1) Proper movements for tucking are made, but the bird seems unable to let go of the strip even after repeated attempts at tucking;
- (2) The strip is tucked but soon falls out—usually while the bird is busy cutting the next one;
- (3) Tucking is attempted at locations

other than the lower back and rump—a more "primitive" or ancestral pattern; (4) The strip is grasped somewhere other than at one end, making proper tucking impossible; (5) Tucking movements are begun; but the behavior gradually merges into preening movements, and the strip falls unnoticed to the ground; (6) Tucking-intention movements are made but not completed; (7) Inappropriate objects such as twigs are tucked; and (8) Sometimes the bird attempts to get its bill near its rump by running backward. These hybrids are only successful in carrying material in the mouth. After two years of this behavior, in the presence of both normal *fischeri* and *roseicollis* females, these hybrids have not learned to carry nesting material more efficiently and still spend as much time in attempting to tuck before flying off with a single piece. This is interesting as these birds are amazingly quick to learn new behaviors in other contexts such as opening cage doors, evading capture, and so on. They are also favorite birds for use in trained-bird acts where they are easily taught all manner of tricks such as riding miniature railroad trains, washing clothes, posting letters, and pushing little wagons. The hybrids give every indication of being as quick to learn such behaviors. This merely emphasizes the fact that abilities to learn various behaviors do not extend equally throughout the entire spectrum of an animal's activities.

A second example is in the field of imprinting, a subject which has been of some interest in recent years. Recent evidence (3, 4) indicates that ease or difficulty in imprinting of ducklings, for example, is, in part, genetic and the progeny of the imprinters is more easily imprinted than that of the non-imprinters. Recent studies have suggested a relationship between the quantity of RNA in the cells and the ability to imprint.

A recent and highly intriguing hypothesis and experiment by Dingman and Sporn (5) on the possible biochemical basis of memory in relation to RNA is of great importance. They postulate that memory traces in the nervous system are produced by the formation of altered RNA molecules. Their experiment consisted of introducing into the cistern of rats a substance which is known to interfere with the normal RNA molecule, and consequently produce altered protein products. They were able to demonstrate that such interference with the brain RNA

in the living rat did not depress the rat's ability to perform and recall a previously well learned maze but did decrease the rat's ability to learn a new maze. Although rudimentary, this experiment and these data can have far reaching results.

The studies of Corning and John(6) on Planarians are of great significance. Planaria have the ability to regenerate a complete organism after transection. The head bearing portion regenerates a new tail section, and the tail section regenerates a new head section. This organism is capable of learning both a classical conditioned response and a T maze. It was discovered that when cut in half and allowed to regenerate both the new head and tail sections retained the previously conditioned response. "Conditioned Planarians were transected and allowed to regenerate in a ribonuclease solution or in pond water. Heads which had regenerated in ribonuclease displayed a retention level equal to that of head and tail sections which had regenerated in pond water. However, tails regenerated in ribonuclease performed randomly although they could be retrained to criterion." These studies strongly suggest that RNA may be the substance involved in information transfer of conditioned behavior in the regenerated transected animal.

On the basis of the material presented I would like to offer several suggestions and speculations to indicate the importance of the addition of the dimension of modern dynamic genetics to the further understanding of psychiatric illness and treatment:

First, we have become too quickly disillusioned because we have not found clear-cut evidence of simple single gene inheritance as a determinant of psychiatric syndromes. Secondly, we will benefit greatly by thinking in terms of the known genetic principles in the study of our patients and their families. This includes pedigree study of any behavioral, psychological or overt or latent metabolic abnormality that can be detected and quantified. Third, the reaction types of psychiatric illness from schizophrenia through the various neuroses and behavior disorders will be further understood if we recognize that polygenic or multiple gene effects are involved. The result is that the basic protein and enzyme

structures through which psychological work and behavior are mediated can vary, qualitatively and quantitatively. I suggest that it is the interactions between many systems at the polypeptide and RNA level as well as the DNA level that will give us our clues. I further suggest that changes in psychological or social behavior of individuals secondary to life experiences or to psychotherapy may, in time, be understood more fully by determining alterations in the local environment of RNA and polypeptide synthesis resulting from "psychomolecular" influences. To be more specific, can it be that the successful results of psychotherapy which results in an altered psychological and physiological response to a standard stimulus are the result of a gradual and continuous corrective *message* on existing proteins and enzymes, or even the formation of *new* protein and enzyme in critical cells or systems? Many of us have been impressed by the apparent desensitizing aspect of successful psychotherapy in altering a standard biochemical, physiological, psychological and behavioral response of an individual. Can it be that we have approached more closely the bridge between the symbolic and the molecular?

I have attempted to draw parallels between one dynamic science and its disillusionment in biology—psychodynamics—with another basic biological science—genetics—which from a static position of some disillusionment, in the eyes of many, has grown into a virile dynamic and adaptive science that offers an extension of our understanding of human psychological mechanisms and their behavior.

In conclusion an analogy, suggested, in part, by a geneticist and colleague, Dr. Edward Glassman, may help clarify the principles suggested previously. Let us suppose that the development of a paranoid schizophrenic reaction requires the accumulation by the individual involved of 100 points to become apparent. These points are acquired from interaction between nature and nurture. Let us suppose, in a given individual, that 25 points are determined by several fixed, unalterable genes and their structural and biochemical products. Let us call these basic *qualitative* gene points. Then let us say that 50 points are dependent on the rela-

tionship between *quantitative* variations of a number of other gene products at the RNA and polypeptide synthesis level. The variation in these gene products is a function of reaction of these systems to the daily internal and external environment of the individual. This includes the primary physical and chemical stresses and adaptive demands of human living. The remaining 25 points required to reach 100 can be related to alteration in RNA and protein products, as discussed earlier, in certain *critical cells or metabolic systems* in reaction to specific psychocellular responses. Thus, "person-specific" critical life situations and their symbolic meaning and reverberations would determine, via neural and histochemical processes, these last essential alterations. When these are added to the basic qualitative 25 points and the 50 adaptive quantitative points, the schizophrenic reaction is precipitated. Conversely, reduction in any of the point accumulations would result in amelioration of the reaction.

Different point systems may be critical for different individuals. If the 25 basic fixed qualitative points are not present, that individual might never be affected, even if the other two categories were present in higher numbers. Another individual may start with 75 points of unalterable base predisposition genetically and require only minor alteration in the adaptive or the psy-

chocellular fraction to develop the schizophrenic response. This analogy can be applied to all illnesses. The question of the quantity of smoking and lung cancer can be expressed the same way, *e.g.*, some people start with 75 genetic cancer points and need 25 adaptive environmental points from mild smoking to reach 100. Others may start with five or ten fixed genetic points and could never smoke enough to produce the change involved. This analogy and the concept of psychocellular response of RNA and its products by no means answers our questions. However, it serves as a model for our thinking and the investigation of genetic dynamics and psychodynamics as interacting and mutually dependent factors. This modern genetic dimension will, I believe, become an outstanding factor in our search for truth in the field of human behavior and psychiatric illness.

SCHIZOPHRENIC-LIKE MECHANISMS IN MONKEYS¹

PETER G. S. BECKETT, M.D., C. E. FROHMAN, Ph.D., J. S. GOTTLIEB, M.D.,

J. B. MOWBRAY, Ph.D., AND R. C. WOLF, Ph.D.^{2, 3}

Biochemical Background. The study of biologic mechanisms in schizophrenic patients is being actively pursued in many centers at the present time. One particular area of investigation, the control of certain phases of carbohydrate metabolism, has been discussed previously by several of the present authors (1, 2, 6, 9). These studies have suggested that a factor in the blood plasma of schizophrenic patients interferes with the metabolism of normal cells (6, 7). The following is a brief outline of the method being used in current attempts to study this factor. Blood plasma is obtained from the subjects. One cc. of this plasma is incubated for one hour with 4 cc. of washed erythrocytes obtained from chickens. These erythrocytes represent a homogeneous sample of normal cells. Following the incubation, measurements are made of lactate and pyruvate produced by the chicken cells. The results are expressed as a lactate-pyruvate ratio (L/P ratio). It has been found that the ratio is low when cells are incubated in plasma from control subjects and high when plasma from schizophrenic subjects is used. The precise enzymes involved are not known at present, but the search for their identification continues intensively. It is possible that interference with hydrogen-transport systems may be involved (7).

Another very important unanswered question concerns the identity of the factor in the plasma of schizophrenic patients which is responsible for the elevated L/P ratio. Information to date indicates that

this factor is closely related to the alpha-globulins; again active investigative work continues.

Clinical Aspects of the Studies. To gain maximum information from these various biochemical studies, attempts have been made to relate the findings to the clinical picture. Ratings of clinical information, including important aspects of the history, were made on a large number of rating scales. The scales have been described previously (3). It has been reported elsewhere that the primary symptoms, and some aspects of the course and of the history, have been found to be significantly related to certain biochemical measures (1, 2).

One of the most interesting of these findings has concerned the historical information. When relationships between biochemical abnormality and historical information concerning the patient's early life were examined, it became apparent that the data showed a trend: biochemical abnormality in the adult schizophrenic subject appeared to be associated with clinical ratings which indicated a quiet, monotonous, unvarying, nonstimulating very early life (1). Specifically, high scores on the scales listed in Table 1 were associated with biochemical

TABLE 1

Clinical Measures of the Rearing Environment

1. Degree of social and economic security in the rearing environment
2. Feelings of dependency on the mother
3. Degree of continuity and responsibility, and physical stability in the early relationship between the mother and the patient
4. Degree of favoritism by the mother
5. Absence of beatings by the mother
6. Degree of overprotection and overindulgence by the mother

abnormality. These relationships were not strong; nevertheless, they seemed worthy of serious consideration. In a previous report the suggestion was made that such a monotonous early life might fail to produce the stimulation necessary for the proper

³ The authors would like to express their deepest gratitude to Dr. Harry F. Harlow of the Primate Laboratory without whose pioneering work the study would not have been possible.

maturation of certain enzyme systems(1). It is most likely that infancy and early childhood is the period involved.

The historical information used in this study was of course retrospective. As such it is notoriously open to bias, both from the viewpoint of the subject's recollection and of the clinician's theoretical framework. Also, the observed relationships were only suggestive; they did not indicate a strong relation. A prospective clinical study might, in theory, resolve some of these difficulties, but such a study would be almost impossible to do. Were there any other possibilities—could the questions raised by the above study be answered in any other way? Several recent experimental studies of animals suggested that perhaps this could be done.

Relevant Animal Studies. There is evidence that the plasma factor found in schizophrenia is in some way involved with the globulin fraction of the plasma proteins(8). It is also known from the experiments with germ-free animals that environmental influences, for instance the presence of exogenous bacterial antigens, play an important role in the development of normal amounts of these proteins(20, 21). While these experiments are far removed from schizophrenia (and it is not being suggested that bacterial antigens are involved), they do suggest that an environmental influence might possibly affect a plasma globulin factor.

The well-known experiments of Levine, *et al.*, on rats are also relevant(16-19). This work has provided evidence that lack of stimulation in infancy, principally tactile stimulation, leads to a slower maturation of several biologic systems and to lessened resistance to physical deprivation. There is also a great deal of evidence that various manipulations in early life lead to long-lasting behavioral changes(5, 16).

The Primate Laboratory of the University of Wisconsin has been rearing rhesus monkeys under carefully controlled and, in certain instances, very isolated circumstances for a number of years. The conditions of these experiments and the details of the rearing have been reported previously (4, 11, 13). It has also been reported that some of the animals reared under conditions of social isolation, *i.e.*, alone in a cage, with

or without an inanimate mother surrogate, show bizarre behavior and social withdrawal as adults(12). This combination of circumstances, 1) the availability of a group of rhesus monkeys reared under conditions of quite extreme social isolation and tactile monotony, and 2) the fact that some of these animals showed bizarre behavior when adults, suggested a nonclinical and objective way of answering the questions raised by the clinical-historical data. Are any aspects of a controlled early environment that is known to be nonstimulating and monotonous related to the factor found in the blood of schizophrenic patients? An objective biochemical method of testing for the factor was available, and a group of monkeys reared under known and controlled conditions of social isolation and tactile monotony was available also. Hence it was possible to predict that monkeys reared in this isolated way might show the factor, and a group of control normally reared monkeys might not show the factor. An experiment was therefore set up to test this hypothesis.

Method. The study used the biochemical facilities of the Primate Laboratory in Madison, Wis. The subjects were 31 male rhesus monkeys. All animals were housed in the laboratory in cages 30 in. by 30 in. by 27 in. The diet of all was identical, consisting of Purina monkey chow daily, and apples or lettuce three times a week. In addition each animal received a daily "vitamin sandwich" which contained 18,000 units of vitamin A, 4 mg. of thiamine, 2 mg. of riboflavin, 40 mg. of nicotinamide, 50 mg. of ascorbic acid, 3,600 units of vitamin D, 20 mg. of folic acid, 4 grains of ferric ammonium citrate, 35 mg. of isoniazid, and powdered milk, on half a slice of bread. The animals had been receiving no other medication for at least two months before the study. Isoniazid might possibly affect the biochemical system in question; this drug was received by all animals, however, so that group differences can presumably not be explained on this basis.

Blood samples from the animals were in all cases presented to the biochemistry laboratory identified only by a code number. On each of two visits to the Primate Laboratory the code was not broken until

after all animals had been studied.

The 31 animals were divided into four groups as follows :

The 11 monkeys in the *control group* had been reared under natural conditions in the wild and captured between ages 2-4 years. These animals were approximately between 3 and 10 years old at time of test and weighed between 3.98 and 13.05 kg. The rhesus monkey reared in the wild is an alert, aggressive and vicious animal. The male is antagonistic toward people and other males and is ready to attack anything or anybody not to his liking. When threatened he lays back his ears, bares his teeth and attacks. Because of these aggressive qualities blood was drawn from 10 of the 11 control animals in a squeeze cage. All wild raised monkeys, male and female, show normal sex behavior; that is characterized in the male by dorsoventral mounting, clasping the legs of the female by the feet, and holding the buttocks by the hands while achieving intromission.

The *surrogate group* consisted of 10 animals born in the Primate Laboratory. The conditions of their birth and neonatal care have been described elsewhere(4). The infants were separated from the mother at birth and placed in cages 18 in. by 18 in. by 24 in. All were in the same room where they could see and hear—but not touch—each other and experimenters walking through the room. An external source of heat has been found to be necessary for neonatal monkeys. A heating pad covered with a diaper was therefore provided for the first 15 days.

In the cage with the infant animals were placed inanimate mother surrogates. These were of various types as described elsewhere(10, 11). However, all the animals used in the present study had access in their home cage to a cloth mother surrogate for a significant part of their rearing. Two animals (#64 and #67, see Table 2) had no access to a mother surrogate until 250 days of age. Two other animals (#69 and #71, Table 2) had no access to a mother surrogate after 160 days. The remaining animals had a mother surrogate continuously available in the home cage.

All the infants had extensive training experiences beginning in their first week.

These experiments included maze performance and object discrimination tests both in the Wisconsin General Test Apparatus and in other situations. None of these animals had any shock conditioning experiences; all the learning was for reward(13).

At the time of study these animals ranged in age from 3 years 4 months to 4 years 1 month. They weighed between 2.80 and 7.37 kg. Their behavior showed a number of abnormalities including repetitive stereotyped circling movements about the cage, clasping the head with the hands, rocking in autistic-like movements, and chewing on their own arm or leg as a response to fear or external threat. These animals engage in excessive masturbation and some vomit food intentionally. No appropriate heterosexual behavior is observed when these males are placed with females. Mounting is random with respect to the body of the females and complete copulation never occurs.

The blood samples were drawn not in a squeeze cage but by having animal handlers hold the animal. While no precise measurements were made, it was our impression that these two techniques led to an approximately equal amount of muscular activity on the part of the animal.

The remaining 10 animals were all born in the laboratory under the same conditions as the previous group and then raised in similar single cages except that no surrogate mother was provided. As in the surrogate group the infants could see and hear activity around them but could not participate. After 15 days their only tactile contact in the home cage was the wire mesh of the cage itself. All had extensive learning tests, as in the surrogate group, beginning in the first weeks of life.

In behavior at present these animals present a picture of emotional disturbance that is similar to the surrogate group but is rather more extreme. They sit and stare fixedly into space, bury their heads in their arms while engaging in rocking, or tear at themselves and beat their heads against the cage in self-destructive reactions. These responses to the laboratory staff or even other monkeys may be so severe as to produce bleeding lacerations. Although masturbation occurs frequently, often by

males and females in the same cage, no normal heterosexual activity is seen. The males will not appropriately mount experienced cooperative breeding colony females and never achieve intromission.

An important experiential variable divided these 10 animals into two groups. During the first two or three months of life 4 of them had been exposed to a shock conditioning experience. This consisted of a shock paired with a tone which was administered through the floor of the cage. Ten trials a day on 5 days a week were given for a month. The details have been reported elsewhere (13). The 4 animals who had this experience are being called for the purpose of this paper the *shock group*. At the time of study their ages ranged from 3 years 5 months to 6 years 2 months, and their weights ranged from 5.99 to 7.60 kg.

The remaining 6 animals were also raised in a cage devoid of either a natural or surrogate mother but did *not* have this shock conditioning experience. Their ages ranged from 4 years 7 months to 5 years 6 months, and weights from 5.92 to 7.04 kg. For purposes of this paper they are called the *non-shock group*.

Analysis of Data. At present 31 animals have been tested. The goal has been to test each animal twice but owing to laboratory and other difficulties this repeat study has

only been possible for 24 animals. It is hoped to correct this deficiency, and to add more animals to the shock and nonshock groups in the very near future.⁴

In Table 2 the L/P ratios are given on each animal for both the first and the second tests together with the mean L/P ratio. For

⁴ With this in mind a third visit of the Lafayette Clinic group to the Primate Laboratory was made on Feb. 27-Mar. 1, 1962. This visit coincided with a spell of exceptionally cold weather with maximum daytime temperatures around 0° and minimum night-time temperatures of 20° below zero. The chickens which were available and which provided the erythrocytes had been housed in poorly heated or unheated quarters. They were found to have about three times as many erythrocytes as usual (their hematocrit being 45% instead of the usual 15%). The L/P ratios produced by these cells were widely beyond the expected range. This led us to doubt the reliability of the results.

To check on this in early March some chickens which had been housed outside in zero weather were obtained from upper Michigan. They were studied in the Lafayette Clinic laboratories and were also found to have very high hematocrit readings. Tests using these chicken erythrocytes with the plasma from well studied control and schizophrenic subjects indicate that a different substance appeared to be driving the significant reactions. It is concluded that the Feb. 27-Mar. 1 data on the monkeys are unreliable, and that a further effort must be made to complete the study using chickens raised under more controlled conditions.

— Indicates missing data because of biochemical laboratory difficulties.

each group of animals a mean L/P ratio is also given; this mean is used in the tests of significance between groups.

Results. Table 2 illustrates that the mean L/P ratio for the control group is 5.94, for the surrogate group 6.54, for the shock group 2.52 and for the nonshock group 17.82. In attempting to assess the significance of these findings it must first be noted that in addition to the fact that the groups are small, in both the control and surrogate groups the distribution of mean scores is not normal. Hence if tests of significance are to be made nonparametric methods must be used. Using the median test with the chi-square corrected for small cell frequencies, the control group was significantly different from the nonshock group at the 1% level of confidence. The surrogate group was also significantly different from the nonshock group at the 1% level. The mean scores in the shock and nonshock groups are approximately normally distributed. A t-test showed these scores to be significantly different from each other ($p < .01$) after correction for heterogeneity of variance.

On the other hand the mean L/P ratio of the shock group is not significantly different from either the control or the surrogate group.

The tests therefore indicate that the L/P ratios of the nonshock animals were significantly higher than the ratios of any other group and that the control, surrogate and shock groups were not significantly different from each other. Since only 6 animals have been studied so far in the nonshock group, however, the results must be interpreted with considerable caution.

DISCUSSION

The hypothesis that rhesus monkeys reared in conditions of social isolation and tactile monotony would show evidence of a metabolic disturbance which is consistent with the presence of a blood factor as found in schizophrenic patients was supported, although only a small group of animals reared under the most extreme conditions was available, and only these animals, as a group, showed the abnormality. It is likely that the present biochemical technique only identifies extreme conditions. More animals need to be studied; however, several points

can be made concerning the data thus far obtained.

There was no biochemical difference found between the control and surrogate animals. Thus jungle rearing versus laboratory rearing cannot by itself account for the findings. The control animals were on the average older and heavier than the surrogate group; their blood had to be drawn using a different technique—the squeeze cage. The results suggest that these factors were not of prime importance.

The shock and nonshock animals were of similar age and weight and were reared under very similar circumstances. Yet biochemical study showed differences, even though only small numbers are available so far. To attribute these differences to intense tactile stimulation in the form of a series of shocks to the feet and hands during infancy is consistent with the theory proposed at the beginning of this paper. The nonshock group which experienced maximum social isolation and minimum tactile stimulation would be expected to be most abnormal biochemically, and this is what was observed.

Is this result reasonable? Could intense tactile stimulation during infancy lead to the development of certain normal biochemical mechanisms? And on the other hand could lack of such stimulation be responsible for a biochemical deficit? Such results are indeed surprising but are not altogether without precedent. Levine's rats showed neurobiochemical changes persisting into adult life (19). Other experiments in the field of biochemistry have shown that, for instance, failure to expose young animals to any one of several substrates during a critical early life period may prevent the induction of the enzyme systems necessary to metabolize these substrates (14).

This abnormality in the nonshock animals may be related to social isolation and tactile monotony in infancy. After diligent search no other factor in the rearing or present handling of the animals has been uncovered which might account for the observed biochemical differences. This is particularly true of the differences between the nonshock group on the one hand, and the shock and surrogate groups on the other. However, it cannot be denied that some

unidentified difference in past experience, present physical handling, diet, *etc.*, could possibly exist. With this in mind the experiment has been repeated with another species of primates reared in a different laboratory; these data, which are supportive, will be reported elsewhere.

In addition, an important point must be answered. Behavioral peculiarities were observed in the animals in three groups, surrogate, shock and nonshock. This behavior is somewhat less disturbed in the surrogate group, and somewhat more disturbed in the other two groups, but at present no objective measures of these differences are immediately available. Yet biochemical abnormality was found only in the nonshock animals and not in either the surrogate or shock groups. If this biochemical abnormality is really related to the abnormality found in schizophrenia, why are not the behavioral disturbances and the biochemical disturbances more closely correlated?

This is a good question. It may be answered in several ways. First of all the disturbance of behavior is quite complex. Is it reasonable to expect a one-to-one relationship between a biochemical abnormality and such a complex behavioral disturbance in a primate? Most psychiatrists would probably agree that this is not likely, for such a theory would ignore the everyday clinical observation that much behavior is learned from experience. It is quite likely in fact that a great deal of the disturbed behavior of the monkeys is due to the absence in their experience of a suitable monkey model—a mother. Similarly, much of the disturbed behavior of schizophrenic patients is probably not biologically determined, but is environmentally acquired from constant exposure to family pathology.

Secondly, there are several biochemical reasons which make it unlikely that biology and behavior should be closely related, at least using present methods. In a previous study we found that one biochemical disturbance was present in a large majority of schizophrenic patients, while another disturbance was found only in those with more severe and chronic illness(2). The second of these two abnormalities is probably more closely comparable to the L/P ratio, and this may be another reason why an abnor-

mal L/P ratio was found only in the most severely isolated animals.

A further and related significant point is the following. Present evidence indicates that the L/P ratio is a relatively crude indicator which reflects only a maximum enzyme disturbance, the end result. A less severe disturbance in the enzyme system specifically concerned, and it must be remembered that the exact identity of this system has not as yet been determined, may not be reflected in an abnormal L/P ratio but in some other more subtle biochemical manner. It is to be hoped that in the future when more delicate biochemical techniques are available it may be possible to delineate this abnormality more precisely and perhaps demonstrate it in animals such as the surrogate group.

Thus the lack of close correlation between biochemical abnormality and behavioral disturbance allows several different but not necessarily mutually exclusive explanations; some of these emphasize the importance of advances in biochemical techniques, others the importance of detailed behavioral study.

In the control, surrogate, and shock groups there was in general good agreement between the first test and the second test (see Table 2). With a few exceptions all the L/P ratios were under 10. One control animal (#527) had a high ratio on each occasion. The reason for this is not clear. One surrogate animal (#78) had a high ratio on the first occasion, but a low ratio in the second study. On the other hand, another animal in the surrogate group (#86) was low in the first study, but high the second time. Any comment on this must be very tentative, but it can be suggested that the partially isolated conditions of surrogate rearing may predispose some biochemical system toward the occurrence of an abnormal ratio in later life under certain circumstances. It has already been noted that the L/P ratio is probably abnormal only if there is a serious disturbance in an important adaptive system; a less severe disturbance may not be detected using this method. Consequently the amount of stress requiring adaptation immediately preceding the individual study may have an important bearing on the degree of abnormality in the biochemical findings. This may well account

for some of the variability in the data, some animals having a greater response to stress than others. As a matter of fact this phenomenon of variability to stress is very characteristic of schizophrenia; data of this nature concerning the L/P ratio in patients and control subjects have recently been reported elsewhere (15).

It was noted that in the surrogate group animals #64 and #67 had no mother surrogate until 250 days of age, and #69 and #71 had no surrogate after 160 days. All these animals tested within the normal range. This result based on such small numbers does not answer one way or the other the important question of the duration of experience necessary to produce changes in the adaptive biologic system.

Finally Table 2 illustrates that in contrast to the other three groups the L/P ratios of the nonshock animals did *not* show close agreement between the first and second tests. Several individual animals varied considerably. Yet in the nonshock group every animal was clearly in the abnormal range on one or the other occasion. This finding also emphasizes the importance of stress immediately before the individual study, and points again to the similarity of response to stress of this measure in the nonshock group and in schizophrenia.

CONCLUSION

These preliminary results are of interest in that they relate a biochemical abnormality similar to the one found in schizophrenia to social isolation and an experimental lack of tactile stimulation in early life. It is important to note that in this study the biochemical defect was found not to be correlated closely with disturbed behavior, indicating amongst other things that the complexities of behavior probably have many other antecedents besides biochemical maladaptation.

Such antecedents must almost certainly include patterns of behavior learned from whatever models were available in the environment during psychologic maturation. Hopefully in future studies it will be possible to manipulate both these sets of variables with some precision. The interaction of biologic or general somatic factors,

and psychologic or learned factors, in the origins of disturbed behavior has always been a central issue for psychiatry. The present study may enable these problems to be approached using primates as an experimental model.

From the biologic point of view alone it would probably be very worthwhile to investigate the type, timing and intensity of stimulation necessary to produce the effect discussed in this paper. For instance is stimulation of certain areas of skin, such as the oral or genital areas, especially important? And what about other types of stimulation—proprioceptive, vestibular, visual or auditory? Is it possible that more complex experiences are significant such as the affective components of the perception of objects, or the learning of patterned responses? The scientific manipulation of both biologic and psychologic variables in a monkey colony might give answers to these questions, and to many others still unasked.

PSYCHOTOMIMETIC DRUGS AND BRAIN BIOGENIC AMINES¹

DANIEL X. FREEDMAN, M.D.²

In the study of biochemical determinants of psychoses it is not compellingly clear what biochemical processes we ought to measure, where, when and in what rates and quantities we ought to measure them, nor what dimension of such a chosen measure *could* be correlated with specific organizations of psychological functions. Even for drug induced psychoses, we are as yet not sufficiently able to detail how biochemical change could become behaviorally manifest. Pharmacologic studies could be of model and heuristic value to the problem of the relationship of neurochemical states and behavioral states. They should broaden understanding of intrinsic biological mechanisms operative in behavior and suggest—both negatively and positively—the kind and order of relationships which may have to be sought in clinical disorders.

Between 1954 and 1956 a number of new observations and generative hypotheses were advanced concerning the relevance of endogenous amines of the brain to behavior. Woolley (1, 2) noted that LSD-25 and congeners were “structurally analogous” to serotonin and that they blocked, imitated or facilitated the effect of serotonin on various isolated peripheral tissues. He proposed that an excess or deficiency of serotonin in the brain would account for both drug-induced and clinically encountered mental dysfunction. In effect, an altered (but, in fact, probably unmeasurable) balance of the amine at the active receptor was to be etiologically involved. In a short time, some non-psychotogenic but psychoactive compounds such as reserpine or MAO inhibitors were found *actually* to increase or decrease levels of brain amines; the large decrease in levels induced by reserpine was correlated with a crudely

defined sedation(3); the increases due to the serotonin precursor or MAO inhibitors were correlated with various patterns and levels of excitement(4, 5). These excesses and deficiencies were measurable in the whole brain. They were not measured at a synaptic receptor, but a sequence of stimulating guessing games arose: what do the amines mean? By an often tortuous series of inferences, changes in whole brain levels became an index for knowledge of events at the active synaptic receptor and hence a canon was established whereby the physiologic and behavioral significance of changes in whole brain levels of a specific amine could be evaluated prior to data. This is metapharmacology—signally useful in launching research and bridging gaps in knowledge but limited as a substitute for empirically established sequences. In terms of measurable processes, we actually know very little even about acetylcholine even at peripheral receptors.

When we measure changes in levels of amines, we are measuring effects on a number of complicated processes prior to the active synaptic receptor. Many of these can be named, but are only beginning to be defined operationally(6-9). In speaking of the significance of changes in levels, Giarman and I(10) have felt it may be best to refer to changes in mechanisms regulating the traffic of amines within the subcellular compartments of a neurone. Total levels, then, will reflect the *net* result of these processes. In inferring the mode of action of a drug on endogenous chemicals located in cellular substructures, one should probably anticipate the general rule in pharmacology: that a drug has more than one action and more than one site of action. In speaking of receptors, we refer to sites of chemical interaction of a drug with components of a substructure (Figure 1). A drug, then, may influence intra- or intercellular transport of the amine or its precursors; influence accessibility to sites of synthesis, storage and inactivation; block or induce enzymes; and alter physical-

FIGURE 1
MECHANISMS GOVERNING BRAIN AMINE LEVELS

chemical properties of membranes, ion flux, metabolic processes or rates of binding and release. Whatever the drug may do, we have little knowledge as yet about the intrinsic regulators of this traffic.

These studies were undertaken to see if a change in whole brain levels of serotonin and norepinephrine might reflect an effect of LSD-25 and other psychotogenic procedures on some of these intrinsic mechanisms governing these amines. There is evidence which shows that LSD-25 and congeners can influence levels of brain amines (7); that the status of these intrinsic mechanisms can, in turn, influence the

chemical, behavioral and autonomic response to LSD-25 (8); and finally, that the level of amines can be influenced by non-pharmacologic procedures (11).

Table 1 shows the effect of LSD-25 on the whole rat brain as determined by bioassay on the clam heart and by fluorimetric assay.³ In early studies, we were convinced of the reliability of small increases by noting the effect on brain levels 22 hours after reserpine had depleted stores of brain amines. LSD-25 increases brain serotonin

³ The methods for bioassay (7) and fluorimetric assays (28, 29) and the specific experimental designs (7, 10, 25).

TABLE 1
Effect of LSD-25 on Brain Amines

MEAN

Control	132	525	46		
LSD-25 (520-1300 μ g/kg)	175	628	57	+ 17%	<.001
NOREPINEPHRINE					
Control	8	560	54		
LSD-25 (1300 μ g/kg)	18	442	51	- 21%	<.01

Rats sacrificed 22 hours after reserpine (R) and 30-120' after LSD.

by 117%. When unpretreated rats are sacrificed at 10, 20, or 120 minutes following LSD-25 a 17%-24% increase is apparent with either assay; an increase of 80-100 $\mu\text{g/gm}$ is generally observed. The minimal effective dose and time for onset of *grossly* observable behavioral and autonomic effects is the threshold dose for measurement of increased levels of serotonin. Individual animals have not been matched for behavioral changes and concomitant brain change. Doses of 520-1300 $\mu\text{g/kg}$ lead to less variance (and perhaps longer sustained changes), but they do not differ significantly from the immediate effect of 130 or 260 $\mu\text{g/kg}$. Recent experiments show that LSD-25 leads to a decrease of levels of norepinephrine of 21%.

In studies with 18 rabbits, the serotonin increased approximately 100 $\mu\text{g/gm}$ or 13%, the same absolute increase in quantity noted in rats, but a smaller percentage increase; Siva-Sankar (12, 13) had previously reported such elevations in regional areas of the rabbit brain. In this species we find effects on norepinephrine which are marked; *i.e.*, a decrease of 30% at 2 hours and 55% at 6 hours. The duration of measurable effects on serotonin is 6 rather than 3-4 hours, as in the rat. In previous experiments with 4 dog brains (10), areas

with normally high concentrations of serotonin showed an increase (non-significant) following the drug.

A similar pattern of a rise in serotonin and fall in norepinephrine is seen with some of the psychoactive drugs related to LSD-25 (Table 2): mescaline, ALD, MLD, psilocybin. Since mescaline interferes with the norepinephrine assay and bufotenin with the serotonin assay, these compounds were not studied; Himwich correlated effects of bufotenin with release of catechols from binding sites (14). BOL is without marked effect; the effects of psilocybin, seen only with the dose of 50 mg/kg , are more marked on norepinephrine than on serotonin. No such effects were seen after single doses of metamphetamine, but McClean and McCartney (15) reported a similar pattern of effects on serotonin and norepinephrine which occurs after chronic, increasing and toxic doses of amphetamine. While these patterns are seen with procedures which produce psychotomimetic effects in man, not all such drugs influence these systems; *e.g.*, no such effects were seen with Sernyl (10). The central effects of the ergot series do not correlate with peripheral antiserotonin potency (*e.g.*, no effects with UML), but Woolley's notion that LSD-25 and psychoactive congeners

TABLE 2
Congeners of LSD-25
Effect on Brain Amines

TREATMENT (mg/kg)	NUMBER	MEAN $\mu\text{g/gm}$	s.d.	Δ %	P

Control	4	468	22		
Psilocybin (50 mg @ 90')	8	375	54	-20%	<.02

would interact with central serotonin mechanisms seems confirmed if one selects changes in brain levels rather than organ-response as an effect.

In order to see if the level of serotonin would respond to the interaction of drugs at a central site, drugs which can partially inhibit the LSD-25 effect on behavior (16, 17) and which interact with serotonin at peripheral receptors (18) were tested. Table 3 shows that when 1800 μg BOL/kg are

that this describes the locus and *not* the function of serotonin. The effect of increasing the dose of reserpine is to decrease the amount of serotonin bound after LSD-25; which would indicate some interaction of these agents at related receptor sites. After reserpine, a large dose of BOL does show a LSD-like effect on levels of serotonin (7), indicating, perhaps, a changed accessibility of BOL to mechanisms which induce binding.

TABLE 3
Partial Inhibitors of LSD-25:
Effects on Brain Serotonin

	NUMBER	Δ IN $\text{m}\mu\text{g}$ FROM CONTROL	% REDUCTION OF LSD EFFECT	P
LSD-25 (520 $\mu\text{g}/\text{kg}$, 30')	13	+100	—	<.01
BOL-LSD-25 (1.8 mg/kg 10' before 520 $\mu\text{g}/\text{kg}$)	12	+ 50	—50%	
LSD-25 (1300 $\mu\text{g}/\text{kg}$, 30')	21	+ 96	—	<.001
CPZ-LSD-25 (2 mg/kg 60' before 1300 $\mu\text{g}/\text{kg}$)	24	+ 34	—64%	

given 10 minutes before 520 μg LSD-25 the rise in serotonin is reduced. We have observed this in various dose and time combinations, but at certain dose and time ratios we have observed facilitation; *e.g.*, with 1800 but not 1300 μg BOL/kg and 520 μg LSD-25/kg in the same syringe. Similar findings are obtained when 2 mg chlorpromazine/kg are given 1 hour prior to 1300 μg LSD-25; the LSD-25 effect is reduced by 64%.

While changes in serotonin respond to the presence of LSD-25 at central sites, the mechanism of this LSD-25 effect is difficult to discern. No effects were found on synthesis or destruction of brain serotonin, although these mechanisms are not rigorously ruled out (7). Since reserpine releases serotonin and somehow impairs binding capacity, and since LSD-25 induces an elevation after reserpine, binding mechanisms could be involved. About 70% of brain serotonin was found by Giarman and Schanberg (19) in subcellular particles; this compartment rather than the supernatant is depleted after reserpine. When LSD-25 was so tested (7) the increases in the whole brain could be accounted for by increases in the particulate. For descriptive purposes, LSD-25 may be said to induce binding of serotonin; it should be clear

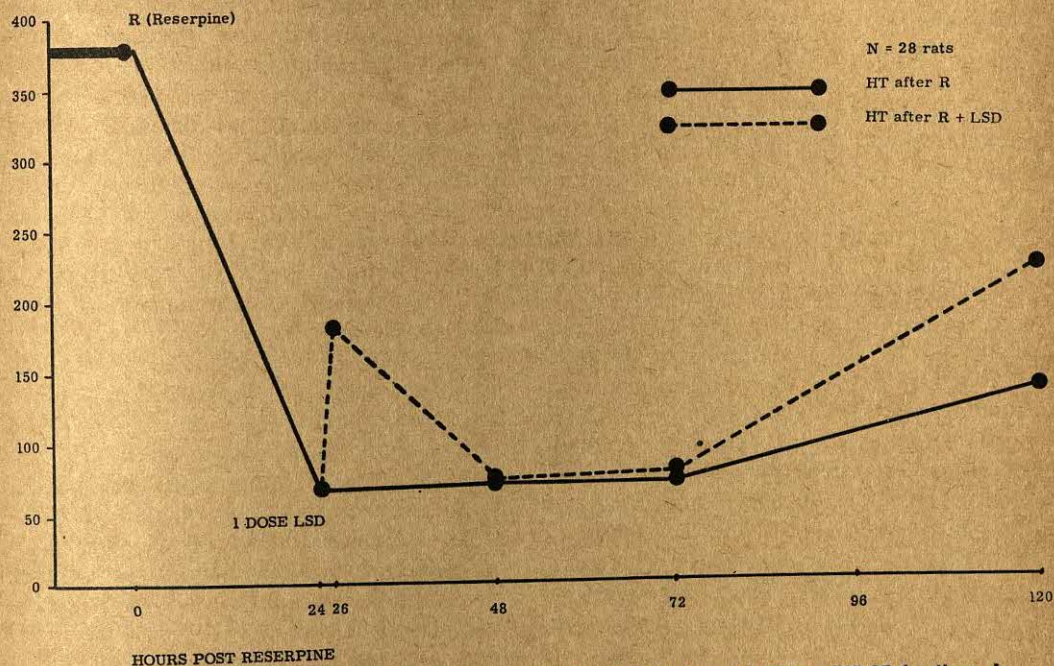

There is one further bit of evidence of an effect of LSD-25 on intrinsic mechanisms which bind and release amines. There are at least 2 phases of the effect of reserpine: 1. Immediate, leading to release of serotonin during the presence of the drug; 2. A later phase in which the capacity of normally operative mechanisms for binding is slowly restored. For example, about 72-96 hours following a large dose of reserpine, the onset of an increasing capacity to bind becomes apparent in following the repletion curve of brain amines. When LSD-25 is given 24 hours after reserpine, the effect of a *single* dose of LSD-25 can be seen in both these phases; *i.e.*, 2-4 hours following the dose of LSD-25 and again at 96 hours (Figure 2). LSD-25 appears to induce binding and stimulate endogenous repletion following release. There are no pharmacologic data which explain the persisting effects of either LSD-25 or reserpine (20); both drugs are rapidly metabolized.

Turning from evidence of an effect on central amine mechanisms, there is the question as to the effect of altered amine regulation upon behavioral and autonomic effects of LSD-25. Rats given a single dose of reserpine and tested 3-4 days later (after their bar-pressing has returned to normal) show a prolonged response to a subthres-

FIGURE 2
Effect of LSD-25 on Repletion of HT

(See text)

mpg HT

2 groups of rats: R and R + LSD; R = 2mg reserpine/kg; after 1 dose of 520 μ g LSD-25/kg there is an immediate rise in serotonin (HT) and a second phase 96 hrs. later (at 120 hrs.) where the differences between R and R + LSD are significant ($p < .01$)

hold dose of LSD-25 (40 μ g/kg) and an erratic development of tolerance if dosage is continued(21). These studies are not based on an interaction of 2 drugs, since reserpine has been metabolized; rather, they test an effect of LSD-25 in a brain with altered mechanisms for the regulation of biogenic amines.

Similarly, in humans(8) the effect on both behavioral and autonomic response is markedly different if LSD-25 is given 2 days after a *single* dose of reserpine. In collaboration with Benton, 14 chronically schizophrenic women were tested. Two days after 10 mg of reserpine the patients felt recovered from the reserpine; the only sign of an altered brain milieu was the miosis. They then received 120 μ g LSD-25 and showed prolonged and toxic reactions: marked tremor and akathisia in the majority, and in 1 an oculogyric crisis. Each felt the drug was less pleasant than her control LSD-25 and that the effects lasted longer.

While it was difficult to be sure that the specifically psychotomimetic effects were increased, toxic effects of LSD-25 were clearly apparent.

With the exception of pupil size, tolerance developed normally in these women. Normally LSD-25 induces a fairly prompt mydriasis. The 9 AM pupil size 24 hours following the first dose of LSD-25 also shows a relative mydriasis and can be used to measure tolerance. After pretreatment with reserpine, the 9 AM pupil size shows miosis rather than mydriasis 24 hours after LSD-25; daily (tolerance) doses of LSD-25 enhance the matinal miosis. The data indicate that autonomic response to LSD-25 is different in the presence of an altered status of central amine mechanisms; the mechanism is not known. It may be that LSD-25 exhausts available stores of adrenergic mediators which leads to an unmasking of the parasympathetic effects both of LSD-25 and of the amine-depleted central systems.

In view of the above, several features of amine metabolism may be stipulated as relevant to the effects of LSD-25 on autonomic and behavioral functions: 1. The total level of amines (*e.g.*, LSD-25 increases serotonin and decreases norepinephrine, and a change in levels changes autonomic and behavioral effects of LSD-25); 2. Their subcellular distribution (*e.g.*, LSD-25 induces binding of serotonin in particulate); 3. The presence of a drug at a receptor (*e.g.*, effect of LSD-25 on amine levels is reduced or enhanced with BOL or chlorpromazine); 4. The status of normally operative mechanisms for release and binding at several phases after such mechanisms are altered by drug action (*e.g.*, LSD-25 stimulates repletion after reserpine, and autonomic and behavioral effects of LSD-25 are changed); and 5. The rates at which serotonin and norepinephrine are bound and released (*e.g.*, different time course of effects in rats and rabbits).

Beyond the studies cited here, there are reports which show effects of different classes of psychoactive drugs on levels (22-24) and differential effects of classes on distribution of biogenic amines (19, 25). We do not know in any definitive way what the function of such small changes could be, nor the function of amines in normal physiology, nor what the intrinsic factors are which regulate them. For purposes of model-making, we were interested in testing on the rat parameters of procedures which, if done in man, could induce psychotic behavior. We wanted to know if psychotomimetic drugs changed the chemistry of the brain and if a changed brain chemistry changed the effects of psychotomimetic drugs. We also were interested

to see whether non-pharmacologic procedures could influence amine mechanisms.

Since small changes in levels proved to be reliable in drug studies, Barchas and I explored a number of procedures involving excessive deprivations or demands which tax—or surtax—adaptive mechanisms. Table 4 summarizes some very recent experiments (11). Garratini (26) and Brodie (27) had shown that extremes in environmental temperature could influence the extent to which serotonin was released by reserpine. Scrutiny of these data showed that such extremes elevate serotonin levels slightly, so at the least it appeared that serotonin resists *drug-induced* release in cold or heat stress. Hypophysectomy of cold stressed rabbits abolished the resistance to reserpine-induced release of serotonin. The experiments we are doing already show that a 4-6 hour swim in water at room temperature or a 15-30 minute swim in 15° C. water lead to a decrease in norepinephrine and an increase in serotonin; this occurs in hypophysectomized rats. Anoxia induced in a nitrogen chamber showed no effects. Changes in serotonin (but not norepinephrine) are, at this point in our work, not impressive with the treadmill. The extent and rate of change in level of each amine vary in part with the procedure, in part with the individual rat; extensive work remains to specify the extent of change and variables influencing these changes. A treadmill or a swim are quite different procedures. Each requires different patterns of exertion, activation, and adaptation; *e.g.*, walking on a wheel does involve exertion and sleep deprivation, but apparently little vigil; these animals tend to give up and take a free ride as far as they can. They do not seem to be as acti-

TABLE 4
Non-Pharmacologic Change of Brain Amines

vated as a swimming animal.

A change in functional state and brain amines can also be seen in rats permitted to recover from a cold water swim (Figure 3).

psychophysiologic function in the face of excessive activation or demand.

These studies refer largely to changes in the rat brain. If we are not to anthropo-

FIGURE 3
Brain Amines After Swim Stress

Immediately after a 15-30 minute swim to exhaustion, norepinephrine is decreased 11% and serotonin increased 13%. Two hours after the swim, norepinephrine was decreased 20% and serotonin values were not significantly different from normal. Upon removal from the water at 0 hours, rats exhibited a sporadic uncoordinated activity, but were generally feeble and inactive. At 2 hours, they had begun to sustain a few periods of more coordinated activity with some grooming; and at 4-6 hours they appeared normal.

CONCLUSIONS

These studies would indicate that the endogenous brain amines are responsive not only to LSD-25 and psychoactive congeners but also to some factor or factors of intense stress. If so, this would provide some biological link between psychoactive drugs, their effects upon amine metabolism and conditions which give rise to the need for such drugs. Perhaps, if endogenous amine mechanisms are chemically or genetically impaired, this could be reflected in altered

morphize the rat nor "rodentomorphize" man, our speculation must be limited. Within the rat some psychotomimetic drugs show a pattern of effects on biogenic amines and vice versa. There are little data for the rat which firmly link rates of binding and release within a specific animal with specific patterns of physiological or behavioral response. With respect to psychophysiological effects, these changes in amine levels could conceivably reflect an incidental rather than a necessary and sufficient response to the drug. Differential effects of drugs on amine levels are reliably observed, but for other than time of onset, the changes in levels have not been linked with the pattern of effects. We do not know if the similarity in pattern of amine response to certain stressors and to psychotomimetic drugs reflects similarities in mechanism. Thus, 8 years after Woolley's hypothesis, a relationship of LSD-25 to central amines and certain correlations of amines with autonomic and psychomotor function in the rat and in man can be demonstrated. The mechanisms accountable for these facts and their

specific relationship to disturbed patterns of function have not been unraveled, even in the rat.

SOME BACKGROUND FACTORS IN RECENT ENGLISH PSYCHIATRIC PROGRESS¹

ARI KIEV, M.D.²

Recent American studies have indicated that hospital experience critically contributes to the behavior, management and prognosis of patients with psychiatric illness (3, 8, 41). Interest has shifted from a custodial to a therapeutic orientation and a widespread re-examination of notions long accepted as reasonable and "therapeutic" has been stimulated (14, 48). This interest in the social aspects of illness has led to much enthusiasm about recent English developments which include the development of open-door hospitals, therapeutic communities, day hospitals, aftercare programmes and industrial rehabilitation units (4, 9, 19, 24, 25). Many of these developments have been viewed as recent means of making effective various "dynamic" and theoretical schemas, insufficient consideration being given to the historical and social matrix from which they have evolved (2, 12, 26). An examination of some aspects of this historical complex may thus serve the purpose of enlarging the perspective in which recent progress in English psychiatry may be understood.

The modern reformation in psychiatry which came according to Henry, "two centuries after all other human interests had experienced a rebirth," developed in England during the late 18th and early 19th centuries (49). This was a time of great change in England owing largely to the impact of the Industrial Revolution. It was during this period that the efforts of such citizens as Jeremy Bentham, Robert Owen and John Stuart Mill led to political and constitutional reforms, increased suffrage, reduced power of landed interests and an increasing centralisation of government. This period was one of intense social legislation: the Factory Act of 1833 limited child employment; the 1834 Poor Law Act

encouraged rational arrangements for the care of the ill and unfortunate, by distinguishing between able-bodied individuals, the feeble, orphans and lunatics; the 1835 Prisons Act established inspection of prisons and the 1832 Reform Act altered the electoral basis of Parliament, giving the new middle classes proportional representation (43).

At the start of the Industrial Revolution the only statutory social service in operation dated back to the Poor Law Act of 1601 which made it the duty of the local community to provide for the poor, the old, the blind, the lame and the impotent (15). The reforms which were subsequently provoked and finally effected were in large part a reaction to the new needs created by a rapidly expanding, industrialized urban society. These reforms were especially directed towards the creation of suitable conditions in factories, mines and towns and improving health conditions to protect people from infectious diseases.

Developments in psychiatry reflected this spirit of reform. The humane treatment of the mentally ill can be traced back to the middle of the 18th century. William Battie of St. Luke's Hospital in his *Treatise on Madness* (1758), William Perfect in his *Annals of Insanity* (1787) and many others advocated the moral approach to patient care before the time of Pinel and Tuke (46).³

While Pinel was unchaining patients at the Bicetre, William Tuke was instituting similar reforms at the York Retreat in 1796 (44). Both men emphasized exercise, occupational therapy and the absence of restraint. In addition to the work of individuals public interest in the treatment of the insane was also being aroused. A House of Commons investigation of "mad-

¹ This paper was written during the tenure of a Post Doctoral Research Fellowship from the National Institute of Mental Health, U. S. Public Health Service.

² The Maudsley Hospital, London, England.

³ These enlightened developments were not confined to England and France. The psychiatry of the late 18th and early 19th centuries was stimulated elsewhere by such innovators as Joly in Geneva (1787), Chiarugi in Tuscany (1788) and Langermann in Bayreuth (1805) (1).

houses" in 1815 described the famous York Asylum as "a very horrid and filthy situation," and recommended the discharge of incompetent hospital officials and new measures to improve the safety, comfort and welfare of the patients(38). The 1828 Lunacy Commission in England reported that in one London asylum, "Several of the pauper women were chained to the bedsteads . . . in crowded, ill-ventilated places." Only 30 years later however, Lord Shaftesbury was able to write(44),

At the present time when people go into an asylum they see everything cleanly, orderly, decent and quiet . . . When we began our visitations, one of the first rooms that we went into contained nearly a hundred and fifty patients, in every form of madness, a large proportion of them chained to the wall, some melancholy, some furious, but the noise and din and roar were such that we positively could not hear each other.

As a result of numerous investigations, legislative reforms and the success of such places as the Retreat, therapeutic workhouses became popular, aftercare programmes were introduced and patients came to enjoy greater freedom in some asylums. Among the prominent developments of this period were increased liberties for patients, the abolition of airing courts, the development of open wards and the development of occupational and recreational programmes.

In this same period John Connolly at Hanwell developed the nonrestraint policy initiated by his predecessor Charlesworth, eliminating the use of mechanical means such as leg-locks, strait-waistcoats, handstraps and coercion chairs. With fewer restraints more efforts were made to know and understand the patients(42). Tuke has written that mental attendants were expected "to engage them [the patients] in such occupations as would make them contented, to provide an orderly outlet for their energies and to divert their minds from thoughts of escape"(42).

The Lunatics Act of 1845 embodied many of the principles of reform begun during the first half of the 19th century. Whereas the 1774 Inspection Act was ineffective because of lack of power, the

Lunatics Act called for a national framework governing the care of the insane and an inspection body to maintain the standards found possible and desirable(18). It made recommendations for exercise and amusement facilities and advocated increased numbers of attendants to prevent the use of harsh and unnecessary restraints.

These developments in the concept and practice of moral treatment were not universally accepted. There was, according to Walk, much misuse of the concepts of Tuke and Connolly by lay hospital committees who felt such management could be directed by lay people in large institutions (47). Thus in 1858 Connolly could say:

The government of our County Asylums is highly defective and more especially that of our large county asylums near the metropolis. The governing bodies discourage and repudiate the aid of their medical officers and show a want of discrimination between the requirements of the insane and those of mere paupers or prisoners in gaol.

Despite the progress noted by Shaftesbury in 1858, the Lunacy Commission and the Royal Commissioners Report in 1859 both included many descriptions of inadequate staff and care. Another aspect of the situation in these years was the large number of individuals classified as paupers who were either in workhouses (7000 in 1859) or living with friends or elsewhere (8000 in 1859), constituting about an equal number to those in county asylums or licensed houses. Despite protests from Poor Law authorities that "lunatics" needed medical treatment in asylums, the Board of Guardians interpreted the Poor Law Act loosely and thus continued to keep large numbers of the pauper insane in workhouses, until the 1862 Lunacy Act amendment prohibited such detention for more than 14 days unless medical approval was given(47).

With increasing population, urbanisation and industrialisation mental asylums were enlarged, made more efficient, removed from urban centres and overcrowded with increasing numbers of patients. Such factors, coupled with progressive pessimism in some quarters about the treatment for conditions deemed organically determined,

contributed to the slow spread of moral treatment and the perpetuation of custodial patterns in many hospitals. Despite this a tradition of social reform and social legislation persisted and progress continued to be made(10). Although the Lunacy Act of 1890 and the Mental Deficiency Act of 1913 appear retrospectively to have promoted the isolation of mental hospitals, thus fostering custodialism, they were originally enacted in the interest of patient welfare(18). To safeguard patients, asylums were permitted to admit only those certified by legal authorities. The determination of diagnosis by lay authorities often led to certification in the late stages of illness and late treatment and as a result helped perpetuate a custodial or protective attitude in hospitals with its attendant abuses.

Much as the early 19th century was a period of great reform so the 20th century in England has been marked by a variety of developments in social legislation which have served as a backdrop for many of the experiments and innovations of hospital psychiatry. With the Liberal Party's electoral triumph in 1906 a number of schemes were introduced, including such measures as the feeding and medical inspection of school children, old age pensions and a state scheme for social insurance. Subsequent developments have led to the state playing a bigger role in the creation and extension of personal services, a trend which was further intensified after the second World War. These developments have been to a large extent intertwined with the far-reaching developments in psychiatry itself.

A number of developments in the 2nd and 3rd decades of the 20th century altered the general pattern of the preceding decades. Psychotherapeutic successes with the treatment of war neuroses in the first World War combined with the psychoanalytic theories of emotional phenomena to provide much impetus to treatment(7). Of great importance also was the introduction and widespread use of physical methods of therapy. Between 1917 when Wagner-Jauregg introduced malaria therapy for general paresis and 1938 when Bini and Cerletti reported on ECT, prolonged narcosis treatment (Klaesi, 1922), hypoglycemic coma

treatment (Sakel, 1933), Metrazol convulsion treatment (Von Meduna, 1935) and prefrontal leucotomy (Lima and Monez, 1936) were introduced(16). The renewed interest in the possibilities of psychiatric treatment was reflected in Britain by the legislative acts passed in 1929 and 1930.

The Local Government Act of 1929 transferred the powers and duties of the Poor Law authorities to the local health authorities. The expanded responsibility for local councils increased the ties between psychiatry and medicine in general hospitals and abolished the anachronistic Poor Law system of caring for the mentally ill(23). One year later the Mental Treatment Act made provision for patients to enter mental hospitals on a voluntary basis, retaining the right to leave after three day's notice. It also provided for temporary patients who, although possessed of minimal volition on admission, were considered to enjoy a good prognosis: such patients required certificates from two doctors and could not be detained longer than six months. At the same time gradual steps were taken to improve the freedom of patients so admitted and the ward doors began to be unlocked again. An increased movement in and out of hospitals began and was associated with the increased use of outpatient departments and observation wards(37).

Before 1930, 29 outpatient departments existed in England and Wales; in 1938 there were four times this number(21). While in 1930 there were some 2000 voluntary admissions, by 1938 the number had increased to over 12,000 constituting some 40% of all admissions and by 1945, 75% of all admissions(22). Of the 93,306 patients admitted for mental illness to various private and public mental hospitals, registered hospitals, single care and licensed homes in 1957, 77,288 or 82.8% were admitted on voluntary status(27).

Among the significant results of this Act were a general diminution in stay of patients in hospital and a greater concern for the rehabilitation and aftercare of patients. Increasing proportions of the population were prepared to accept treatment in mental hospitals, a phenomenon which suggested to some writers a greater confidence on the part of the public(17). In addition,

the Act gave statutory powers to local authorities to open outpatient departments in general hospitals, a further step in bringing psychiatric treatment back into the community.

That these new developments and an increased concern for mental patients yielded significant therapeutic effects is suggested by shorter stays, higher discharge rates and lowered death rates at one English hospital between the years 1931 and 1947(35). That these effects were related to nonspecific environmental factors was further suggested by the fact that in the years when physical treatments became available, "almost 60% of newly admitted cases were receiving no forms of specific therapy"(36). Many new approaches were initiated during this period. A therapeutic social club in a mental hospital was first organised in 1938 by J. Bierer(5). Maxwell Jones initiated a therapeutic community at the Mill Hill Emergency Hospital in 1942(20); and T. P. Rees began introducing unlocked wards at Warlingham Park Hospital in 1935(33).

Successful experience during the second World War in treating large numbers of battle casualties by a variety of methods, especially by group therapies and the physical treatments, encouraged optimism about the postwar management of mental illness and "had the effect of bringing psychiatry closer to medicine"(34). Indeed, prior to the war's end, plans were in process to coordinate the work of mental health with the general health services of the country(32). Prior to the National Health Act the psychiatric scene was extremely varied in different parts of England. The Act brought the salary scales of psychiatrists working in mental hospitals up to the level of other specialists and increased the opportunities for outpatient work, all of which brought psychiatry closer to medicine and the general public. Another major step was to give the next of kin of committed patients the power to discharge their relatives unless they were felt to be dangerous by the medical superintendent, which reduced much of the public animus toward mental institutions(39).

The establishment of a National Health Service in 1948 brought mental hospitals

into the same central governing body as general hospitals. The standards of mental hospitals were set at the level of general hospitals and more doctors were attracted to psychiatry. Aftercare continued to be the responsibility of the local health authorities which had controlled most public mental hospitals before 1948. The National Health Service in improving the standards of mental hospitals and bringing more good doctors into full time institutional work further raised the standard of care given to patients(13). The provision of free care increased the possibilities of early care, which in leading to better results and broadening the catchment population to include large numbers from the middle classes, helped remove the stigma of mental disease(31). It has led to the increasing use of outpatient facilities, increased turnover of patients in mental hospital beds and has benefited the psychiatrist by raising his professional status to the level of his fellow medical practitioners.

The recommendations of the Royal Commission in 1954 were embodied in the Mental Health Act of 1959(28). This Act, repealing all previous legislation, made provision for all patients to be admitted to mental hospitals on an informal basis(40). It did away with the necessity for certifying patients or detaining them compulsorily save under special circumstances. The Act provided for patients to be admitted to any hospital, general or psychiatric, and so contributed to the reduction in negative attitudes about "special" hospitals. The new Act also clarified the role of local authorities in the management of hostels for aftercare, social work, old age homes, childrens' training schools and industrial centers and provided for greater contact between local health authorities and hospital authorities. Although it is perhaps too early to assess thoroughly the effects of the Act it would seem that patients are admitted at earlier stages of their illnesses, discharged sooner, and experience greater freedom while in hospital(30). Taking cognizance of the changing attitude towards the mentally ill, the Minister of Health has recently submitted a Hospital Plan to Parliament(29), laying great emphasis on treating patients in the community, in general hospitals,

short-stay units and residential hostels, and when possible at home. Regarding future needs, the Plan states :

Because of the success of new methods of treatment, combined with changed social attitudes, it may be expected that the recent decline in the number of hospital beds required for mental illness will continue.

Whereas the total number of beds in 1960 was 151,899 or 3.3 per 1000 people, the requirement for 1975 is estimated at 92,090 or 1.9 beds per 1000 people.

Much as many of the reforms in 19th century psychiatry were promoted by lay reformers such as Tuke and Shaftesbury in England and Dorothea Dix in America, voluntary lay organisations have actively pressed for many of the recent reforms, a fact not to be minimized in evaluating recent psychiatric progress (6, 11). In England voluntary organisations have engaged in the community care of defectives and aftercare programs and have in some instances done the work of the local health authorities. At present the National Association for Mental Health, made up of the major voluntary organisations which merged during the war, runs educational programs, research, agricultural hostels for high grade defectives, senile homes and mental deficiency and mental illness institutions, and acts as a supplement and a stimulus to statutory powers.

CONCLUSIONS

The factors outlined herein—a 19th century tradition of moral psychiatry, a history of social legislation, the activities of lay reformers and the development of a nationalised health scheme—have all made significant contributions to the current developments in English psychiatry, characterized by therapeutic communities, open-door hospitals, day centers, industrial rehabilitation units and aftercare programmes. From as early as the 1930's British hospital psychiatry has progressively moved away from a custodial position towards the development of an atmosphere conducive to the development of therapeutic communities and giving effect to procedures conceived in the late 18th century. More and more, attention has been directed towards

good hospital-community relations, the betterment of aftercare, and in general the establishment of a preventive psychiatry where patients can be admitted early and treated rapidly. Examination of the factors discussed herein suggests that not only did a fertile soil exist for the growth of these ideas and practices but that an effective machinery for carrying out such programmes has been made available. It is of especial interest that most of these developments were being introduced before the advent of tranquilizers which have been credited for the increasing permissiveness and humanity of hospital policies (45).

Much as the developments in the days of Tuke were part of a larger social picture, so too the current changes in medical and psychiatric care are part of an increasingly liberal political and social policy which has provided much social welfare legislation (15). It is suggested that an examination of such factors is necessary in evaluating the development and success of current experiments in psychiatry which have not developed *de novo* or from some preformulated theoretical position but stem from a long history of social and legislative reform and have been fostered as an aspect of a nationally organised health scheme.

THE DILEMMA OF THE PSYCHIATRIST IN FORENSIC PRACTICE¹

CHARLES A. RYMER, M.D.²

Few branches of medicine have fallen so low in public opinion as has psychiatry at the present time. In large part this is the result of the so-called "battle of the experts" as it takes place in one court after another when the plea of insanity is entered as a defense to a crime. Whenever a particularly heinous crime occurs, members of the lay population speculate that some "sharp headshrinker" will no doubt get the alleged criminal off the hook. One or several psychiatrists will testify that the perpetrator of the crime was sane, and an equal number of eminent psychiatrists will testify that he was insane. There is neither affection nor respect on the part of the public toward those who engage in these contests, and there is a deep-seated suspicion that any psychiatrist's opinion is for sale.

As psychiatrists—especially those in private practice—we should be deeply concerned about these attitudes, and we should begin to seek within ourselves the causes and the remedies. Why the battle of the experts? Shall we ourselves continue to subscribe to this esteem-destroying procedure?

In two earlier studies on Colorado cases for the period of August 1, 1927 to August 1, 1947, we (1, 2) reported that 750 persons were admitted by court order to Colorado Psychopathic Hospital for observation. Of these, 190 or 25% were reported insane; 30% of those charged with murder were reported insane. Statistics from the same hospital (3) for 33.5 years since its establishment indicate that 1771 persons have been committed for observation. Of these, 245 or 14% were reported insane; 28% of those charged with murder were reported insane.

Data from the Colorado State Hospital (4) for the same 33.5 years indicate that 1438 persons have been sent there for observation. Of these, 756 or 52% were

reported insane; two-thirds of those charged with murder were reported insane. The combined data from the two institutions for 33.5 years show that 3207 persons in Colorado were committed for observation under the plea of insanity; 1001 or 31% were reported insane. Among the total committed for observation, 440 were charged with murder; nearly one-half were reported insane.

Since the M'Naghten case in 1843, the plea of not guilty by reason of insanity has become increasingly popular. All states except New Hampshire recognize this plea and have provided for psychiatric examination of the defendant and a report of the findings to the court. The examination is usually conducted by a tax-supported agency, such as the state hospital, the psychiatric department of a medical school, or a specially appointed agency.

The plea is entered in a variety of cases—sometimes in those in which it seems to have little validity. Frequently it is advanced when the crime is so horrible or repulsive that it seems to the general public that the perpetrator must have been out of his mind to have committed it. We have observed this plea to be entered occasionally as one of expediency. The defense counsel (for any one of a number of reasons) has not had time to prepare for the trial and resorts to this plea, since it almost automatically results in a postponement of the trial. Further, a report of insanity decreases the probability of prosecution. In this connection, it may be that the public prosecutor's usual unwillingness to prosecute in the face of a report of insanity has accelerated the abuse of this plea. Needless to say, the plea is increasingly used in all cases in which there is real question as to the competence of the defendant. The plea may be suggested by distraught relatives, sympathetic judges, defense counsels, and by the defendant himself. Recently, we have noted that the defendant uses this plea as a method of "self-analysis." He may say to the examining

¹ Read before the 26th annual meeting of the National Association of Private Psychiatric Hospitals, Scottsdale, Arizona, January 1961.

² 230 Majestic Building, Denver 2, Colorado.

psychiatrist, "Sure, I know that I'm not crazy, but you tell me why I do these things. You tell me why I behave as I do."

If the court-directed examination reports the defendant *insane*, the public prosecutor may still elect to try the defendant. In this event the jury occasionally will find the defendant sane and hold him responsible for his crime. Usually, though, the report of insanity with its implication of non-responsibility is accepted, and the remaining portion of the trial is simple. All thought of prosecution is eliminated; only the nature of the mental illness need be established to substantiate the defendant's incompetence. The declaration of not guilty by reason of insanity wins for the defendant absolution for his crime. He is, as the verdict states, "not guilty"—though insane.

If the original court-directed examination reports the defendant *sane*, a plea of not guilty by reason of insanity may still be entered. Since support must then be found for this plea, the defense seeks one or more psychiatrists who will find his client insane; if not totally insane, at least insane for the duration of the crime. The private psychiatrists³ are usually sought, since the institutional psychiatrists have already been forced to the side of the prosecution by their report of sanity. Thus, the psychiatrists are marshalled against each other and become pawns to prove or disprove points made by either counsel.

The psychiatric opinion expressed by either side may often be just that—"opinion." Neither expert can disprove the other, although each is talking about the same defendant, the same crime, and has used the same tools of examination. Each has listened to the same history and presumably has obtained the same facts necessary for him to come to an opinion. Or does each listen to the same story and does each obtain the same facts?

Let us consider the procedure. When an alleged criminal is apprehended, the police

attempt to obtain a confession, or at least a statement. How many times the defendant tells his story in these early phases is unknown, but finally it is committed to writing, and this document becomes the statement or confession, and *one* of the histories of what happened. With the appearance of the defense counsel, the "story" is told again—for as a rule, the defense is not permitted to see the defendant's statement. In this retelling, inconsistencies may creep in, circumstances appear to change, and emphasis seems to be shifted to place the defendant in a better and more understandable light. Some of the harshness of the crime is wiped away, and some justification is sought. In fact, sometimes it is almost made to appear that the deceased invited the murder, and actually it was his own fault that he was killed. The influence that the defense counsel plays in shaping the defendant's story at this time must be significant. Often the plea of not guilty by reason of insanity is formulated here.

If the defendant is placed under psychiatric observation for examination and report to the court, he must again tell the story of his life, probably several times. By the time the psychiatrist recruited by the defense enters the picture, the defendant has told his story many, many times. Days, weeks, and even months may have elapsed since the commission of the crime or even since the arrest. Is the story the same as told immediately after the arrest? Is it the same as told to anyone else? By repetition has the defendant inadvertently been forced into a "black out" state to escape pain and guilt and sense of total rejection?

In any event, the psychiatrist allied with the defense may be looked upon as a friend who must search for any and all mental changes which might relieve the defendant of responsibility. In this search, the psychiatrist need not be bound too closely by the right and wrong principles as set forth by the M'Naghten rules, since it is far easier to report that the defendant did not have the ability to refrain from doing the wrong because of his mental disturbance. If this thesis is unacceptable, an alternative can be presented that the defendant could not formulate the intent to kill because of

³ For purposes of discussion, we define as institutional psychiatrists those primarily affiliated with tax-supported institutions and all those not primarily associated with tax-supported institutions as private psychiatrists. The distinction is admittedly somewhat artificial and not entirely satisfactory.

his mental disturbance. Still other explanations can be given; to wit: because of the defendant's personality and his ensuing emotional conflicts, he could not formulate intent to kill; or because of the social pressures on the defendant, he could not refrain from doing what he knew to be wrong; or, simply, whatever the wrong, it was the result of the defendant's defect.

While the defense counsel is preoccupied with saving his client from the penitentiary, and perhaps death, he is quite unconcerned about the length of time which the defendant may spend in a state hospital should he be found not guilty by reason of insanity. This unconcern has a logical basis, for experience has shown that a verdict of insanity is more favorable to the defendant than a penitentiary sentence for the following reasons: 1. Even though the defendant in fact be insane, the chances of his recovery are good. Most of those found criminally insane are eventually released from the hospital; so being sent to a state hospital is almost the equivalent of receiving a suspended, or indeterminate sentence. 2. If the verdict is one of temporary insanity, commitment to the hospital is a mere formality until arrangements can be made for release. 3. The defendant really may not be insane, although the jury found him to be. He is then committed to the state hospital, and it is usually a relatively short time until he wins his release.

A recent Colorado case illustrates many of the aspects of forensic psychiatry.

David Francis Early, 26, shot and killed three members of the Merrill Knight family on March 25, 1958 in Denver. He was quickly apprehended and within five hours had made a complete confession. He gave a history of repeated difficulty, including incarceration in a Federal Correctional Institution, violated parole, and imprisonment in the state penitentiary. Because of his belligerent attitude, he had been studied psychiatrically at both institutions.

Mr. Knight, an attorney and a distant relative, had provided legal counsel for Early's defense for a series of aggravated robberies which had led to his imprisonment at the state penitentiary. Upon his release from the Federal Correctional Institution, he returned to Denver, apparently with the idea of obtaining money from Mr. Knight.

Early gained entry to the Knight home in the afternoon when no one was home. As members of the family came home individually between 3:00 and 6:00 p.m., he systematically at gunpoint bound, gagged, and placed each in a room. Apparently Mr. Knight, the last to come home, attempted to free himself and lunged at Early, who promptly shot his victim. Following this, Early shot Mrs. Knight and the 14-year-old daughter, but failed to kill the 17-year-old son because ammunition had been exhausted. During the interval required to return to the gun room and reload, the son broke his bonds and fled to the nearest neighbor as Early fired wildly.

Early pled not guilty by reason of insanity. At the trial four psychiatrists and two psychologists testified variously for the defense that he was ugly, paranoid, dangerous, and schizophrenic. Five psychiatrists for the prosecution testified that he was neither schizophrenic nor psychotic, but rather a sociopath, sane and responsible for his acts. Following final arguments, the case was given to the jury, and within 22 minutes they found the defendant guilty of murder and recommended the death penalty. This case was appealed through several courts, but the United States Supreme Court refused to review it. Early was executed on August 11, 1961.

What are the real factors which account for the increasing use of the plea of insanity? Many may be cited, but we believe that the most important are five:

1. A general liberalization of society's attitude toward the person as an individual. The roots of this are found in the Reformation; they are reflected in the revolutions of the peoples throughout the world for independence; they are the mainsprings of democracy; they are the reasons for the safeguards with which our courts are surrounded. The dignity and worth of the individual man and woman has increasingly been emphasized in our western civilization. We are reluctant to take any steps which suggest a reversal of this trend. We not only assume that a man is innocent until he is proven guilty; we place every device at his disposal to help him prove his innocence.

2. Very closely allied to the first reason is the second: an unwillingness on the part of society to punish in a vindictive manner and to exact extreme penalties. A whole new theory of penology has grown up, and

our current philosophies and practices are a far cry from the days when debtors languished in prison for insignificant sums and an even further cry from the inhumanities currently practiced by the Russian police state. The death penalty is in the process of being abandoned by western civilization, and society is increasingly loathe to condemn a man to death or even life imprisonment. For this reason, society not only condones, but actually welcomes the plea of insanity as a way out of the conflict created by this changing attitude which still must function within the framework of relatively severe laws.

3. Many see in the increasing use of the insanity plea a reflection of a current physical softness and moral laxness widely decried by leaders in schools, churches, police agencies, and the press. The United States Army found softness and lack of self-discipline in United States soldiers in the Korean war which led so many to collaboration, capitulation, and even death, in contrast to the behavior of allied soldiers from other countries. Many thoughtful persons believe that the leniency of courts, juries, and police—to say nothing of the apparent breakdown of discipline in the home—is breeding a generation of decadence and lawlessness. In such a society, almost anything goes. No matter how horrible the crime, the important thing is not to get caught; if caught, the next important thing is to escape punishment. Insanity offers one of the most convenient escapes.

4. The fourth basic reason is a better understanding of the mechanics of behavior and better diagnostic measures. Undoubtedly, some of our criminals are insane; perhaps we are better able to recognize these. Even here, though, excesses and abuses occur. An increasing number of our psychiatric group has an explanation for everything—an excuse for every misbehavior. No longer do we need to explain Johnny's delinquency on the basis that he was dropped on his head as a baby; we now have a range of causes from a feeling of being rejected by society to hatred for one's mother. But shall we accept the thesis that every aberration from the normal is a defect of sufficient magnitude to deprive a

person of intent, or self-restraint, or of ability to know the difference between right and wrong?

5. Finally, one of the reasons for the increasing use of the plea of insanity is the willingness of the present day psychiatrist to be for sale. Too many of us seem quite able to render an opinion indiscriminately for a price. It seems strange that in this field we forsake our traditional role of unprejudiced diagnosticians and open-minded searchers for medical truth. Instead of coworkers, we become paid proponents of a point of view. We are too easily and eagerly available on a partisan basis.

We have discussed so far some of the problems that beset our practice of forensic psychiatry, and we have pointed out some of the related shortcomings. Is there anything that we can do about these? Several solutions may be considered.

1. First, as private psychiatrists, we could consider staying out of this field altogether. We could refuse to be drawn into these contests and could stop being pawns of the defense or prosecution. In general, this is a negative solution and, hence, not one to which most of us would subscribe. Defendants are still going to be referred by courts for psychiatric observation. For the most part, this referral is to a tax-supported institution. If the private psychiatrist makes himself unavailable, this would leave only the institutional psychiatrist as the authority. Even though the latter be most competent, few of us would be willing to agree that these should be the only authorities. Further, if we as private psychiatrists should withdraw from this field, we would withhold a vast reservoir of skills and knowledge and experience which ought to be available alike to courts, to defendants, to plaintiffs, and to defense and prosecution attorneys. So withdrawal is not the solution.

2. A second solution might be to serve as a public service without pay. Even as this Utopian suggestion is made, one can hear the cries of indignation—the self-righteous protests that undue advantage would be taken of us under these circumstances. However valid this allegation may be, I believe that, if the financial incentive were removed, we would see overnight a virtual disappearance of the battle of the

experts. We would no longer be recognized as an item for sale, and our professional stature would be raised—not only in the eyes of others, but also in our own.

3. A third solution is the establishment by the court of a commission of one or more psychiatrists to examine the alleged criminal and report to the court. This would require a change in the laws of some states. The psychiatrists for this commission would be drawn on a rotation basis from a panel of all the institutional and private psychiatrists in the area who had indicated their willingness to serve. In this way no one of the psychiatrists would represent one side or the other, since together, or separately, each would report his findings to the court and each could be cross-examined by either side. Lest this solution appear impractical, a good parallel may be found in the procedure used in the civil courts in charge of commitment procedures. In Colorado, for example, a medical commission of two psychiatrists is appointed to examine the person concerned. As a rule, there is little difficulty in reaching a decision in these cases; there seems not to be the great conflict of opinion that is engendered in criminal cases. The report is made to the court, and, although the court has the option of setting aside the findings, rarely does this happen. The spectacle of psychiatrist set against psychiatrist seldom occurs in a civil case.

4. A fourth solution is the establishment of psychiatric court clinics. This, too, would require revision of the laws of some of our states. Guttmacher(5) reports that this procedure has been successfully used in Baltimore, Chicago, Cincinnati, Cleveland, Detroit, New York, Philadelphia, Pittsburgh, and Washington, D. C. Massachusetts is outstanding for its progress in the development of psychiatric court clinics; ten of these have been created for juvenile and adult criminal courts. Certainly, this procedure has much to recommend it, and it may well be the best solution, at least in the larger cities and the more heavily populated states. In summarizing the benefits of this system, Guttmacher states :

It represents the recognition of the truth of the doctrines that in the proper disposition of

criminal cases the focus should be on the criminal rather than on the crime and that the goal of justice is rehabilitation of the individual and the protection of society, rather than vengeful punishment. . . . Where an effective court clinic exists, the unseemly partisan battles characteristic of hired psychiatric experts have virtually disappeared. Wherever it has functioned, the court clinic has, I believe, created an increased respect for psychiatry and its contribution to criminal justice.

5. One much-needed reform is the provision for immediate psychiatric examination upon arrest of every case involved in a capital offense. It is my belief that the psychiatrist, private or institutional, should be one of the first to interview the defendant after arrest, for it is at this time that he comes the closest to telling the truth. The longer the interval between the commission of the crime and the psychiatric examination, the more unreliable is the history. For example, in conducting a series of interviews in the Colorado State Penitentiary on nonpsychotic criminals at periods considerably removed from the dates of their crimes, we(2) found that most of them seemed to have developed a partial or complete amnesia for the details of their crimes. Too often the story told by the defendant changes with repetition; too often the psychiatrist is placed in the untenable position of judging, much later, a prisoner's mental and emotional state at the time of the commission of the crime. Certainly, the reliability of the psychiatric evaluation would be enhanced by immediate examination, and this is true, irrespective of the mechanics established for the examination.

To meet the objection that the constitutional rights of the person might be violated by immediate examination, it is the practice in some jurisdictions for the examining physician not to question the defendant about the crime. However, this poses an obstacle in the understanding of the defendant, for it is difficult to separate the defendant from his crime. Hence, the American Law Institute(6), in writing its *Model Penal Code*, has suggested a statute which reads in part as follows :

A statement made by a person subjected to

psychiatric examination or treatment . . . for the purpose of such examination or treatment shall not be admissible in evidence against him in any (criminal) proceeding on any issue other than that of his mental condition but it shall be admissible upon that issue, whether or not it would otherwise be deemed to be a privileged communication.

6. As a final solution, may I suggest self-discipline in these matters? Let us stop being for sale to any bidder; let us stop prostituting ourselves and our profession; let us be a little less greedy and nondiscriminating in our alliances with the defense or the prosecution. Is it too much to ask that we examine ourselves more criti-

cally before we enter into tstraint, or of Could we once again becombetween right who render diagnoses of illness.

purveyors of biased purchased as for the nsanity is

A FAMILIAL ORGANIC PSYCHOSIS OF ALZHEIMER TYPE IN SIX KINSHIP OF THREE GENERATIONS

LUIGI BUCCI, M.D.¹

In 1907 Alzheimer described the clinical-pathological features of a condition that later came to be known as Alzheimer's disease or presenile psychosis. More than 50 years have passed but the nosological position of this disease remains debatable. In fact, while the symptomatology is well defined and characteristic, the histopathological findings have given rise to several interpretations and theories not completely accepted.

Alzheimer(1) published his first report on a "peculiar disease of the cerebral cortex." A few years later Perusini(2, 3) reported 4 more cases and contributed more substantial data. Simchowicz(4), who studied extensively the histopathology of the brain of senile psychosis, formulated the hypothesis that senile psychosis was due to the argentophilic plaques and the neurofibrillar degeneration always present in the patient's brain. Kraepelin(5) considered this disease as a presenile psychosis, because of the similarity of the histopathological findings and proposed to call it "Alzheimer's disease."

As the knowledge about this disease increased, the hypothesis of Simchowicz became more and more debatable. Many authors reported cases of aged people who, at autopsy, showed the presence of argentophilic plaques and neurofibrillar degeneration and who in life had not shown any signs of senile psychosis. Similar histopathological findings were found in brains of patients who had died from different conditions, demonstrating that neither the argentophilic plaques nor the neurofibrillar degeneration could be considered typical of this condition(6). Schaffer(7) and Lafora(8) reported the presence of fibrillar degeneration of Alzheimer's type in a case of familial spastic paralysis and in one case of schizophrenia. Schnitzler(9) published a case of myxedema with the same findings of fibrillar degeneration; Bogaert and Bert-

rand(10) described both types of lesions in two cases of amyotrophic lateral sclerosis. Barret(11) and Schaffer(7) described Alzheimer changes of neurofibril in the brain in cases of spastic paralysis in a patient 33 years old and in one 28 years old. A similar case is also reported by Braunmuhl(12). The same pathology was reported by Malamud and Lowenberg(13) in the cortex of a 23-year-old man who became demented after an episode of scarlatina at the age of 7. Kleist(14) reported degeneration and neurofibrils in a case of symptomatic psychosis in pseudouremia. Chanutina(15) reported similar findings in a case of Asiatic cholera.

All these reports in such a variety of conditions led many investigators to believe that the histopathological findings described as typical of Alzheimer's disease are far from being typical; they can be produced by different causes which are responsible for some metabolic derangement.

This opinion was strongly emphasized by Braunmuhl(12) who based his conclusions on experimental work. He explained the Alzheimer changes as due to hydration and swelling of the structures previously dehydrated in life. The cause of this change always, according to Braunmuhl, is in the colloidal medium, leading to hysteresis and syneresis of the protoplasm of which the senile neurofibrillar changes are one special form and they may be due to a metabolic as well as an endocrine cause. Literature on the subject contains data concerning the relationship between endocrine disorders and neurofibrillar degeneration.

Schob and Guntz(16) reported a case of pituitary cachexia in a 64-year-old woman with dementia who showed Alzheimer's alterations of the brain. Balli(17), Lewy(18) and Rasdolsky(19) found alterations of the neurofibrils similar to those seen in Alzheimer's in animals after complete removal of either the thyroid gland, parathyroid gland or both. On the basis of these experiences, Grunthal(20) concluded that the

¹ Staff Physician, Rockland State Hospital, Orangeburg, N. Y.

alterations seen in the senile are presenile psychosis and are caused only indirectly by old age.

Alexander(21), on the basis of the experimental work by Lotmar(22) who was unable to demonstrate in humans what other investigators had demonstrated in animals, concluded that an unknown, specific factor is responsible for the histopathological findings.

Recently, in a review of the subjects, Newman and Cohn(23) published a systemic study of 210 patients and reached the conclusion that the findings of Alzheimer's disease are not typical, but they considered the disease as a specific entity. The possibility that Alzheimer's disease might be a heredo-degenerative disease has also been taken into consideration.

The disease has been described in twins by Braumuhl(12) and in father and daughter by Scottky(24). Lowenberg and Waggoner(25) reported the occurrence of the disease in several members of a family, in two generations.

Though this condition described by Alzheimer is still known as a presenile psychosis because the first cases were described in people in their 4th or 5th decade, today it is known that the disease may occur in the 2nd or 3rd decade, therefore the term presenile psychosis is inaccurate and it might better be called Alzheimer's disease. From what has been said one conclusion may be drawn, namely, that there is no agreement about the possible cause of this condition and of its nosological entity.

Several hypotheses have been formulated about the pathogenesis of this condition, which can be summarized as follows (Bini(26)): 1. The "Alzheimer" is a syndrome and not a disease; it is a variation of the presbiophrenia (Fisher, Francioni, Reichardt, Reinhold(26)). 2. It is a well defined disease, both from a clinical and pathological point of view (Alzheimer, Perusini, Frey, Bonfiglio, Runge, Rostroem, *etc.*(26)). 3. It is only a clinical syndrome due to "involutional processes" and characterized by no specific symptoms and at times by neurological signs from spread of foci lesions (Schnitzler, Stief, Marchand, Altman, Vermeylen(26)). 4. It is a clinical syndrome characterized only by the appear-

ance in the presenile age, and by the presence of extensive and severe lesions which partially affect the psychic functions giving rise to false focal symptoms because of the involvement of the mnemonic-associative apparatus (Sterzt, Kehrer, Hilpert, Flugel, Kaplinsky, Hakenbuch, Geier(26)). 5. It is a clinical syndrome which can be caused by different etiological factors, lues, senility and other exogenous causes (Hilpert, Rothschild, Kasanin, Malamud, Lowenberg and Rothschild, McMenemey(26)). 6. It is a well defined disease, more than clinically or histopathologically, in its specific etiology, and is a systemic heredo-degenerative type (Grunthal and Wenger, Bogaert, Maere and De Smedt, Braunmuhl(26)). To this group belong the cases seen in young age and characterized by particular neurological syndromes. Although each of the above hypotheses has its pros and cons, the last, probably of metabolic nature, seems to be the most satisfactory. Only in this way can some cases in several members of the same family be explained. The diagnosis of Alzheimer's disease is relatively easy, particularly when the clinical picture has completely developed.

Usually the appearance of the symptoms can be divided into three stages: The first stage (mild forms of Grunthal(20)) is characterized by rapid and progressive mental deterioration. The onset is, as a rule, insidious and judgment and insight are first affected. Patient is unaware of being sick, and has a tendency to smile when unable to remember some familiar data. The memory is affected from the beginning. A mild state of euphoria can be present but indifference or anergy are not noticeable. The second stage (moderate cases of Grunthal) shows aphasia, agraphia, agnosia and apraxia. According to Reich(21) these symptoms are due to the involvement of the mnemonic-associative apparatus and are characteristic of a "partial dementia." Kaplinski, Hakenbuch and Geier(21) consider these symptoms typical of Alzheimer's disease. The third stage (advanced cases of Grunthal) exhibits complete mental deterioration with regression and appearance of primitive motor activities, such as continuous chewing, sucking and making noise with the mouth. Loss of weight is frequently noticed

and the patient becomes completely anergic, ending his days bedridden.

The diagnosis, except for the atypical forms, does not offer difficulty. The differential diagnosis between senile and presenile psychosis is also simple and the following outlines elaborated by Alexander and Looney(21) may be a useful guide.

Senile Dementia

Change of personality with loss of memory and mental abilities; alteration of libido; insidious onset in severe forms; amnesic delirious syndrome.

Age over 55.

Presenile Dementia

Mild or severe focal symptoms; aphasia, apraxia, agnosia, loss of memory and mental abilities; overactivity; paraphasic talkativeness; occupational hyperactivity.

Age over 45.

Laboratory findings show no abnormal findings in the serological examination of the blood, except in cases of coexistence of lues. The spinal fluid is also negative. Encephalography: there are cases in which the atrophy is very mild, almost absent, and others in which the atrophy is very pronounced. When the atrophy is quite noticeable a dilation of the ventriculi is also present. There is no relationship between degree of atrophy and mental condition as Grunthal(20) first demonstrated. The histopathology has already been mentioned.

Lowenberg and Waggoner(25) reported cases of Alzheimer's disease in several members of a family in two generations. Recently, we have had the opportunity to study a similar instance; in fact, in this person's family a few other members in two previous generations suffered from a condition similar to hers.

Patient was admitted to Rockland State Hospital on July 22, 1961 with the following history: about 4 years ago patient started to show some change in her personality. She began to neglect her usual housework, judgment impairment developed and she became somewhat belligerent in her attitude. For example, she went shopping and bought more than she could pay for or more food than she needed. She frequently turned on the stove and forgot to turn it off. During the 6 months prior to admission, her condition became so serious that she needed continuous supervision, being practically unable to take care of her simplest needs. For a while patient became very tense and nervous. She was

unaware of her impairment and incapacity and did not tolerate help. At this time she was seen in an outpatient clinic and her sister was told that nothing could be done to help her condition. She was therefore taken to this hospital primarily for custodial care.

At admission this 58-year-old white woman is in poor contact and poorly related, showing psychomotor retardation, apraxia, agnosia, agraphia and aphasia. Patient is unable to understand the simplest command. When asked to identify a common object she is unable to do so. When asked her name she is unable to do so and when asked to write it, she holds the pencil upside down. She has practically lost the capacity to write. It is almost impossible to obtain any information from the patient due to her complete disorganization of thoughts.

The physical examination shows a fine continuous tremor of the head, poor balancing and patellar hyperreflexia. The finger-nose and heel-knee tests are poorly performed. No choreiform or athetoid movements. Blood pressure is 200/80. On the ward, patient is idle, seclusive, indifferent and requires continuous supervision. Both history and clinical examination are typical of Alzheimer's disease.

The family history seems to support the theory that the presenile psychosis should be considered as a heredo-degenerative disease. The patient's maternal grandfather died in a mental institution at the age of 67 or 68. The disease started several years before and was characterized by a progressive mental deterioration whose main characteristics were memory impairment, lack of interest and inability to perform any simple act or to recognize familiar objects. The disease started in his middle 50s. The patient became unmanageable toward the end, as well as becoming incontinent. He was admitted to a hospital and died shortly thereafter, bedridden. At the time a diagnosis of "arteriosclerosis" was made. This was in 1910. No autopsy was performed because of religious reasons.

The patient's mother died in 1935 with a diagnosis of "arteriosclerosis" at the age of 52. The disease started in her middle 40s and the first symptoms were vertigo and headache. Slowly the patient began to neglect her homework, became absentminded, developed memory impairment and insomnia. After a few years patient became unable to perform any job, take care of her needs and became confused and disorganized. Toward the end she became irritable and incontinent. She terminated her days bedridden. No autopsy was performed.

Patient's two uncles and one aunt, on her mother's side, died after a long-lasting illness. This was characterized as in all the cases by an insidious, progressive process the main symptoms of which were forgetfulness, loss of interest in usual occupation, inability to perform simple acts and to recognize familiar objects, loss of memory and mental deterioration. At the end the patients became incontinent and bedridden. The cause of death in all these patients was given as "pneumonia." The disease started in their middle 40s and lasted an average of 10 years. In none of them was autopsy allowed by their relatives for religious reasons.

All this information has been obtained from the patient's sister who, at the time of the interview, appeared to be free from any symptoms. She arranged to have the patient released to her custody, because she felt it was her duty to take care of her as a religious obligation.

In summary, 6 members in 3 generations in this family suffered from a condition which can be identified as Alzheimer's disease, inappropriately named also, presenile psychosis.

SUMMARY

A familial organic psychosis of Alzheimer type is described in six kinships of three generations. The literature and the possible theories are reviewed and the hypothesis that Alzheimer is a heredo-degenerative disease of unknown etiology is supported.

BEHAVIOUR THERAPY, SPONTANEOUS REMISSION AND TRANSFERENCE IN NEUROTICS

H. J. EYSENCK¹

Any general theory of neurotic behaviour must attempt to account for the main phenomena in this field of psychology, and its acceptability must in part depend on its success in thus creating a "nomological network" within which otherwise isolated events can be ordered and understood. One of the most important, most universal, and most widely acknowledged of these phenomena is that of *spontaneous remission*; as is well documented in several research reports(1, 2, 14, 18) neurotics tend to get better without any form of specific psychiatric treatment. This improvement appears to be a function of time; Eysenck(5) has suggested the following formula as descriptive of the situation:

$$X=100(1-10^{-0.00435N})$$

where X stands for the amount of improvement achieved in percent and N for the number of weeks elapsed. He comments that "while the exact values in this formula should not be taken too seriously, its general form is of course that of the typical learning curve with which psychologists are familiar."

It is also well-known that psychotherapeutic treatment, whether psychoanalytic or eclectic, does not accelerate this rate of recovery(1, 3, 5, 6, 8, 14, 15, 20, 23). Under these circumstances it may be worthwhile to take a closer look at the phenomenon of spontaneous recovery from a theoretical point of view in order to determine possible causative factors; it is clearly impermissible to implicate "time" as such, because it can only be *events* happening in time which can exert a causal influence, and our formula does not tell us very much about the possible nature of these events. It is the purpose of this article to present a theory of "spontaneous remission"; this theory is derived from a general body of knowledge sometimes referred to as "learning theory"(11, 13). It also links up with a rational theory of diagnosis and treatment

in neurosis which has been called "behaviour therapy"(6, 8) and which purports to achieve results superior to those for which "spontaneous remission" can be held responsible(7, 20).

Before proceeding to a discussion of this theory, we may note with some surprise that what may be called the currently prevailing "orthodox" set of psychiatric hypotheses, which are closely identified with psychoanalytic and "dynamic" notions, have nothing to say about spontaneous remission; indeed, they seem to suggest that such remission cannot occur, or that, where it does, it can only be of very short-term duration. This follows directly from the Freudian notion that neurotic behaviour is motivated by some underlying complex or complexes, and that the treatment of the symptom without some form of "uncovering" of the underlying complexes must lead to a recrudescence of the same, or the appearance of some other symptom. The evidence is decisively opposed to this belief (21, 22) and it is notable that no adequate documentation has ever been put forward by psychoanalytic writers who seem entirely to rely on anecdotal evidence, on repetition of doctrinal pronouncements, and on uncontrolled studies incompletely presented. Such an important point, one might have imagined, should have been established a little more securely before being accepted and interpreted as ruling out of court *a fortiori* all nonpsychoanalytic methods of treatment. As the evidence stands now we may perhaps say that the failure of symptoms to recur after spontaneous remission, or after some form of behaviour therapy, is a decisive argument against the Freudian theory.

How does behaviour therapy deal with spontaneous remission? In order to answer this question we must first state the main tenets of the general theory, without however being able here to bring forward all the supporting evidence; this task has been attempted elsewhere(5, 16, 20). For con-

¹ Institute of Psychiatry (Maudsley Hospital), University of London, England.

venience, we may number the points in order. 1. Neurotic behaviour consists of maladaptive conditioned responses of the autonomic system, and of skeletal responses made to reduce the conditioned (sympathetic) reactions. 2. While the term "symptom" may be retained to describe neurotic behaviour, there is no implication that such behaviour is "symptomatic" of anything. 3. It follows that there is no underlying complex or other "dynamic" cause which is responsible for the maladaptive behaviour; all we have to deal with in neurosis is conditioned maladaptive behaviour. 4. Treatment consists of the *deconditioning*, by reciprocal inhibition, extinction, conditioned inhibition, or in some other way, of the maladaptive behaviour, and the *conditioning*, along orthodox lines, of adaptive behaviour. 5. The treatment is a-historical and does not involve any "uncovering" of past events. 6. Conditioning and deconditioning will usually proceed through behavioural channels, but there is no reason why verbal methods should not also be used; there is good evidence that words are conditioned stimuli which have an ascertainable position on the stimulus and response generalization gradients of the patients(19).

Consider now a typical case history involving the establishment and cure of a cat phobia(9). A traumatic event involving the patient's favourite cat produces a conditioned fear of cats; this develops to such an extent that she is effectively home-bound for many years, refusing to go out for fear of encountering cats. Treatment is by means of graduated presentations of cats (first symbolically, *i.e.*, by words and pictures, then bodily, but at a distance, *etc.*) under conditions of relaxation and parasympathetic stimulation (desensitization, reciprocal inhibition). After a few weeks treatment is completely successful, and a permanent cure achieved (no relapse for several years). In this case history there is no spontaneous remission, and we may enquire 1) why such a remission might have occurred, and 2) why in fact it did not do so.

First, we have a traumatic event which, by means of classical conditioning, produces a conditioned fear reaction to a

previously neutral set of objects, *i.e.*, cats. It is easy to see how this conditioned fear arose, but it is not so easy to see just why it should have persevered so long. Solomon and Wynne(17), on the basis of their work with dogs, have offered the principle of "partial irreversibility" in avoidance conditioning, but it should be noted that the aversive stimuli in their case were probably stronger than in the case of the patient, and also that they report no single-trial learning, as seems to have occurred in this patient. On general learning-theory principles one would have expected the gradual *extinction* of the conditioned fear response in the course of time. Each time the patient saw a cat (the CS), without a recurrence of the traumatic events which precipitated her original fear (the UCS), this unreinforced presentation of the CS should lead to an increment of inhibition potential leading to extinction. Similarly, each time she discussed her troubles with a sympathetic listener this should have had an effect similar to that of "reciprocal inhibition," also leading to extinction of the fear response. In other words, behaviour theory seems to have no difficulty in explaining the extinction of neurotic symptoms by "spontaneous remission"; this extinction is the natural result of the inevitable recurrence of the CS in the absence of reinforcement. We may thus reinterpret our formula for the time course of spontaneous remission by saying, not that it resembles the typical learning curve, but rather that it resembles (and indeed is nothing but) the typical extinction curve. Our hypothesis, then, is that *all neurotic symptoms are subject to extinction*, and that this process of extinction is reflected in observable behaviour in the form of "spontaneous remission." The theory would appear to fit the facts reasonably well, but it would also appear to assert too much; not all cases of neurosis do in fact remit, and a theory predicting universal remission is clearly in need of an extension.

Such an extension is indeed implied in the first of our numbered postulates of behaviour therapy, given above, in which attention was drawn to the importance of "skeletal responses made to reduce the conditioned (sympathetic) reaction." What is asserted here is that in many cases of

neurosis the original stage of classical conditioning is followed by a stage of instrumental conditioning, and that it is this secondary development which makes impossible the process of extinction by removing the conditions of its occurrence, *i.e.*, the presentation of the CS under conditions of non-reinforcement. Consider the events in the laboratory during the extinction of a conditioned response. The dog, lashed to his stand, is presented with the CS a number of times; his conditioned responses get weaker and weaker until finally they cease altogether. This paradigm differs profoundly from that of our patient encountering a cat in the street after her conditioned fear has been established. The patient is not lashed to a stand, and thus forced to witness the conjunction: CS-non-reinforcement; she is free to turn her back and run away. This course of conduct produces an entirely different paradigm, one favourable to the growth of an instrumental response of running away from cats. Simplifying the situation grossly, we may say that what happens is something like this. The patient approaches the cat and experiences a conditioned sympathetic response (fear) which is profoundly disturbing and (negatively) reinforcing. She turns and runs, thus excluding the cat from her field of vision, and also increasing the distance between herself and the feared object. This behaviour reduces the sympathetic arousal, and is thus reinforced by the resulting lessening of fear. The next time the patient encounters a cat, the newly acquired habit of running away will again, and more easily, be brought into play, until finally an instrumental conditioned response of running away is developed to such an extent that it permanently excludes the possibility of encountering the CS at all. In this way the secondary process of instrumental conditioning "preserves" the primary conditioned response; putting the whole matter into psychiatric terminology, instrumental conditioning makes impossible the "reality testing" of the classically conditioned response.

There is no doubt, of course, that in most cases the situation is much more complex than this. The original conditioning is not always, and perhaps not even usually, a traumatic, single trial event; repeated sub-

traumatic trials may produce an even stronger conditioned fear response than a single traumatic event. Little is known about the precise dynamics of this process in individual cases, largely because psychiatric attention has not usually been directed at these events from the point of view of learning theory. Again, few neuroses are mono-symptomatic, and there may be a very complex interweaving of several different habit-family hierarchies (12, 20), each subject to extinction at different rates, and by exposure to different events (CS's). Lastly, experience indicates, and theory suggests, that extinction of conditioned fear responses in one habit-family hierarchy facilitates (through a process of generalization) extinction in others, whether this extinction is occurring during "spontaneous remission" or during behaviour therapy. To mention these complications, to which many others could have been added, is simply to remind the reader that while in principle the explanation of spontaneous remission here given is perhaps correct, nevertheless much experimental and observational work remains to be done before the details of the process can be said to be at all well understood.

It is interesting to note that several observationally well attested phenomena can be brought into this theoretical framework. Consider the pilot who has crashed his plane, or the cowboy who has been thrown by his horse. It has often been stated that if the pilot, or the cowboy, is allowed to walk away from the plane, or the horse, he will never fly, or ride, again. If, however, he makes himself fly or ride again immediately, then there will be no such disastrous after effect. We may regard the original event as productive of a conditioned fear reaction to planes or horses; this by itself would not be strong enough to preclude future resumption of the particular activity which produced the traumatic event. However, bodily removal from the now feared object produces instrumental conditioning, along the lines indicated above, and it is this additional process of avoidance conditioning which, when superadded to the original classical conditioning, makes the total aversive forces too great to be overcome.

Much the same explanation could be given to the well-known fact that psychiatric casualties during the war tend to go back to combat easily and readily if treated in front-line conditions, but hardly ever if sent back to base hospitals first and then treated. Here also the part played by classical conditioning is fundamental, but can be counteracted by a process of extinction in the front-line situation; if instrumental conditioning is allowed to add its share, *i.e.*, through removal of the patient to a base-line hospital, prognosis is poor because now *extinction is made almost impossible!* Other applications of this general theory will easily occur to the reader.

This may be an appropriate place to consider another event which is frequently claimed to be an almost invariable concomitant of the therapeutic process, namely *transference*. Here there is indeed a psychoanalytical theory to explain the phenomena alleged to occur, namely, the development of certain strong emotional feelings on the part of the patient for the analyst (and perhaps vice versa). This theory depends on the *transfer* of certain childhood emotions originally attached to the parents; these, it is suggested, are transferred to the analyst. Now there is little doubt that such emotional dependence does in fact occur, although there is very little well-established evidence to suggest just how frequent, how strong and how lasting such emotions are. Indeed, similar facts have been known to occur in the Catholic confession for many hundreds of years, and the priest taking the confessional is taught how to deal with these feelings. How does behaviour theory account for the facts?

In the first place, it is important to dissociate T_F (the facts conveniently summarized under the heading "transference" and T_T (the psychoanalytic theory of literal "transference"). The writer would hold that T_F is a real phenomenon requiring an explanation, but that T_T is a speculative theory without any sound experimental background. It is unfortunate that the name for T_F immediately suggests the truth of T_T ; it might be better if a more neutral name were to be chosen. In any case, it will be clear from what has been said that when it is stated that behaviour therapists

reject the notion of transference, what is meant is a rejection of the speculative theory, and not of the facts themselves.

As for an alternative theory, consider the position of the therapist in his relation to the patient. Whether because of spontaneous remission, or because of the reciprocal inhibition produced by the permissive attitude of the therapist, there is a tendency for the patient to improve. Consider the therapist as a CS in this situation, consider the unknown cause of the improvement as the UCS, and consider the improvement and its attendant emotions and feelings as the response. It will be clear that there will be a tendency for the therapist to be credited with the properties of the UCS, through a process of classical conditioning, and that attitudes and emotions appropriate to the latter are shifted to the former. A well-known example is given by Pavlov, who reports that when an electric light was used as the CS for a feeding-salivation experiment, the dog after a while licked the light bulb! In other words, there is a transfer of reactions appropriate to the UCS to the CS. As an example of such a transfer in a human subject, consider Connie, a 5-year-old girl being treated for enuresis by means of the well-known bell-and-blanket method(10). When the first signs of a cure became noticeable after 4 applications, she spontaneously kissed and hugged the red light on the apparatus which illuminated the switch activating the bell, saying "The ting-a-ling is my best friend." No doubt it would seem almost sacrilegious to many psychiatrists to consider this analogous to full-blown "transference," but the fundamental identity or lack of identity of the processes involved must be established on a more experimental basis than mere shocked disbelief. The explanation here given accounts for the facts as well as does the Freudian, and in addition it is based on well-documented laboratory experiments; nevertheless it would be most desirable to submit it to direct experimental investigation before regarding it as anything but an hypothesis.

This paper has been kept short on purpose, being purely theoretical in the first place, and lacking direct experimental support in the second. It would be idle guess-

work to extend speculation beyond the points raised, although promising extensions do suggest themselves in considerable number. Its primary purpose, however, will have been served if it reawakens interest in the phenomena of spontaneous remission and transference, and leads to more experimental investigations of these interesting and perhaps even crucial events in the life-history of the neurotic. The formulation of an explanation in terms of learning theory here given is not the only one possible, and it may not be the one preferred by other psychologists; it may nevertheless repay investigation. But primarily it is hoped that the reconsideration of these phenomena will serve to raise doubts about the adequacy of that "premature crystallization of spurious orthodoxy" which is present-day psychoanalytic theory.

APHASIA : A REVIEW

M. H. CHARLTON, M.D.¹

In 1861 Broca opened the subject of aphasia for medical discussion and research. As if to celebrate the centenary of this event, three books (1-3) have recently been published on the subject of aphasia: so it seems appropriate to review our present knowledge both for celebration of these hundred years, and because, as I hope to show, there may be reasons for expecting new advances on the basis of recent work. In addition, emphasis will be laid on what there is of clinical value in our present understanding, and on what I think is a substrate of agreement by most authors, a substrate obscured by theories and innovations of terminology.

The word "aphasia" in classical Greek was used for the speechlessness induced by strong emotion (fear or surprise). Today its use is restricted to disorders of speech central in origin but organic in nature. Thus the term would neither include an hysterical aphonia nor disorders due to lesions of the motor apparatus (*i.e.*, the dysarthria of lower motor neuron and muscular disease, the scanning speech of cerebellar lesions, the explosive utterance of pseudobulbar palsy, and other less well-defined disorders such as the speech of parkinsonian patients). In addition to these restrictions the word has also undergone an extension of meaning to include defects of comprehension, where these are of cerebral origin and not consequent on, *e. g.*, eighth nerve deafness.

Before Broca in 1861 it is possible to discern glimmerings of discussion in earlier writers such as Dax; but aphasia before Broca was like the theory of evolution before Darwin. His contribution was revolutionary for two reasons, both of which have had and will continue to have implications far beyond the field of aphasia. Firstly, he introduced the concept of cerebral dominance, or, as I would rather say, asymmetry of hemispheric function for higher mental functions. Since the experience of

Hippocrates with traumatic cases, it had been known that the right hemisphere controlled the left half of the body in crude motor acts, and the left hemisphere the right half of the body. But on the basis of his twenty patients Broca enunciated the theory that "one speaks with the left hemisphere" ("on parle avec l'hémisphère gauche"). Repeated series of patients studied since that time have only served to reinforce the essential truth of his observation. It seems that in the overwhelming majority of right-handed people the conceptual aspects of speech are dependent on the integrity of the left cerebral hemisphere. In left-handed subjects the question is more complex. Over half of them seem to have a left hemispheric dominance for speech, despite their left-handedness. Others have a right hemispheric dominance or a mixed dependence on both hemispheres. This observation of Broca thus opened the door to a new world of questions about psychophysiological function. For example, we would like to know why the relation between speech and handedness exists, and, indeed, the relation between genetic endowment and environment in the determination of handedness. (In his well-written but somewhat overargued book *The Master Hand* Dr. Blau attempts to show that dextrality and sinistrality are entirely of environmental determination, although some of the evidence he himself adduces, such as Gesell's twin studies,² surely disprove his view.) In addition, the discovery of dominance for speech was followed by observations of hemispheric dominance for cognate mental functions such as reading, writing, calculation, and the appreciation of music, as well as less obvious factors such as the constructional apraxia found in lesions of the left parietal lobe. More recently it has been pointed out that while the left hemisphere may be dominant for speech and related activities in right-handed subjects, the so-

¹ Columbia Presbyterian Medical Center, New York, N. Y.

² Concordance for handedness was found in all but one of 253 pairs of identical twins, but of 161 dizygotic pairs 26 were discordant.

called "minor" hemisphere, the right, may play a preponderant part for other mental functions. For example anosognosia (neglect or denial of a hemiplegic limb) is common in right hemispheric lesions, and rare in left; prosopagnosia (inability to recognise faces, confusion of sexes, and similar disorders)(4) seems commoner with lesions of the right hemisphere; and it has been suggested that the occurrence of complex visual hallucinations in temporal lobe epilepsy is in favor of localisation of the lesion in the "nondominant" hemisphere. On these subjects it is possible to think of many fruitful questions for research(5).

Apart from the matter of cerebral dominance, Broca's contribution raised the question of cerebral localisation of higher mental functions. Dominance is itself a crude type of localisation; so it was natural to ask whether the different categories of speech disorder could be, as it were, "sub-localised" within the dominant hemisphere. For it seemed to be agreed that there were different species of aphasia, although writers might attempt to be original, while merely introducing a new terminology. These may be listed as follows:

1. *Expressive*: Synonyms for this are subcortical motor, verbal, and "Broca's." In this type of aphasia the patient retains ability to comprehend spoken speech, but is unable to speak himself. Included also are patients who retain a vocabulary of one or two words, usually "Yes" and "No." Sometimes these patients' vocabulary will be restricted to an oath, which they will use for any purpose, to express any proposition or feeling. The most famous patient of this type is probably Baudelaire, who during his aphasic period could only say "cré nom." This preservation of oath when declarative speech is absent might be taken as a text for a sermon on how much more deeply rooted are our emotions than our intellect.

2. *Receptive*: Synonyms are word deafness, auditory, sensory, and semantic aphasia, and "Wernicke's" aphasia, since Wernicke wrote particularly about this type. Here the defect is the reverse of type 1, since the patient has a defect of comprehension but is able to express his wants and feelings. Brain quotes a patient who said "Voice comes but no words. I can

hear, sounds come, but words don't separate. There is no trouble at all with the sound. Sounds come, I can hear, but I cannot understand it."

3. *Syntactical*: Synonyms are subcortical and conduction aphasia, paraphasia, paragrammatism, and jargon aphasia. Here the patient's speech is marred by poor grammar, omission of certain parts of speech (leading to a so-called "telegraph style"), and may even approach a word salad. This form of aphasia is often accompanied by defects of comprehension and is then called "central" aphasia by some. But it seems on occasion to occur alone.

4. *Nominal*: Sometimes called "Anomia."³ In this form of aphasia the patient can understand speech and form sentences, but finds difficulty in naming objects when requested. It often seems strange that a patient able to form such elaborate periphrases as "thing you tell the time with," is yet unable to say "watch." *A priori* one might be inclined to dismiss nominal aphasia as a *forme fruste*, a touch, as it were, of expressive aphasia, but, as we shall see, there are good reasons why it is assigned to a category of its own.

Although, by the nature of the clinical causes, the above types of aphasia may occur in mixed forms, there seems to be agreement that they can and do occur frequently enough in "pure culture" to make the above classification reasonable. Thus the question arises naturally whether we can localise the different types in different areas of the dominant hemisphere. Here again there seems to be agreement that the expressive difficulties tend to occur with more anteriorly placed lesions and that receptive difficulties more posteriorly in the "speech quadrilateral" (an area which stretches from the third frontal convolution anteriorly to the region of the angular and supramarginal gyri posteriorly). Syntactical difficulties are conventionally assigned to lesions affecting the commissural fibres between these areas. Nominal aphasia seems to be produced nonspecifically from a wide area

³ Anomia (= "lawlessness" in Greek) was originally applied to the antisocial behavior of post-encephalitic children, but, by confusion of the word "nominal" (from Latin "nomen" = a noun), has invaded the field of aphasia.

of cortex both within and outside the speech quadrilateral. Authors may differ in the degree to which they are prepared to be precise in their localisation of the different forms of aphasia, but of the general tendency of anterior lesions to give rise to expressive difficulty and the posterior to receptive there seems to be little disagreement.

The evidence adduced for these localisations had until recently been clinicopathological, *i.e.*, the correlation of the type of aphasia found clinically, with the post-mortem findings. There are obvious difficulties and objections to such crude correlations. But recently they have received some striking confirmation from the work of Wilder Penfield and his associates, who observed the defects of speech consequent upon electrical stimulation of different areas of the exposed cortex of conscious man, as well as those following restricted cortical excisions. They tended to confirm the difference between anterior and posterior lesions, as well as the nonspecificity of the localising value of nominal aphasia. (Incidentally they showed the possible importance for speech of an area outside the "speech quadrilateral," the "supplementary motor area." This would correlate with the speech disturbances occasionally found in parasagittal meningiomas(6).)

On the basis of the above categories of aphasic defect found clinically and the anatomical substrates found pathologically there has arisen a profusion of semiphilosophical theories, either taking the form of

diagrams joining the various "speech areas" in the form of electrical circuits, or of logical schemas purporting to explain the cerebral mechanisms behind speech and its acquisition and decay. All of these theories are open to objections of a logical and philosophical kind, and are in any case without any evidence to support them. But even the little we know seems encouraging in view of the agreement between so many authors, and the possibilities for the future. I would venture to prophesy that these lie in two directions : firstly, in a more rigorous examination of the case material such as I have suggested in questions of handedness, dominance, the relation of speech defects to the loss of other faculties, *etc.*; secondly, in the employment of quasi-experimental techniques such as those used by Penfield in electrical stimulation of the conscious cortex. Such techniques have often invaded biological studies in the past half-century to their great enrichment.

THE ARMY, THE SOLDIER AND THE PSYCHIATRIST

J. THOMAS UNGERLEIDER, M.D.¹

The purpose of this communication is to re-examine some concepts of intensive psychotherapy, particularly as they apply to the military population. Psychotherapy has been defined in many ways although the difficulty in defining it, as well as in learning, understanding and applying its principles, has been noted(1). It has been defined broadly as any emotional contact that makes somebody feel better, and more narrowly as "an interview technic practised purposively by people trained to do it, who aim at getting the patient better and who, in the patient's eyes, are healers"(2). It is this latter definition which is most useful for our purposes. By intensive therapy is meant that which deals primarily with intrapsychic phenomena, has insight into unconscious determinants of behavior as a goal, and is not restricted to providing support and environmental manipulation.

The proposal to be advanced here is that, as defined above, effective intensive psychotherapy among active duty military personnel (and particularly with outpatients) is not feasible and perhaps not even possible. Those factors inherent in the military situation and those operative upon both the military patient and the military psychiatrist which reduce the effectiveness of such therapy will be examined. These observations were made at a large Army basic training center but the principles seem applicable to other military installations as well.

The Military Situation. Szasz has called attention to the psychotherapeutic difficulties which arise whenever the therapist has divided loyalties. He feels these are inherent in the training analyses of candidates in psychoanalytic institutes, in the military service, in prisons and in several other situations(3, 4). In October of 1920 Freud presented a report to the Austrian Medical Commission, investigating alleged harsh-

ness in psychiatric treatment methods among Austrian military doctors in World War I. Freud pointed out the conflict between a doctor's duty to put his patients' interests always first and the demand of the military authorities that the doctor should be chiefly concerned with restoring patients to military duty(5). Thus we hear the oft repeated Medical Corps phrase "You are an [Army] officer first and a doctor second"—and, we might add, a psychiatrist third. It is this split loyalty which, by its very nature, precludes effective intensive psychotherapy.

The motto of the Medical Corps "To Conserve Fighting Strength" is one of the primary guides for the Army psychiatrist. Duty performance, not personal happiness, thus becomes both the criterion for individual and group effectiveness and an index of mental health as well(6). When the soldier does not perform his duty, for whatever reason (including symptoms), several alternatives are possible. He may be counselled or admonished, transferred to another duty assignment, hospitalized, punished or separated from the service. And, this is the crux of the matter, it is the psychiatrist who largely decides what becomes of the soldier who does not perform.

He is guided by a set of regulations, to be sure, and the usual military tribunals still exist but it is the psychiatric certificate that is crucial to the soldier's disposition. How then can we expect the soldier to place enough trust in the Army psychiatrist to voice those very personal and perhaps even antisocial thoughts and feelings so necessary for progress in intensive psychotherapy?

The Patient. And what of the soldier himself? He lives in a world of physical activity where the premium is on strength and duty performance, not on introspection and verbalization of personal problems. It is a world of frequent, and often sudden, temporary or semipermanent changes in duty station.

The soldier is concerned about his career; he is often preoccupied with what information will be placed in his medical

¹ Formerly, Chief, Mental Hygiene Consultation Service, U. S. Army Hospital, Fort Ord, Calif. Presently, Asst. Prof. of Psychiatry, Neuropsychiatric Institute, U.C.L.A. Medical Center, Los Angeles, Calif.

records and how this will affect his next promotion. He is particularly reticent when it comes to revealing intimate information about himself. For example, he knows that army regulations require separation from the service for any homosexual acts (even repeated thoughts will do) should they be revealed. At our post few officers will come to the Mental Hygiene Clinic for help because of this concern about privileged communication. They seem to know just whom the psychiatrist must primarily represent. Some even object to their wives seeking help for the same reasons.

Of course most active duty personnel come to the Mental Hygiene Clinic psychiatrist quite frankly to ask for discharges, compassionate transfers, or changing of overseas orders and not for relief of symptoms. We frequently hear the comment "I heard that this was the place to get my orders changed" (or to get out of the Army). Those few soldiers who initially seek help for symptoms soon focus upon real or imagined injustices on the job or in duty assignments.

So psychotherapy becomes possible only under one of two conditions: 1. If there is some sort of agreement on the part of the psychiatrist not to record or reveal everything which occurs during the interviews (an agreement that makes the psychiatrist negligent in his efforts to represent the military, as well as derelict in his duties as prescribed by Army regulations) or, 2. If the patient withholds these "illegal" thoughts or acts from the psychiatrist. It is not hard to imagine the therapeutic difficulties under either condition. Concerning the former we cite Waelder: "In totalitarian societies of our time . . . every day will the analyst . . . find himself confronted with the alternative of either, through his silence, becoming the accomplice of an illegal act—*qui tacet consentire videtur*²—or setting

himself up as an executive agent of the government . . . the analysis itself will probably be wrecked in either case" (7). And, for the latter condition, one is reminded of Freud's comment on withholding information (in analysis): "It is a most

remarkable thing that the whole undertaking becomes lost labour if a single concession is made to secrecy" (8).

The Psychiatrist. And what of the Army psychiatrist? He, like any soldier, must train for combat and be prepared for sudden transfer to areas of crisis. His training must include overnight field trips, weapons firing on the range, gas chamber exercises, map reading tests, etc. The psychiatrist also has frequent military, medical and psychiatric obligations off the military post. The author made a trip to a prison some 300 miles away to evaluate an inmate and a longer trip to screen applicants for the United States Military Academy. He received a week of schooling in leadership off the military post and served a tour of duty as medical officer at a summer troop training camp (as well as working in post medical dispensaries and emergency room).

The result of these military demands on the psychiatrist's time, as he also functions as soldier, officer and physician, is a continuous cancelling and juggling of appointments from week to week with both patient and psychiatrist uncertain when they will next meet. How then can the military psychiatrist be expected to employ intensive psychotherapeutic technics when one of his most important tools, a regular appointment time, cannot be guaranteed to his patients.

Comment. Thus the active duty soldier cannot be expected to effectively utilize the military psychiatrist in a traditional way. Recent military publications now stress the importance of preventive psychiatry and of working with group characteristics rather than with individual problems in the military population (6, 9, 10). On the job psychiatric evaluation with improved performance of duty is stressed and much enthusiasm has been generated among both medical and line officers for this Mental Hygiene "Field Clinic" type of program.

SUMMARY

Some concepts of psychotherapy in the service have been discussed, considering the military situation, the military patient and the military psychiatrist. The proposal has been advanced that effective, intensive psychotherapy among active duty military

² He who keeps silent gives the impression of agreeing.

personnel is not feasible and perhaps not even possible.

ABSTRACTS

A PSYCHIATRIC CASE REGISTER CONFERENCE

ANITA K. BAHN, Sc.D.¹

Epidemiologic information on patients of psychiatric hospitals and outpatient facilities have been available for a number of years through a nationwide reporting program. However, because of the increase in number and types of psychiatric facilities and the rapid flow of patients among these facilities, reports from different facilities referring to the same individual must be collated or linked in order to provide a coordinated record for the individual. In essence, such record linkage constitutes a case register.

Two statewide and five community psychiatric case registers have been established to date. On June 7-8, 1962 at Bethesda, Md., a conference of representatives of these 7 case registers was held under NIMH auspices² 1) to review the on going psychiatric case registers in the country, their objectives, and preliminary findings, 2) to discuss common problems in collection and analyses of data, and 3) to develop, where possible, comparability among registers with the goal of designing cooperative studies.

The principal conference topics of interest to the psychiatrist were: the uses of psychiatric case registers, reporting aspects, and the need for and confidentiality of identifying data.

Uses of psychiatric case registers. Uses of the register may be summarized under two headings: operational research and epidemiologic research.

Clinicians and administrators want to determine the answers to a series of questions: What are the needs and the fate or prognosis of a patient population? How large is the patient population? How long is the typical treatment period? Is treatment provided in two or three different facilities or in only one? If the former, what is the sequence of care? What proportion of the

treatment time is spent in an institution? Does the patient spend long intervals at home or does he go rapidly from one institution to another? What happens to the individual who drops out of clinic care—is he likely to return to a psychiatric facility?

Without a case register, one cannot identify the same individual as he enters the system of psychiatric facilities, moves around in it, leaves it, and perhaps re-enters it later. At present, we may obtain data from all treatment settings but cannot follow an individual through them. Therefore, some persons are counted a number of times and there is no clear understanding of the logistics. We cannot say with certainty how many individuals with certain characteristics received care during a one- or two-year period. This study of the relationship of the various kinds of psychiatric facilities to the various kinds of patients may be called operational or administrative research.

Epidemiologic research is also facilitated by the case register. Answers can be obtained to such questions as: What is the course of illness following first clinical contact? What is the frequency and duration of recurrent episodes of care and the eventual outcome? How do the reported diagnoses and symptoms change with time and how reliable is the diagnostic classification? How does the fate of the person diagnosed relatively early in the course of his illness differ from that of the person first diagnosed at a later stage? Do persons identified through community surveys or other medical records as "high risk" groups actually become mentally ill at a greater rate than those not so earmarked? What follow-up services aid in the prevention of readmission?

Thus, a register is a mechanism for closing some of the gaps that now exist in our administrative and epidemiologic knowledge of mental illness.

Reporting aspects. For purposes of mor-

¹ Chief, Outpatient Studies Section, Biometrics Branch, National Institute of Mental Health.

² Public Health Reports, Dec. 1962.

bidity studies, a case register should include all mentally ill individuals who are identified by case finding and service agencies but data are obtained primarily from public facilities. Private psychiatry would seem as important a source of information as public psychiatry since patients frequently move from one type of care to another. Also, the distribution of mental disorders by demographic and socioeconomic characteristics and the lifetime pattern of disease cannot be studied adequately without data from private psychiatrists. Because of its research potential, it is probable that many private psychiatrists would wish to report to a register which adequately safeguards patient identity. Data from one of the registers in which half of the cases reported during the first year were private patients illustrate the feasibility of obtaining reports from private psychiatrists and the importance of such data.

Continued reporting interest and cooperation is necessary in order that complete and accurate information flows into the register. Obviously, the research output can be no better than the quality of data input. Registers should represent a cooperative research program in which the clinicians participate in determining the data to be collected and in designing the research studies and statistical analyses, both on the entire register population and on the agency's own patients. Data "feed-back" through periodic and special statistical reports was considered essential. Involvement of psychiatrists, sociologists, demographers, and others in this research will enhance its intrinsic value and broaden its application.

Identifying data. The register staffs agreed that no method exists for linking reports on persons seen by different facilities unless the patient's name is reported. This fact is emphasized because of the belief by some that record linkage is feasible without name reporting. However, no preassigned person-number is available for all individuals; Social Security numbers, for example, pertain to only a selected portion of the population. A number of persons have the same birthdate, and furthermore, the birthdate is often inaccurately reported. No unique factor or combination of factors without name,

therefore, is available for record linkage. For these reasons the reporting of a patient's name has been supported by the executive committee of the American Psychiatric Association, which stated that, where adequate safeguards are provided, supplying a patient's name, address and diagnosis in governmental reports comes within the purview of ethical practice.

Once records are linked, identifying data can be coded, placed on electronic tape, or otherwise dissociated from the psychiatric data file. These and other safeguards with regard to identifying information reported to the register are both desirable for the patient, and necessary to obtain reporting cooperation. If research is the sole aim of the register, assurance should be given to reporting agencies and physicians that the register will not be used for any purpose other than research. If direct service or case management are additional register objectives, reporting agencies should be assured that identifying information will be used only for these purposes. Legislation which protects the confidentiality of identifying information collected in such research surveys is recommended.

SUMMARY

Case registers have long been a tool for administration and for epidemiologic research in tuberculosis, rheumatic fever, venereal disease, and cancer. Their use as a research tool in mental illness is relatively new. Mental disorders pose problems of definition and classification that are different from problems faced in other disorders; except for the organic disorders and suicide, associated death is less common than with some other illnesses, and the impact of mental illness on the individual and the community is unique. Many problems arise, therefore, in the establishment of psychiatric case registers which require new solutions and sophisticated methodology. But the yield to the psychiatrist, program planner and other interested persons in terms of new knowledge in this field may be immeasurable.

The comments of psychiatrists and other professional persons on this new program are invited.

DRUG-WITHDRAWAL PSYCHOSES

I. PIERCE JAMES, D.P.M.¹

Isbell, *et al.*(1), showed that when the drug was abruptly withdrawn after a period of chronic barbiturate intoxication an acute withdrawal psychosis clinically resembling delirium tremens occurred in 3 of 5 cases studied. Similar acute withdrawal psychoses have also been reported in association with other drugs having a hypnotic action on the CNS(2, 3). In the writer's experience this condition is not uncommonly encountered in general hospital practice—although its nature is not always recognised.

Habituation and addiction to sedative drugs are much more prevalent than is often realized(4, 5). However such patients seldom disclose their addiction voluntarily and the symptoms of chronic drug intoxication (depression of mood, irritability, poor memory and concentration, episodic drowsiness and ataxia, *etc.*) may mimic other forms of psychiatric, neurological or medical illness. If such a patient is hospitalized for investigation, *etc.* (and consequently deprived of his customary dose of the drug concerned), he may develop a withdrawal psychosis 2 to 3 days after admission. The course and clinical features of acute sedative drug withdrawal psychoses may be identical with those of delirium tremens. However when no history of alcoholism is forthcoming (and if the patient does not disclose his drug consumption) the episode is usually regarded as a toxic or infective delirium and the physician is surprised when subsequent investigations fail to disclose any underlying pathology.

The three patients described below developed a drug withdrawal psychosis between 24 and 56 hours after admission to a general hospital. All had been addicted to and consumed large quantities of some sedative drug prior to admission but had not disclosed the extent of this to the hospital staff. In each instance excessive alcohol consumption could be discounted.

Case 1. A 42-year-old single woman had

been under psychiatric care for 5 years and habituated to various hypnotics.

In June 1962 she was admitted to the surgical ward of a general hospital for investigation of abdominal pain. On admission she was noted to be 'excessively drowsy' but next day was 'agitated and restless.' She became acutely disturbed 48 hours after admission and presented the clinical picture of delirium tremens. She was totally disoriented in time and place and vividly hallucinated. She answered hallucinatory voices and reacted violently to bodily hallucinations—including abdominal and genital sensations which she interpreted as labor or coitus. Her delirium remitted after 4 days and it was learned that she had been taking large quantities of chloral hydrate (over 6.0 gm. per day) prior to admission. Extensive clinical and biochemical investigations disclosed no other cause for her delirium.

Case 2. A 46-year-old woman had been admitted to a general hospital on three occasions between 1958 and 1960. On each occasion she had developed a confusional psychosis with agitation, disorientation, hallucinations, *etc.*, but extensive investigations had not disclosed any pathology to account for her delirium and the nature of her illness remained obscure.

In July 1961 the patient was transferred to a psychiatric reception unit under certificate with the diagnosis of delirium tremens and when seen there by the writer presented the typical features of that condition. Three days previously she had been admitted to a private hospital and had become acutely disturbed 36 hours later. The husband was indignant at the diagnosis. He insisted she did not drink—but stated that for a long time he had found half-empty packets of carbromal tablets hidden in her room. She disclosed that she had been taking 20 or more tablets a day for years.

Scrutiny of the hospital records showed that on each occasion her sensorium had been intact on admission but that she had become delirious 2 to 3 days later. For this reason (and as her serum bromide was below 80 mgs.%) carbromal-withdrawal and not bromism was almost certainly the cause of her confusional psychosis.

Case 3. A 40-year-old woman was admitted to hospital because of barbiturate addiction. For some months she had been taking 15 or

¹ Hon. Psychiatrist, Royal Perth Hospital, Perth, Western Australia.

more capsules of Nembutal (sodium pentobarbital 1.5 gm.) per day. The pentobarbital was withdrawn and in spite of chlorpromazine therapy she developed a marked withdrawal state with agitation and tremulousness, but remained well oriented and reasonably cooperative. She had a major epileptic fit 56 hours after admission and after recovery from this she became acutely disturbed, disoriented, deluded and hallucinated. The clinical picture resembled that of delirium tremens. Her delirium remitted over the space of 48 hours but she remained very tense and tremulous for some days.

Although delirium tremens is a common clinical condition, perusal of contemporary textbooks of psychiatry reveals some controversy over its precise aetiology.

Mayer-Gross, *et al.* (6), write "it is now probable that the direct cause is a nutritional deficiency caused by or associated with alcoholism," but Thompson (7) states that it is the "direct result of the effect of alcohol on the brain" and "not due to avitaminosis or other nutritional deficiencies."

However most authors agree that alcohol withdrawal is a usual if not invariable antecedent to the delirium tremens. Hart (8) regards delirium tremens as a variant of the alcohol withdrawal syndrome which occurred in 39 of 175 patients studied by him with this syndrome.

In the writer's view there are reasons for regarding the syndrome of delirium tremens simply as the occurrence of a confusional psychosis in association with the alcohol (or drug) withdrawal syndrome. The form and content of the delirium is determined by the psychic and somatic manifestations of the withdrawal state (the restless agitation, tremulousness, rebound ataxia, startle phenomena, *etc.*, are also seen in the withdrawal syndrome without delirium; whilst the characteristic haptic and motility hallucinations probably occur as a confusional misinterpretation of sensations arising peripherally or within the hyper-excitable CNS).

This association may arise spontaneously as a severe withdrawal reaction after sudden or relative deprivation of alcohol. It could also occur if a confusional state develops (following an epileptic fit, as a toxic mani-

festation of inter-current infection, dehydration, metabolic disorder, *etc.*) during a period of chronic alcohol intoxication and leads to withdrawal of alcohol because the patient is too disorganized to continue his drinking or is otherwise deprived of his customary supply.

If this view of delirium tremens is correct then there is no essential difference between the tremulous withdrawal psychosis of barbiturate addiction and the delirium tremens of alcoholism. The three patients described developed an acute withdrawal psychosis indistinguishable from delirium tremens following withdrawal of chloral hydrate, carbromal and pentobarbital respectively.

SUMMARY

Three patients who developed drug-withdrawal psychoses clinically resembling delirium tremens two to three days after admission to a general hospital are described. All three had been addicted to a hypnotic drug (chloral hydrate, carbromal and sodium pentobarbital respectively) prior to admission but had not been taking alcohol.

It is suggested that the syndrome of delirium tremens results from the association of a confusional psychosis with the alcohol (or sedative-drug) withdrawal syndrome and that the tremulous withdrawal psychosis of sedative drug addiction and the delirium tremens of alcoholism are clinically identical.

THE RELATIONSHIP BETWEEN SEROTONIN ANTAGONISM AND TRANQUILIZING ACTIVITY¹

D. M. GALLANT, M.D., M. P. BISHOP, Ph.D.,
C. A. STEELE, M.D., AND C. D. NOBLIN, Ph.D.²

Methysergide, 2-methyl lysergic acid butanolamide (UML-491),³ is considered to be the most potent serotonin antagonist available at the present time. It has consistently shown maximum antiserotonin activity against serotonin edema induced in rheumatoid patients and maximally inhibited the bronchospasm induced in guinea pigs by serotonin aerosol (2).

A fair degree of correlation has been reported to exist between the central serotonin antagonist activity of the phenothiazines and their tranquilizing activity in laboratory animals (3, 4). The benzyl analogue of serotonin, BAS, an entirely different type of compound with a definite antiserotonin effect, was evaluated in a group of chronic psychotic female patients, and the most prominent beneficial action seen in 22 of 24 patients was that of tranquilization (2).

However, at least one serotonin antagonist, BOL-148, has shown no tranquilizing activity although some sedative value has been attributed to it (1).

RESEARCH DESIGN

In view of these divergent findings, it was decided to investigate this area further on a clinical level. Under double-blind conditions, effects of the new compound methysergide (UML-491) were contrasted with effects of placebo and chlorpromazine in a group of chronic schizophrenics who had been off all medications for at least 60

days. Forty male and female subjects were divided at random into three groups, equated on such variables as sex, age, length of hospitalization, *etc.* The total period of study was 12 weeks, with maximum dosage of chlorpromazine (800 mg. daily) and methysergide (16 mg. daily) attained at the beginning of the fifth week. Measures employed in the evaluation of drug effects included the Lorr Psychiatric Rating Scale, Overall and Gorham Psychiatric Rating Scale, independent global ratings of improvement by two psychiatrists and the research nurse, the Tulane Research Battery of psychological tests, and routine laboratory measures.

RESULTS AND CONCLUSION

None of the rating measures employed demonstrated any difference in therapeutic effect between methysergide, the most potent antiserotonin drug available, and placebo. Chlorpromazine did produce a definite beneficial effect, with 56% showing significant clinical improvement over their baseline studies. There was excellent reliability among the various clinical measurements.

These results would appear to question the concept of a direct relation between serotonin antagonism and tranquilizing activity.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

VALIDATION OF THE DIFFERENTIAL TREATMENT SUCCESS OF "A" AND "B" THERAPISTS WITH SCHIZOPHRENIC PATIENTS

BARBARA J. BETZ, M.D.¹

A follow-up study was done on discharged patients who were classified as "improved" or "unimproved" in the Whitehorn and Betz studies(1-3). The readmission rates of the patients during the 5-year follow-up indicate that the original assessments, based on psychiatric judgment and patient behavior, had a significant predictive validity.

In 1954 Whitehorn and Betz reported the results of research concerning the characteristics of physicians who were differentially successful in treating hospitalized schizophrenic patients at the Henry Phipps Psychiatric Clinic. From a group of 35 resident psychiatrists of comparable clinical experience 7 were selected who achieved a high "improvement rate" and 7 were selected who achieved a low "improvement rate."

"The improvement rate of schizophrenic patients achieved by each of the 35 physicians was . . . calculated by dividing the number of patients discharged as 'improved' by the number treated. The 35 physicians were then listed in descending order. The improvement rates were found to range from 100.0% to 0.0%; the average improvement rate was 56.6%. The 7 high-ranking physicians (. . . referred to as group A physicians), with improvement rates ranging between 68.0% and 100.0% (average 75.0%) and the 7 low-ranking physicians (. . . Group B physicians) with improvement rates ranging from 0.0% to 35.0% (average 26.9%) . . ." were selected and compared (1).

The two groups were compared relative to the kinds of relationship formed with the patient, to the doctors' perceptions of patients as recorded in their diagnostic formulations, to the type of strategic goal selected by the physician and the type of tactical pattern(2). The A and B doctors could be differentiated from each other by such patterns. A further study was done in which the treatment results of "an entirely new series of patients," 109 hospitalized schizophrenic patients, were evaluated. In this study the research results were consonant with the earlier findings (3). It was further found that the A and B doctors could be differentiated from each other by the use of selected items and scales of the Strong Vocational Interest Inventory(4).

For the purposes of these studies the patient's discharge status, "improved" or "unimproved," as recorded in the medical record, was used as the dependent variable. The following criteria were used to arrive at the judgment whether a patient was to be considered improved or unimproved: the clinical appraisals of the treating physician, senior resident psychiatrist, senior consultants and psychiatrist-in-chief of the clinic; also, the disposition of the patient at the time of his discharge, the patient's increased participation in the clinic activity programs, and changes in Behavior Chart(5) markings which were kept by the nursing staff.

In the years subsequent to the above studies, 5-year follow-up data have been obtained on 155 of the 209 patients who were the subjects in the original studies. This information was obtained by letters, hospital files and community practitioner contacts and was carefully cross-checked for accuracy. The following table presents the 5-year follow-up of psychiatric hospitalization of the original patients. These data support

¹ Dept. of Psychiatry, Johns Hopkins Medical School.

I wish to express appreciation to Eugene Meyer, M.D., The Johns Hopkins Hospital, and to Jonas C. Kolker, M.D., and Ronald Lipman, Ph.D., Psychopharmacology Service Center, N.I.M.H., for their contributions to this paper.

SITUS INVERSUS TOTALIS: A SURVEY OF LATERALITY AND SOME OBSERVATIONS ON THE FREQUENCY OF MENTAL DISORDER¹

HENRY C. EVERETT, M.D.²

Inasmuch as the major body viscera are reversed in situs inversus totalis, the question arises as to whether handedness might also tend to be reversed, *i.e.*, whether left-handedness might be more frequent.

The records of adult patients admitted to the Johns Hopkins Hospital over a 10-year period (1952-1961) revealed 10 cases of complete situs inversus, with ages ranging from 29 to 68 at the time of this study. The handedness of 6 of these cases was determined by personal inquiry or by hospital records, and all 6 were found to be right-handed. Handedness was not determined in the remaining 4 cases, of whom 2 were untraceable and 2 had died.

An incidental finding in reviewing the records of the 10 patients was the high frequency of mental disorder. Five of them had histories in their charts of incapacitating psychiatric disturbances (*viz.*: a man with severe hypochondriasis, for whom psychiatric hospitalization was considered; 2 cases with histories of psychotic episodes; and, finally, 2 cases with mental retardation, of whom one was an alcoholic, while the other complained of hearing voices).

Two more patients had notations suggesting milder psychopathology; *viz.*, nervousness and excitability. (One of these 2 women was described as "hyperkinetic" and was on sedatives.)

The present sample of 6 cases in which laterality could be determined is rather small for statistical purposes, but the fact that all turned out to be right-handed casts strong doubts upon the hypothesis that situs inversus totalis might predispose to left-handedness.

Situs inversus totalis is part of Kartagener's triad, which also includes sinus and bronchial abnormalities. Finkelstein(1) reported a case of mental deficiency and schizophrenia in a 23-year-old woman with the triad. He has urged that others report such case material in the hope that a genetically significant discovery regarding mental illness may be made. Karani(2) reported a "low mental grade" in two sisters with the triad. The records of 5 of the 10 patients in the present study attest to severe psychiatric disorder, while those of 2 more suggest some degree of disturbance.

The genetics of situs inversus totalis is not yet fully understood. It has been thought by some(3) to be a rare Mendelian recessive. Gorham and Merselis(4), performing a family study on a patient (with

¹ This study was undertaken during psychiatric residency at the Johns Hopkins Hospital, Baltimore, Md.

² Director of Education and Research, Mendota State Hospital, Madison, Wis.

the syndrome) at Johns Hopkins Hospital, found the triad in the patient's sister but not in other generations. They comment that in other such studies the triad has been found to be shared only among siblings. In conclusion, they express the suspicion that the syndrome is a product of intrauterine environment, rather than of heredity.

SUMMARY AND CONCLUSIONS

The findings of this study did not support the hypothesis that situs inversus might predispose to left-handedness. However,

the incidental finding of a high frequency of mental disorders in the histories of the patients studied adds evidence to that from previous authors that situs inversus totalis may predispose to such disorders.

THE INFLUENCE OF TWO SELECTED TRANQUILIZERS ON DRIVING SKILLS

WARREN J. HUFFMAN, Ed.D., AURELIO E. FLORIO, Ed.D.,
JOBE L. PAYNE, M.S., AND FLOYD E. BOYS, M.D.¹

The increasing use of tranquilizers and other drugs is a matter of concern to those connected with traffic safety programs. Do these drugs impair driving skills, reduce alertness or render the individual less likely to conform with traffic rules? Definitive answers to these and related questions are lacking.

It seems unlikely that "blanket" answers can be found. The term "tranquilizer" embraces a host of different drugs, with different chemical compositions and different actions on the human nervous system. It seems that each new agent which comes into popular use requires a critical evaluation of its effect upon driving, in addition to the more usual pharmacologic investigation which provides background information for the physician.

The present study was designed to test the behavioral effects of normal or double the normal dosage of a relatively new tranquilizing drug on reaction time, visual acuity, and hand steadiness.

The New Drug. Hydroxyphenamate (Listica)² was compared with both a placebo

and meprobamate. Meprobamate was selected for comparison purposes because of its widespread use and because its actions and clinical effects are well documented. The three materials were provided in tablets of identical appearance. One contained 200 mg. of hydroxyphenamate, the second 400 mg. of meprobamate, and the third was the placebo tablet.

The Subjects. Twenty-five healthy young adults, 15 males (mean age 22.5 years) and 10 females (mean age 20.5 years), were selected from student volunteers. There was no unusual medical history among them; physical development was within normal limits for their ages; vision (with corrective glasses when worn) was judged normal; each subject had a current operator's license for a motor vehicle.

METHOD

The study was conducted in two phases. First, the subjects were tested after normal dosages of the two drugs. After about a month they were retested at double the original dosage. To minimize the effect of learning, all subjects were familiarized with the test procedures before the actual experiment. The tablets were given according to a "double-blind counterbalanced design" so that each subject served as his

¹ Dept. of Health and Safety Education, University of Illinois, Urbana, Ill.

² The materials for this study were provided by the Armour Pharmaceutical Company, Kankakee, Ill.

own control. The tablets were administered one hour before testing, and the subjects sat quietly in the interval. At each session, testing was completed in less than one hour, *i.e.*, within 2 hours of drug administration. Radioactive tracer studies with hydroxyphenamate- H^3 in humans showed maximum blood levels of the drug to be present in the 1-2 hour time period.

For each subject, 16 different measurements were recorded on 6 occasions; after placebo (twice), after hydroxyphenamate 200 mg., after hydroxyphenamate 400 mg., after meprobamate 400 mg., and after meprobamate 800 mg. The variables measured were as follows: 1. Reaction time; 2. Hand steadiness; 3. Far visual acuity, both eyes; 4. Far acuity, right eye; 5. Far acuity, left eye; 6. Far stereo (depth perception); 7. Color perception; 8. Far vertical deviation; 9. Far lateral deviation; 10. Near visual acuity, both eyes; 11. Near acuity, right eye; 12. Near acuity, left eye; 13. Near lateral deviation; 14. Reaction time distance; 15. Braking distance; and 16. Total stopping distance. The last 3 variables were measured in an automobile using a brake reaction detonator.

RESULTS

Using the *t* test of significance, 5 significant differences (of 96 comparisons) were found. In the first phase (normal dosage) far visual acuity, right eye was improved after hydroxyphenamate as compared with placebo ($t=2.21$). Visual acuity, left eye was improved after hydroxyphenamate as compared with meprobamate ($t=3.03$).

In the second phase (double dosage) reaction time was slowed after meprobamate as compared with placebo ($t=2.38$); far acuity, both eyes was diminished after hydroxyphenamate as compared with a placebo ($t=2.15$); near acuity, both eyes was diminished after meprobamate as compared with placebo ($t=2.20$).

CONCLUSION

Since this was a multivariable study and some statistically significant differences would be expected by chance, it was concluded that under the conditions of this experiment hydroxyphenamate had no significant effect on the performance of the subjects, neither at the normal nor double the normal dosage.

NARCOTHERAPY WITH METHOHEXITAL SODIUM

WALTER W. WINSLOW, M.D.¹

Narcotherapy, a technique employed by Horsley(1) in the middle 1930's, is a procedure in which a patient is interviewed while under the sedative effect of an intravenous barbiturate. This technique has enjoyed intermittent popularity, particularly during World War II, and at present is most commonly known as the amytal or pentothal interview. The purpose of this paper is not to argue the merits of this interviewing technique(2), but to report my experience with a relatively new short-acting barbiturate, methohexital sodium.²

Methohexital sodium is an ultrashort-acting barbiturate for intravenous use which has been generally accepted in the field of anesthesia as a safe and useful drug(3). It

is approximately three times as potent as thiopental sodium (Pentothal), by weight, is metabolized, primarily by the liver, 50% faster than thiopental. The technique, indications and contraindications are very similar to those encountered with amobarbital (Amytal) and thiopental sodium, and the same general precautions should be observed as in the more classical amytal interview. Adequate equipment and medication to meet anesthetic emergencies should be immediately available.

With the patient in the recumbent position a syringe containing 20-30 cc. of 1% methohexital is used to inject the solution slowly into the antecubital vein. The rate of injection is approximately 1 cc. per 5 seconds, with the average person requiring about 5-8 cc. (50 mg.-80 mg.) to reach the

¹ VA Hospital, Cincinnati, O.

² Brevital Sodium, Lilly.

desired level of consciousness. The optimal level of consciousness is determined similarly as with amytal sodium, the development of slurred speech, and the observation of nystagmus. The needle is left in the vein and the remainder of the 20-30 cc. is injected in sufficient quantities to maintain the desired level of consciousness, the average being approximately 1 cc. (10 mg.) every 3-4 minutes. Due to the rapid recovery rate it is relatively easy to titrate the amount of the drug required to maintain the exact level. If too much of the drug is given and the patient becomes non-communicative it is necessary to wait a very few minutes before resuming the interview, whereas, if an overdose of amytal or pentothal sodium is given the patient will fall into a deep sleep and the interview has to be terminated. A modification of this technique with methohexital sodium has recently been described by Dorfman(4).

When the interview is terminated and the injection discontinued, the patient will return to almost full consciousness in from 15 to 20 minutes. In my experience with 25 patients, all were able to talk without slurred speech, and walk unassisted without ataxia, in 20 minutes or less. Only a mild feeling of drowsiness remained longer than 20 minutes, but even this did not interfere appreciably with psychomotor function. Post-interview symptoms such as prolonged

drowsiness, confusion, nausea or vomiting were not encountered.

From this preliminary study the value of methohexital sodium over either amobarbital sodium or thiopental sodium, used in the manner described above, appears to be as follows: 1) the relative ease by which minute to minute control of the level of consciousness can be accomplished; 2) the rapid rate of recovery from the drug which makes it of particular value as an outpatient procedure; 3) the apparent safety of the drug as reported by those working in the field of general anesthesia; and 4) the reduced incidence of unpleasant side effects, particularly in the post-interviewing state. In all cases the verbal productions of the patient were entirely comparable with what might be obtained with either amobarbital or thiopental sodium used for a similar purpose.

DRUG-INDUCED EEG ABNORMALITIES AS PREDICTORS OF CLINICAL RESPONSE TO THIOPROPAZATE AND HALOPERIDOL

LEO E. HOLLISTER, M.D., J. L. BENNETT, M.D.,
SAMUEL C. KAIM, M.D., AND ISHAM KIMBALL, JR. M.D.¹

Since the hypothesis was first proposed by Wikler, drugs increasing synchronization of the EEG have been associated with

¹ Respectively, Assoc. Chief of Staff, VA Hospital, Palo Alto; Chief, Psychiatry Service, VA Hospital, Salt Lake City; Director, Psychiatric Research, VA Central Office, Washington; Chief, Acute Intensive Treatment Section, VA Hospital, Houston.

This study was a corollary to one of a continuing series in the VA Cooperative Studies of Chemotherapy in Psychiatry.

sedation or tranquilization, drugs with a desynchronizing effect being associated with opposite behavioral changes(1). Recently, a consensus of electroencephalographers and clinicians was that in the absence of EEG change there was no behavioral change in patients treated with psychotherapeutic drugs(2). Two previous studies bearing directly on the problem have led to conflicting opinions(3, 4).

During a controlled comparative study of

thiopropazate and haloperidol, EEGs were obtained on 40 patients before treatment and six weeks later. These tracings were obtained simultaneously with clinical evaluations using an objective rating scale (Brief Psychiatric Rating Scale) based on a clinical interview of the patient(5). This scale yields a total pathology score which indicates the present severity of the patient's illness, changes in which may be used to evaluate effects of treatment. EEGs were obtained under comparable technical conditions, being read independently by two readers, who were not aware of the sequence of tracing in each pair. Differences in readings were arbitrated by a third reader.

Twelve patients showed definite changes from an initially normal tracing to varying degrees of abnormality. Fourteen patients had essentially normal tracings on both occasions. The remainder of the sample had either equivocal or definitely abnormal initial tracings or equivocal changes from initially normal tracings. All drug-induced abnormalities consisted of mild slowing of the rhythm, usually in the 4-7 sec. range. This slowing was sometimes generalized, but most often limited to frontal or anterior temporal leads. Frequently it was paroxysmal. The number of patients with abnormalities was equally divided between the two drugs. In general, they resembled those changes previously reported during chronic administration of phenothiazine derivatives or haloperidol(4, 6).

Mean change scores from the Brief Psychiatric Rating Scale were examined both for the group which had persistently normal tracings and those showing drug-induced synchronization. The mean reduction of total pathology in the former group was 23.1; for the latter, reduction was 19.0.

Differences between these scores were not significant, though the improvement produced by both drugs over pre-treatment scores was.

The relationship of dose to EEG change was also examined. The main daily dose of 10 patients on thiopropazate with normal tracings was 64 mg. per day; among 6 with abnormalities, 80 mg. per day; for haloperidol, doses were 6 mg. and 8 mg. respectively. It is probable that high doses of both drugs are more likely to evoke EEG synchronization, but not likely that the differences in this sample were of consequence.

No relationship between EEG abnormalities from tranquilizing drugs and clinical response of individual patients could be demonstrated in the present study. Obviously, EEG changes may occur subcortically which are missed in scalp electrodes. Possibly computer analysis of EEG rhythms might detect more subtle relationships. For practical purposes, drug-induced changes in the usual clinical EEG cannot be considered as more predictive than their absence of a favorable response to drug therapy.

PRELIMINARY INVESTIGATION OF PIPERACETAZINE

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

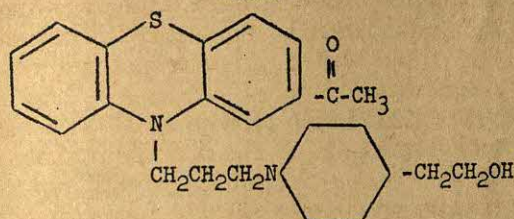

Piperacetazine (Quide)² is a new phenothiazine derivative, with the structural formula shown in Fig. 1.

¹ Fairfield State Hospital, Newtown, Conn.

² Generous supplies of Quide were furnished by Pitman-Moore Co., Indianapolis, Ind.

The manufacturer indicates that, in comparison with chlorpromazine, various biological tests revealed that piperacetazine is 50 times more potent as an antiemetic, 25 times as a tranquilizer in dogs, 8 times in lowering avoidance behavior, and 2.5 times

FIGURE 1

in reducing spontaneous activity.

The drug was administered to a series of 50 newly admitted female schizophrenic patients. The diagnostic sub-groupings and duration of present illness are indicated in the tabular summaries. Age distribution was as follows: 20 or under—5; 21 to 30—8; 31 to 40—19; 41 to 50—17; and 51 to 60—1. Dosage was usually initiated with 10 mg. t.i.d. and increased up to 30 mg. t.i.d. Medication was maintained from a minimum of 3 weeks to over 20 weeks.

Therapeutic results are summarized in Table 1. Group A exhibited good or excellent improvement; and Group B, mild or no improvement. The over-all picture revealed 42% with good or excellent improvement, and 58% with insignificant improvement.

TABLE 1
Correlation of Results with Schizophrenic Sub-Grouping

SUB-GROUP	A LEVEL OF IMPROVEMENT	B LEVEL OF IMPROVEMENT	%A
Acute undifferentiated (16) or schizo-affective (2)	12	6	67%
Paranoid (14)	5	9	36%
Chronic undifferentiated (11)	3	8	27%
Simple (6) or catatonic (1)	1	6	14%
Totals	21	29	42%

Correlation of results with 1) duration of present illness (Table 2) and 2) diagnostic sub-grouping reveals the significant influence of these factors.

Thus, there was an A level of improvement in 75% of patients whose present illness was not more than 1 year in duration,

TABLE 2
Correlation of Results with Duration of Present Illness

	A LEVEL OF IMPROVEMENT	B LEVEL OF IMPROVEMENT	%A
1 year or under	18	6	75%
Over 1 year	3	23	12%

as compared with 12% in those whose illness was longer than 1 year. Those with an acute psychosis exhibited an A level of improvement in 67%, with sharp and progressive decline in this rate in the paranoid, chronic undifferentiated and simple sub-groupings, respectively. Statistical correlation with type of symptomatology cannot be recorded so readily. However, as in a previous study of proketazone,³ it was noted clinically that favorable results were associated with acute type of onset, vigorous emotional reaction, and acute hallucinations or delusions, frequently accompanied by apprehension or panic reaction. Least satisfactory results were observed in patients who had an insidious type of onset, autistic reaction, lack of emotional reactivity, evidences of general personality disintegration and inadequate functioning, and vague, poorly-crystallized thought processes. It is again evident, therefore, that satisfactory results were obtained in patients with innately favorable prognostic features. In such instances, the drug appeared to hasten improvement or remission.

Significant complications were not observed. Side effects were mild and relatively infrequent: 8 patients exhibited mild somnolence, which tended to disappear; 1, slight dizziness; and 1, very mild akathisia at a level of 90 mg. daily. Parkinsonism was not observed within the dosage level indicated. Alkaline phosphatase and transaminase levels were normal.

It may be concluded, therefore, that piperacetazine is an effective agent in appropriate, selected cases of schizophrenia. Side effects were minimal.

CASE REPORTS

SEVERE ORAL MONILIASIS COMPLICATING CHLORPROMAZINE THERAPY

FRANCIS J. KANE, JR., M.D.¹

The voluminous literature reporting the side effects and complications of phenothiazine derivatives has only one such report regarding fungus infections as possible complications(1). In this report, 17 patients receiving large amounts of phenothiazine medication were found to have a brown hairy tongue which disappeared upon discontinuance of therapy. In this group there were none who showed a severe clinical infection as did the following patient.

A 31-year-old married man was admitted to North Carolina Memorial Hospital on 7/26/62, because of a 7-day history of restlessness, agitation, excessive religiosity, and delusions concerning communications with God. Abnormalities found on mental status examination included evasiveness, suspiciousness, auditory and visual hallucinations, ideas of reference, and delusions regarding guilt. He was well oriented in all spheres, and memory was intact; abstract thinking was impaired. On 7/26/62, he was placed on trifluoperazine (Stelazine), 5 mg. b.i.d. with Cogentin 1 mg. b.i.d., but his medication was altered to chlorpromazine (Thorazine) 800 mg. daily when trifluoperazine seemed to increase his restlessness. In addition, he received Cogentin 1 mg. b.i.d., which was increased to 2 mg. b.i.d. when he complained of blurred vision. Severe dryness of the mouth was noted from the second day of therapy. On 8/8/62, the patient was reported to have complained of a mild sore throat the night before, and examination revealed a very reddened pharynx covered with small (1-2 mm. in diameter) white spots in the posterior pharynx; his tongue was covered with a heavy brown and white coat. White blood count at this time was 8750 with a normal differential, temperature was 99°. Dermatologic consultation confirmed these findings, and the following day a KOH preparation was markedly positive for yeast filaments. It was the impression of the dermatologist that the patient

was suffering from a severe pharyngitis and glossitis due to candida albicans. He was started on Mycostatin suspension, 100,000 units q.i.d. on 8/10/62, and in a few days showed a marked decrease in the coating on his tongue and pharynx with a markedly reddened mucosa showing underneath. Chlorpromazine was continued in decreased dosage since the patient showed a good clinical response. On 8/18/62, his mouth was normal in appearance.

This case of severe oral moniliasis accompanying the use of chlorpromazine is the first reported in the literature. This man is not a diabetic, nor had he had any broad spectrum antibiotics recently. It may be that the severe dryness of mouth from which this patient suffered as a side effect of his chlorpromazine medication, may have sufficiently altered the normal flora and Ph of the mouth, so as to make a monilia infection more possible. A similar response to change in Ph is believed to be contributory to the development of vaginal moniliasis in pregnant women(2). The brown hairy tongue is believed to be associated with the presence of candida albicans(3). This is the only known reported case that has progressed to this severity.

SUMMARY

A case of severe oral moniliasis as a complication of chlorpromazine therapy is reported. Therapeutic response to Mycostatin suspension was good. It was not necessary to discontinue chlorpromazine therapy.

THERAPEUTIC USE OF THIORIDAZINE IN PREMATURE EJACULATION

HARBHAJAN SINGH, M.D.¹

Since I first reported a case of inhibition of ejaculation as a side effect of thioridazine (Mellaril) (4) five other similar cases have been published by Freyhan, Green and Taubel. In July 1962 I came across another case which brought to my attention that thioridazine might have some value in delaying premature ejaculation, a very distressing symptom in many neurotic and anxious patients. Therefore, I tried Mellaril in small doses in a neurotic patient with premature ejaculation as one of the main symptoms, and achieved very encouraging results.

A 32-year-old male patient was referred to me because of an acute anxiety attack. He had been subject to these attacks for 15 years. He was very conscious of his half Chinese and half Canadian heritage with hostile identification with his Canadian mother. He underwent various homosexual experiences and had paranoid tendencies. I prescribed for him thioridazine 100 mgm. q.i.d. which made him relaxed in a week's time. At the next visit he asked me if this drug affected his sexual life. On further inquiry he related that at times he had experienced complete inhibition of ejaculation and at other times simply delayed ejaculation. After another week he objected to the use of this drug because of its interference with his sexual life. He was therefore changed over to prochlorperazine 10 mgm. q.i.d. which brought his sexual life to the usual pattern. However, at this time he went into a homosexual panic and decided that he would not go for any more drugs or psychiatric treatment.

¹ 1105 Carling Ave., Ottawa 3, Canada.

Having noticed the above property of thioridazine, it was used successfully in the treatment of the following case of premature ejaculation.

A 51-year-old white male executive was referred to me because of his feeling of inferiority, inadequacy, mild depression, anxiety and premature ejaculation, and most of his anxiety was centred around his consequent inability to satisfy his wife. He was convinced that whenever he could satisfy his wife sexually, he could deal with his family, business and employees adequately. He was placed on thioridazine 25 mgm. t.i.d. imipramine and (Tofranil) 25 mgm. t.i.d. to delay ejaculation and to get him over the depression. When I saw him 2 weeks later he admitted that ejaculation was delayed and he was more confident in sexual as well as other areas. His depression had also been masked at this time.

CONCLUSION

Firstly, thioridazine's property of delaying ejaculation may prove of tremendous value in treatment of anxious and sexually insecure patients who gather many more problems consequent to the symptom of premature ejaculation. Secondly, I would like to emphasize the need for further research in this area.

TREATMENT OF ENCOPRESIS WITH IMIPRAMINE

DAVID ABRAHAMS, M.D.¹

Fecal incontinence, with soiling, has achieved little mention in the standard pediatric or psychiatric literature, even though it is by no means a rare event in

childhood (4). While the symptom frequently co-exists with enuresis, this is not invariably so. The etiology and treatment of encopresis remain a difficult and vexing problem, complicated by the sequelae of additional problems arising from the "dis-

¹ Dept. of Psychiatry, Harbor General Hospital, Torrance, Calif.

tasteful" major complaint. One invariably finds a profound emotional disturbance, not only in the child, but in the home.

Recently there have been encouraging reports of imipramine (Tofranil) in enuresis providing a simple and effective method of controlling this commonplace problem (1-3). The analogous psychological factors of enuresis encopresis suggested a trial of imipramine with encopresis only. The following case report shows the value of this drug.

Because of persistent encopresis, accompanied by increasing masturbation, temper tantrums, and indistinct speech a 9-year-old female was referred for psychotherapy. At the time of the initial consultation the child was in the third grade and doing well in academic studies, but had poor relationships with the other children who avoided her because of the soiling. She was easily excited but was not an isolate. The mother steadfastly refused to recognize psychological etiology for this condition, even though she admitted having resented this child from the time of conception. There was a good deal of crying and spitting during infancy, but no sleep disturbance. In general, she appeared all right until the birth of her brother when she was 14 months of age, at which time she showed marked jealousy. Temper tantrums began at 2, along with attempts at toilet training. She was very stubborn and was kept in diapers until age 3. Enuresis was never a problem and soiling occurred infrequently until age 5 after which it progressively became worse.

The patient was found to be an attractive, well-developed, shy child who tended to be somewhat overactive in the playroom. She was

above average intellectually, but occasionally her thinking became chaotic and she barely managed to keep in control. Neurological examination was negative. EEG was within normal limits.

A variety of treatments failed to ameliorate the encopresis, although ataractics of various types and a supportive relationship with the therapist did seem to improve her general adjustment, and she seemed happier and calmer. The patient was then begun on imipramine 25 mg. daily, and the following day her encopresis ceased. The compound was administered daily for more than one month without any side effects. Encopresis returned when placebos were substituted. The relief of the encopresis significantly altered the course of psychotherapy. The patient's mother became warmer to her daughter, and had a more benevolent attitude towards psychotherapy. The child's milieu improved. There was no longer the need for the futile coercive measures employed in the past. The patient was visibly calmer and happier, and had better control in frustrating situations. She was continued on imipramine 25 mg. daily for over 2 months along with weekly supportive psychotherapy. There has been complete alleviation of the encopresis.

It is felt that on the basis of this report further clinical trials are indicated.

LOEFFLER'S SYNDROME OCCURRING DURING IMIPRAMINE THERAPY

IAN C. WILSON, M.B., JOHN M. GAMBILL, M.D.,¹
AND MYRON G. SANDIFER, M.D.²

Loeffler(1) described the syndrome characterized by pulmonary infiltration and eosinophilia. This was interpreted as an

¹ Respectively, Clinical Director of Research, Staff Physician, Broughton Hospital, Morganton, N. C.

² Director of Research, North Carolina Hospitals Board of Control.

allergic reaction by sensitized lung tissue to various allergens, intestinal parasites being identified in a number of cases. Later publications(2) have described Loeffler's syndrome as occurring as an allergic response to various drugs, such as sulfa drugs and penicillin. Joynt(3) summarized the previous literature on mild eosinophilia oc-

curing during imipramine therapy; he then described an extreme case.

The following case shows an extreme eosinophilia with pulmonary infiltration occurring during imipramine therapy; and it is interpreted that this is a case of Loeffler's syndrome, occurring as an allergic response to imipramine.

A white, female patient (L.J.), aged 43 years, was admitted to Broughton Hospital on March 30, 1962. There was a recent history of depression, agitation, emotional lability, insomnia and anorexia. There appeared to be a degree of reactivity and she had marked difficulties in her interpersonal relationships with her husband. There was a history of a previous admission to this hospital with the diagnosis depressive reaction. The official diagnosis returned on her present admission was manic-depressive reaction, depressed type. She was admitted to the Depressive Research Unit where a double blind study was being undertaken with imipramine and desmethylinipramine.

Imipramine therapy was initiated on April 2, 1962, the dosage being 50 mg. q.i.d. On April 9, the dosage was increased to 100 mg. t.i.d. On April 13, patient complained clinically of respiratory symptoms, namely dyspnea on exertion and mechanical respiratory difficulties. Physical examination revealed broncho-vesicular breath sounds with rales and rhonchi scattered throughout the chest. Clinical findings appeared to be those of a mild case of bronchial asthma but there was no previous

history of this or any other allergy. During the next week her clinical findings remained static but there was progressive improvement during the following week until no positive findings were elicited. There was no pyrexia during her illness. Imipramine therapy was discontinued on April 15, 1962. The following is a record of her laboratory findings:

X-ray of chest: 4/2/62: (Routine admission) —Normal.

4/13/62: There are bilateral abnormal lung changes manifest by minimal peribronchial infiltration, consistent with minimal pneumonitis. Conclusion: Minimal peribronchial changes consistent with minimal pneumonitis.

4/27/62: The final PA film of the chest compared to the study of 4/13/62 shows complete clearing of the peribronchial infiltration at that time.

ENURESIS AND IMIPRAMINE

NICHOLAS DESTOUNIS, M.D.¹

The salutary effects of imipramine (Tofranil) on depression and allied states are well known. Also, recent communications(1-4) suggest its usefulness in controlling enuresis. The following case is in point.

G. P., a 15-year-old boy, was referred for psychotherapy with a history of enuresis accompanied by depression and suicidal preoccupation. On the initial interview, the patient appeared depressed and expressed feelings of hopelessness and futility. Furthermore, he was deeply concerned about his enuresis, and was thinking of suicide. He was put on 50 mg. imipramine at bed time. After the second

night the bed wetting ceased, and the clinical picture of depression disappeared within a week. The psychotherapy was supportive, and now after two months, he is free of the enuresis as well as of the other symptoms for which he was referred. Academically, he has become a better student, thinks constructively, and is looking forward to the future with optimism.

HISTORICAL NOTES

WILLIAM OSLER, S. WEIR MITCHELL, AND THE ORIGIN OF "THE REST CURE"

JEROME M. SCHNECK, M.D.¹

Descriptions of original discoveries, concepts, and techniques have always been part of the recorded history of medicine. The Rest Cure has its place in the history of psychiatry, but few people know that an account is on hand about the alleged first patient to whom it was applied. It is to be found in a memorandum written by William Osler on December 9, 1887 concerning his conversation with S. Weir Mitchell.

Mitchell was a versatile man, perhaps the foremost neurologist of his time, active in treating psychiatric patients, contributor to both specialties and to toxicology, author of poems, short stories, novels and biography. His writings possess evidence of his clinical experience and psychiatric insights(1). The Rest Cure apparently was not a rigid procedure; it was modified in time and depending upon patients' needs involved, in addition to several weeks of rest, proper food, isolation, separation from relatives and surroundings where the illness developed, physical measures including exercise, massage, and electrotherapy, and firm kindness by well-trained personnel. Alcohol might be denied, or whiskey and champagne recommended. Evaluations of its success have considered as especially important the isolation from relatives, the special attention by kindly but firm hands, and particularly the personality of the doctor himself and, as is true of all treatment contacts, the implications of this doctor-patient relationship for the recovery of the patient.

A biographer of Mitchell tells us of at least three different stories of the origin of

The Rest Cure(2). In 1904 Mitchell ascribed it to his hospital experience during the Civil War. His friend W. W. Keen thought Mitchell came upon it when the "nervous ailments" of two patients improved on enforced bed rest due to fractured legs. Osler furnished Mitchell's description in one of their conversations. Earnest, the biographer, offers the reasonable opinion that these accounts need not be in conflict because the treatment was an evolution and not really a "discovery." As a specific clinical description of an alleged first patient, the Osler memorandum is of interest and should have its historical niche. Earnest uses as his reference, but without direct quotation, the biography of Osler by Cushing(3). This, however, contains only part of the memorandum. The complete memorandum is to be found in the Osler Library of McGill University in Montreal. It says:

I have just walked home with Weir Mitchell from the Biological Club at Wm. Sellers' and he told me on the way of his discovery, if one may so call it, of the rest treatment. About 12-14 years ago a Mrs. S. from Bangor, Maine, came to consult him at the advice of a mutual friend. She was a bright intelligent woman who had as a girl attended in Boston a school in which Agassiz and his wife were interested and had passed through the four years' curriculum in three years. She then had married and within as short a time as was possible had had four children with the result of a total breakdown, body and mind. Boston and New York physicians were tried for a year; then she went abroad, and in London and Paris saw the most eminent consultants and spent months at various spas. But in vain; she returned a confirmed invalid. When seen she was a woman of 5 ft. 8, emaciated, nervous, unable to digest any food unless she lay upon her back with the eyes shut, and full of whims and fancies. Standing at the foot of her bed, M. felt that every suggestion he had to make

¹ Clin. Assoc. Prof., Dept. of Psychiatry, State University of New York, Downstate Medical Center.

In obtaining wording of the complete memorandum, the author appreciates the assistance of Miss Cécile Desbarats, Secretary-Librarian at the Osler Library.

as to treatment had been forestalled. Every physician had urged her to take exercise, to keep on her feet, to get about, and she felt herself that this was the best. M. on the inspiration of the moment told her to remain in bed. She took food better but found that on attempting to get up she was so weak that she could scarcely stand from lack of exercise. M. says he felt that he had run up against a stone wall. About this time he had seen on several occasions a quack named Lyons, who professed to cure, by passes and rubbings, a confirmed ataxic in such a way that he could get about for an hour or more at a time. The idea occurred to him to substitute for exercise the movements of the muscles caused by rubbings and friction and after giving to a Miss H. (who subsequently went upon the stage) several lessons he instructed her to rub Mrs. S. for a certain time each day. The improvement began to be noticed and to the rubbing was added the electrical stimulation of the muscle also substituted for the active movement. The food was taken more freely, she gained in flesh and gradually recovered and was sent to her home in Bangor perfectly well. The

improvement persisted; she has since borne several more children and has been the soul of many enterprises in her native town. An incident, post-partum so to speak, was a letter from Mrs. S.'s mother, a wealthy New England woman, a speaker at temperance meetings, full of 'isms, etc. She wrote to Dr. M. to say that bodily comfort and ease, health and enjoyment might be dearly bought if at the price of eternal peace. For he had recommended her daughter to take champagne and to have a maid to assist her in her toilette. The former she considered not only unnecessary but hurtful, the latter quite superfluous, as any well-instructed New England husband was quite capable of helping his wife in her toilette. W. O.

SANTE DE SANCTIS (1862-1935)

GEORGE MORA, M.D.¹

Exactly 100 years ago, Sante de Sanctis was born near Assisi in Italy. After graduating from the Medical School of Rome in 1886 with a thesis on aphasias, he entered general practice in a small town; but soon he dedicated himself entirely to psychiatry in the Psychiatric Clinic in Rome where he did extensive research on neuropathology. Following scientific travels in Paris and Zürich, he became interested in psychology. His first book *I Sogni* (1899—Germ. tr. 1901) was a study, supported by experimental research, of dreams and sleep in hysteria and hypnotism; he emphasized in it the importance of emotional factors in dreams and anticipated views concerning the transference of emotional charges(1). Freud himself paid tribute to de Sanctis in his *Interpretation of Dreams* although, on the whole, he did not consider the book too

original(2). In 1901, de Sanctis became "Privatdozent" of experimental psychology and, six years later in 1907, he was appointed Professor of Physiologic Psychology at the University of Rome, the first chair in this field in Italy. His contributions of this period concern: the definition of the role and aim of experimental psychology as distinct from biology and philosophy; the eclectic application of methods of research from psychological experiment to introspection and to behavioral observation; the elaboration of the doctrine of empirical parallelism between physical and psychological phenomena on the basis of the distinctions between nervous energy and psychic energy; the formulation of the "doctrine of the cycle" representing the biopsychological integrative process between external stimulus, inner elaboration, and feed-back mechanism; finally the study of human mimicry (*La Mimica del Pensiero*, 1904—Germ. tr.

¹ Medical Director, Astor Home for Children, Rhinebeck, N. Y.

1906), especially of the face and of the hand for the evaluation of emotions.

At the Fifth International Congress of Psychology, organized by him in 1905 in Rome, he presented his mental tests for the evaluation of retarded children, which were soon to be overshadowed by the tremendous success of Binet-Simon Intelligence Test. At the same Congress he presented his first important contribution to child psychiatry, namely, his first study on "dementia praecocissima," which he defined as a form of dementia praecox appearing before puberty—either slowly or suddenly—and developing with an acute or chronic course, with uncertain pathological findings and various prognoses. This syndrome was accepted by some and rejected by others, and its autonomy, as well as its nosologic classification, remains problematic(3). A few years later, during 1909-1913, he published (with S. Ottolenghi) a comprehensive treatise on legal psychiatry, *Trattato Pratico di Psicopatologia Forense*, which was widely accepted and followed in Italy. His continuous interest in children brought him also to take active part in the planning and functioning of special institutions and classes for abnormal children and to present his experience in this field in a volume, *Educazione dei Deficienti* in 1915. In the meantime, he continued his research on dreams and was the only foreigner asked to collaborate on this subject for Kaffka's *Handbuch der vergleichenden Psychologie* (1922). In 1924 he published a book on religious conversion, *La Conversione Religiosa*, *Studio Biopsicologico* which appeared in English three years later. The following year, 1925, de Sanctis published his extensive textbook on child psychiatry, *Neuropsychiatria Infantile* (later translated into Russian), a kind of encyclopedic survey of the whole field, which, however, "clung tenaciously to the old nosographic concepts . . . losing sight of personality"(4). In the meantime, he continued his studies on developmental psychology, some of which were also published in this country in the *Pedagogical Seminary and Journal of Genetic Psychology*. In these studies, especially insofar as personality de-

velopment is concerned, he was among the first in Italy to be influenced by Freud's theories, toward which he always maintained a sympathetic attitude(5). Finally, in 1929-30, he published his two volumes, *Psicologia Sperimentale*, a very broad and up-to-date—though not too critical—presentation of the whole field of psychology, from general psychology to educational, industrial and legal and criminal psychology.

De Sanctis, who already in 1920 had become Director of the Psychiatric Clinic in Rome, in 1929 became Professor of Neurology and Psychiatry at the University of Rome(6). Aside from other studies on different fields of psychiatry, in 1932 he published his autobiography, which later appeared in this country(7). He died in 1935 and his chair was successfully occupied by A. Cerletti, who—in collaboration with L. Bini—introduced electroshock in the treatment of psychoses. A modest and true researcher and indefatigable worker, quite intuitive though not too critical(8), and a pioneer in establishing institutions for retarded and abnormal children, Sante de Sanctis was—as Ziehen, Kraepelin, Wundt, Schilder—among the last minds to be able to combine into fruitful unity the manifold aspects of the behavioral sciences.

COMMENTS

BENJAMIN RUSH ON THE IMPORTANCE OF PSYCHIATRY

This year marks an anniversary of importance to psychiatry—one hundred and fifty years ago Benjamin Rush published his book *Medical Inquiries and Observations upon the Diseases of the Mind*, the first book by an American attempting to deal with the problems of mental illness. Much has been said about Rush's pioneering efforts in reforms of mental hospital treatment and his influence in American psychiatric development, and a lot more of a less eulogistic nature has been said about the extremes of his medical treatment, the purging and bleeding which surprises the modern reader with its severity and which was so criticized by Rush's colleagues. Rush will perhaps always remain a controversial figure, but after a century and a half certain aspects of his contributions to psychiatry stand forth to explain why this man receives the title of father of American psychiatry. It is pertinent to celebrate this anniversary by giving Rush an opportunity to repeat some of his views on the importance of psychiatry.

Of greater significance than his archaic theories are his attempts to win physicians to a new perspective in their discipline, to cause them to include the human mind in their observations and their cures. This new emphasis can be seen in Rush's lectures to his medical students at the University of Pennsylvania. He devotes nearly half of the outline of his course on physiology to a discussion of the mind, its operations and its functions. He presents the following credo :

Man is said to be a compound of soul and body. However proper this language may be in religion, it is not so in medicine. He is, in the eye of a physician, a single and indivisible being, for so intimately united are his soul and body, that one cannot be moved, without

the other. The actions of the former upon the latter are numerous and important. They influence many of the functions of the body in health. They are the causes of many diseases ; and if properly directed, they may easily be made to afford many useful remedies.¹

Rush recognizes that physicians are apt to regard the study of the mind as too abstract or unorthodox to be of much practical use in medicine. He warns his students that,

some of these subjects will be new in lectures upon the institutes of medicine, particularly those which relate to morals, metaphysics, and theology. However thorny these questions may appear, we must approach and handle them ; for they are intimately connected with the history of the faculties, and operations of the human mind ; and these form an essential part of the animal economy.²

These new considerations will provide greater responsibilities for the physician, but they will also increase his understanding and skill :

[Knowledge of the mind] should be the *vade mecum* of every physician. It opens to him many new duties. It is calculated to teach him, that in feeling the pulse, inspecting the eyes and tongue, examining the state of the excretions, and afterwards prescribing according to their different conditions, he performs but half his duty in a sick room. To render his prescriptions successful, he should pry into the state of his patient's mind, and so regulate his conduct and conversation as to aid the operation of his physical remedies.¹

And :

Besides the advantages which a physician may derive from a knowledge of the faculties and operations of the mind in furnishing him with numerous and powerful articles of the *materia medica*, he will find it useful in predicting the issue of diseases in life or death.¹

Rush emphasizes a number of the faculties of the mind as playing an important

¹ Rush, Benjamin : Sixteen Introductory Lectures to Courses of Lectures upon the Institutes and Practice of Medicine. Philadelphia : Bradford & Innskeep, 1811.

² Rush, Benjamin : Selected Writings. Edited by Dagobert D. Runes. New York : Philosophical Library, 1947.

role in bodily function and behavior, but he stresses the importance of the emotions, or what were then called "the passions." They are instrumental in causing and curing bodily ills, but they are even more important in mental illness :

I have hitherto mentioned the influence of the passions in curing the diseases of the body only ; but their efficacy is much greater in curing the diseases of the mind, whether they occupy a part or the whole of its faculties. By means of anger and terror, an understanding and memory, that have been torpid for years, have suddenly been excited into healthy action. By opposing a new and fresh, to an exhausted, passion—by combining two passions against one—by giving a passion, that has operated in retrograde (*sic*) course, its natural direction—madness, from the influence of the passions upon the understanding and will, has often been cured, without the aid of any other remedy.

But the empire of a physician who is acquainted with the texture and functions of the human mind, may be extended beyond the diseases which are induced in it by derangement. It may be employed to compose and regulate the passions, when they act with excess or irregularity in the common affairs of life.¹

Rush is over-optimistic for the immediate future of this knowledge when he says,

In the science of government a physician will find his mental knowledge of eminent advantage to him, should he be called to take a part in the public affairs of his country. From his knowledge of the debilitating effects of inactivity and confinement upon the understanding and passions, he will be an enemy to slavery and a friend of liberty ; and from his frequent opportunities of witnessing the destructive effects of the passions upon the human body, he will be the advocate of those governments only, which filter laws most completely from the passions of legislators, judges, and the people.¹

But at the same time he seems cognizant of some of the obstacles before the science of the mind :

I am aware, gentlemen, that the science which I am now recommending to you, is an unpopular one ; and that it is often treated as chimerical and uncertain. While it bore the name of metaphysics, and consisted only of words without ideas, of definitions of nonentities, and of controversies about the ubiquity and

other properties of spirit and space, it deserved no quarter from the rational part of mankind ; but the science, I am speaking of, is as real as any of the sciences that treat upon matter, and more certain and perfect than most of them. As a proof of this, I need only call your attention to the innumerable changes that have taken place in the theories of every branch of what is called physical science, and to the improvements which have taken place in each of them, within the last two thousand years. Very different is the state of phrenology, if I may be allowed to coin a word, to designate the science of the mind. Most of the leading opinions and observations of Locke, Condillac, Hartley, and Reid, may be found in the writings of Aristotle, and Plato ; and discoveries in this science are now as rare, as they are in anatomy. The reason [for] this certainty, and near approach to perfection, is obvious. The mind is the same now, that it was in the time of those illustrious Greek philosophers, and of course exhibits the same phenomena in all its operations to the moderns, that it did to them. It is, moreover, always present with us, and always subject to our observation. It requires no excursions from home, nor apparatus of instruments or agents, to develop its operations ; and hence there is nearly the same coincidence of opinion concerning them, that there is of the qualities of bodies, that act upon the senses.¹

We can well recognize that Rush is too sanguine in his belief that the ultimate nature of the mind had been understood, but we can admire his optimism in the importance of this new division of medicine. How much of his enthusiasm he imparted to the students, some 3,000, who studied under him has yet to be evaluated, but his book on the mind was well enough received, for it went through five editions in America over the next 23 years. Rush's book was widely known in Europe in those years also, for it was published in a German translation, and one finds it mentioned and quoted frequently in the European medical literature. To Benjamin Rush what he called phrenology and what we know as psychiatry today was of fundamental importance in the training of the physician, and he worked as a teacher and writer to gain a wider recognition of its possibilities.

Eric T. Carlson, M.D., and
Meribeth M. Simpson, B.A.

CORRESPONDENCE

IATROGENIC DISTURBANCE

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: A colleague who used to relate his cases to me became, at times, very upset because he could tell when his patients started to become psychotic. At first, I reassured him by saying that he was not to blame, until one day he asked me to see one of his patients. After that, I could reassure him no longer.

Miss R., a Jewish lower middle class woman in her early 30's, had gone into therapy with the hope that it would aid her in getting married. (Therapy has now become a sort of magic that helps us to achieve everything we desire.) Dr. X., in his attempts to cure her "inhibitions," tried to "get out her aggression," with the result that the domestic situation steadily worsened. So Dr. X. persuaded Miss R.'s sister, with whom she lived, to go into therapy with a colleague. Since he also "tried to get his patient's aggression out," the quarrelling now became violent. Dr. X. also tried to remove the patient's sexual inhibitions, so that she became promiscuous and lost all self-respect. Furthermore, he told her not to allow her boss to "exploit" her and she consequently lost the job she held for over 10 years which had stabilized her and given her social standing. She became aggressive, depressed, anxious and agitated and was finally hospitalized by her therapist, who was unable to cope with her. After 6 months, with the help of shock treatment and general care, she had calmed down somewhat and was discharged.

When I saw her, she had gained 20 pounds as a result of the insulin and her

mental and physical condition was such that it precluded any possibility of her getting married. She was neither willing nor able to work and was living on the meagre allowance her brother, who could ill afford it, gave her. I could give her no advice.

A woman, applying to me for a secretarial position, confided to me that her little daughter had developed a neurosis and was receiving psychiatric treatment. The attempts to get "her underlying jealousy out" were so upsetting for the mother, that she too had to undergo treatment and was now looking for a job in order to finance her treatment and that of her child. She could not understand why I, a psychiatrist, was not eager to engage her since she so ardently believed in psychiatry and was making such sacrifices in its behalf. I refrained from telling her that, if they both dispensed with treatment, and the mother devoted more time to the family, the child might feel less jealous and be happier.

Not every maladjustment is neurotic. And not every neurosis is caused by suppressed aggression or cured by an indiscriminate release of aggression. There are cases of very timid, inhibited patients who could be helped by expressing a moderate amount of aggression in a socially acceptable manner. But unlimited and indiscriminate expression of aggression and sexual impulses is harmful to the patient's self esteem and often has disastrous social and family consequences.

Melitta Schmideberg, M.D.,

New York 25, N. Y.

MIND TAPPING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: I feel impelled to write you to express my objection to an article in the October Journal entitled "Mind Tapping: Psychiatric Subversion of Constitutional

Rights," by Dr. Thomas Szasz. Both in substance and in style, this article falls far below the standard to be expected in a professional journal.

The style is luridly sensational, from the first words of the title to the last para-

graph's attempted analogy of mental illness to witchcraft and of psychiatrists to "ecclesiastic witchhunters."

It would require an article almost as long as the original to itemize all the instances of unscientific thinking and writing exhibited. I shall merely categorize them:

Charges and startling assertions (example: "Psychiatrists have shown great alacrity in meting out life sentences . . .") unsupported by any evidence of research, empirical data or documentation of any kind.

The deliberate misuse of words, as when a judicial order of hospitalization is called "conviction" and "sentence," and the hospital stay is called "imprisonment."

Implications that the practices denounced are widespread if not universal, without any data on how prevalent they actually are.

Implications that these practices are generally or even unanimously endorsed by the courts and by legal scholars, without citing a single court decision so holding or

a single scholar.

The use of rhetorical questions to imply that their answers are self-evident, although a moment's thought would show that they are not.

The peculiar use of quotation marks, not to quote but to confess, covertly, that the words so marked are inaccurate.

The failure to present or evaluate the arguments pro and con, and the resort instead to mere invective and wholesale charges—which would raise a serious scandal if supported by evidence—that lawyers and judges, abetted by psychiatrists, deliberately indulge in actions that are unethical, illegal and a subversion of constitutional rights.

The question Dr. Szasz raises is a real one and deserves thoughtful discussion. But his article does not contribute to such a discussion.

Henry Weihofen,
Washington, D. C.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: In my article on "Mind Tapping" I asked: What sort of thing is compulsory pre-trial psychiatric examination? Professor Weihofen states that I did not give much of an answer. I imply, he says, that lawyers and judges, abetted by psychiatrists, "deliberately" deprive people of their constitutional rights. But this is precisely what I did *not* say. My article was an effort to describe a social and legal process, not a personal plot. The gist of my thesis was that though ostensibly for the benefit of the defendant, this procedure was actually to his detriment. My aim was not to attack individuals, but to argue that compulsory pre-trial examination is but another instance of

deprivation of civil liberties. It is a grave mistake to equate this criticism with the view that the critic believes that those who implement such medically-labeled procedures are badly intentioned. Indeed, I wrote that "I have no intention of impugning anyone's honesty. But honesty is not the issue. The issues are mental illness and the right to be tried."

Let us not forget that, to the liberal, what matters is not intentions, but power. For the fundamental threat to freedom is today what it has always been: the power to coerce. Psychiatric power, no matter how well intentioned, is no exception.

Thomas S. Szasz, M.D.,
Syracuse, N. Y.

PSYCHIATRIC RESEARCH

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Dr. Max Levin, in his article in the November, 1962 issue of the *Am. J. Psychiat.* asserts the superiority of investigation based on clinical case study over those which rely upon measurement and statisti-

cal analysis in behavioral studies.

To buttress his thesis Dr. Levin cites a statistical study of the responses of Negro children to white and brown dolls. Without identifying the study or its authors, he castigates this study as only proving the obvious and views this type of research as

"a growing scandal." Unfortunately for Dr. Levin, this particular example rather than supporting his thesis actually refutes it dramatically. It is clear from his summary that he is referring to the study done in the 1940's by Kenneth B. Clark and Mamie P. Clark on "Racial Identification and Preference in Negro Children" reported in the volume edited by Maccoby, *et al.*, *Reading in Social Psychology* (New York: Henry Holt, 1958). The data of this study comprised a significant portion of the psychological evidence proving that school desegregation is harmful to Negro children cited by the U. S. Supreme Court in its historic decision in school desegregation in 1954. So this "confirmation of the obvious," as Dr. Levin puts it, actually represents one of the most significant and definitive pieces of behavioral research done in recent years. It is clear that the data presented by the Clarks would not have had the persuasive influence it has had without the "numerous

statistical tables" that Dr. Levin deplors.

Dr. Levin also moralistically reproaches the Clarks for their "brutality" in "subjecting Negro children of tender years to mental torture." The mental torture to the child of self identification as Negro stems clearly from the youngster's awareness of his disadvantaged status—a status conferred upon him by his environment. It is a strange morality which decries the collection of convincing evidence of the origin of these children's pain for the successful purpose of relieving it, and fails to record the social origin of the pain as the real "brutality." An equivalent reasoning might object to complete medical examination of a child with a painful belly for the purpose of clarifying diagnosis and determining proper treatment on the basis that we are increasing the child's pain.

Stella Chess, M.D.,
New York Medical College.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Dr. Chess says that the illustration I selected, namely the study by Drs. Kenneth and Mamie Clark, fails to support my thesis, and, indeed, "refutes it dramatically." If this were true, I would be guilty only of having chosen the wrong illustration. But I do not agree that the illustration refutes my thesis. The fact that the Supreme Court cited the Clark study in its 1954 decision is irrelevant. I do not have the text of the decision, and do not know in what precise connection the Court cited the study. But will anyone serious argue that not until the Clark study did we know and appreciate the harmful impact of segregation and prejudice on the Negro child? This would be absurd. Thoughtful people understood the evils of prejudice long before the Drs. Clark were born.

The object of my article was not to "castigate" statistical studies, but to criticize the growing impression that such studies alone are worthy of investigation. This growing impression appears to be symptomatic of an age when people are beginning to think that a man and woman

contemplating marriage might well submit their doubts to an electronic computer.

To the charge that I reproach the Clarks for their brutality I plead not guilty. They are obviously decent people of high character, and I was careful to speak of the *unconscious* brutality of their investigation. You may reproach a man for what he does consciously, not unconsciously. And again I plead not guilty to the charge of having overlooked the social origin of the disadvantages that life holds for the Negro child. I am as much aware as anyone of the "real brutality" that confronts the Negro child, and I know that the Drs. Clark are not its authors. But this has no bearing on the (unconscious) brutality of their investigation. To anyone who disputes this, we need put only one question: If *you* were a Negro parent, would you like your child to take part in a study in which there is a possibility that he might break down and cry, and run from the room "convulsed in tears"? The analogy of the child with pain in the belly need not be considered, for it is, I submit, not a valid one.

Max Levin, M.D.,
New York, N. Y.

MATURITY OF PERSONALITY

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : The paper by Dr. John C. Whitehorn, "A Working Concept of Maturity of Personality," which appeared in the September, 1962 issue of the Journal, impressed me as an excellent concept of the term "maturity."

I am taking the liberty of calling your attention to the fact that a similar concept has been developed by me. At the same time I want to emphasize that Dr. Whitehorn could not have had any knowledge of my papers for the following reason :

At the annual meeting of the APA in Chicago, in 1957, I delivered a paper entitled, "Critique on the Application of Hypothesis and Theory of Dynamics." A summary and the axioms were published in "The Scientific Papers," the paper itself,

however, was not published by the Journal.

Some time later I wrote a paper, "Outline of a Theory of Neurosis" which was not accepted for publication by any of the leading psychiatric journals in America. I therefore translated the paper into German. This paper was subsequently published in Germany in 1959. (Z. Psychother. Med. Psychol., 66, Mar. 1959. The editor of this Journal is Ernst Kretschmer.)

I should like to mention also that part of my theory was developed in my paper, "Instinct of Self-Preservation and Neurosis," Psychiat. Quart., 252, 1954. To some extent this is true also of two papers which appeared in the Am. J. Psychother., 366, 1948, and 234, 1949.

Siegfried Fischer, M.D.,
San Francisco, Calif.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : I welcome Dr. Fischer's letter, calling attention to his efforts to take systematic account of the important human needs to feel secure and worthwhile as supports to good social functioning and for the avoidance of neurotic reaction.

Dr. Fischer, however, constructs on this basis a more ambitious, systematic theory of causation than I consider is warranted. We should, I think, reserve judgment as to the complete adequacy of such theories about the causation of neurotic or psychotic illness. There may be important genetic

and biochemical deficiencies, or physiological disturbances, which also play a part in the complex causation, precipitation, and perpetuation of such illness.

Meanwhile, lacking a full knowledge of such factors, and having quite limited means of controlling them, we, as physicians in psychiatry, can do much to assist many of our patients to cope better with their life situations through our compassionate understanding of attitudes and by whatever talent or skill we may have for evoking the patients' emotional resources.

John C. Whitehorn, M.D.,
Baltimore, Md.

CORRECTION

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : We sincerely regret the error, which has been called to our attention, concerning the recording of a reference (#27) in our section on "Clinical Psychiatry and Psychotherapy" in the "Review of Psychiatric Progress 1962," appearing in the *Journal*, 119 : 616-621, 1963.

The reference to *Psychosomatic Medicine* names Sloane, *et al.* as authors. The correct reference is Barber, T. X. : Hypnotic Age Regression : A Critical Review. *Psychosom. Med.*, 24 : 286, 1962. This correction will appear in all reprints distributed.

Nolan D. C. Lewis, M.D.,
Frederick, Md.

NEWS AND NOTES

CENTRAL NEUROPSYCHIATRIC HOSPITAL ASSOCIATION.—The annual meeting of the Association will be held at the Hotel Bismarck, Chicago, Ill. on Mar. 14-15, 1963.

Henry Dollear, M.D., is President of the CNPHA and George T. Harding Jr., M.D., 445 East Granville Road, Worthington, Ohio, is Secretary.

THE ACADEMY OF PSYCHOANALYSIS.—The annual meeting of the Academy of Psychoanalysis will be held at the Hotel Ambassador, St. Louis, Mo., May 4 and 5, 1963. The subjects for the panel will be "Post-Freudian Contributions to the Theory and Practice of Psychoanalysis and Psychotherapy." Inquiries may be directed to Alfred H. Rifkin, M.D., 125 East 65th Street, New York 21, N. Y.

The officers of the Academy for 1962-1963 are: President: Sandor Rado, M.D.; President-Elect: Franz Alexander, M.D.; Secretary: Alfred H. Rifkin, M.D.; Treasurer: Earl G. Witenberg, M.D.

CONGRES DE PSYCHIATRIE ET DE NEUROLOGIE DE LANGUE FRANCAIS.—This congress will be held at Nancy, Sept. 9-14, 1963. Subjects considered will be: 1. Psychiatrie: "Les états délirants oniroïdes," by M. S. Follin; 2. Neurologie: "Les manifestations nerveuses des hémopathies," by MM. R. Labauge et Izarn; 3. Médecine Légale: "Fugues et crises d'automatisme de longue durée chez l'adulte," by M. M. Bonduelle.

THE SOCIETY FOR CLINICAL AND EXPERIMENTAL HYPNOSIS.—The Society will hold its 15th annual meeting at the Barbizon Plaza Hotel, New York City, Oct. 23-26, 1963.

George Wallace, M.D., 9101 Shore Road, Brooklyn 9, N. Y., is chairman of arrangements.

LINDAUER PSYCHOTHERAPIEWOCHES.—The thirteenth Lindau Psychotherapy Week will be observed in Lindau, Bodensee, April 29-May 11, 1963, under the chairmanship of Dr. Helmuth Stolze. The first week will be devoted to papers and discussions on the theme "Vom Wesen der Sexualität." A

workshop will be conducted during the second week. For further information please write to the Sekretariat der Lindauer Psychotherapiewoche, Muenchen 27, Adalbert-Stifterstr. 31, Germany.

INTERNATIONAL JOURNAL OF NEUROPHARMACOLOGY.—Volume 1, numbers 1 to 3, of this Journal bears the date November 1962. It contains the papers presented at the First International Pharmacological Meeting in Stockholm, 1961. This Journal is edited by B. B. Brodie, Bethesda, and C. Radouco-Thomas, Geneva, with an international Editorial Board of 33 members with Nosal of Basle as Associate Editor. There is an Editorial Advisory Board with chairmen C. Heymans, Ghent, and H. H. Jasper, Montreal, with an extensive international list of members. The Journal is published by the Pergamon Press, Oxford, London, New York and Paris, and will appear bimonthly.

Annual subscription rates for libraries, government agencies, industrial establishments, etc., \$40.00; for individuals ordering the Journal directly from the publisher for their personal use, \$15.00.

WISCONSIN PSYCHIATRIC INSTITUTE.—A workshop on psychotherapy and psychotherapy research will be held June 23-29, 1963 at the University of Wisconsin's "Wisconsin Center," sponsored by the Wisconsin Psychiatric Institute. Principal leaders will be Carl R. Rogers, Eugene T. Gendlin and Charles B. Truax. Subject areas will include individual and group psychotherapy with schizophrenics and others, and research instruments, methods and findings in those areas. The workshop is intended for experienced psychotherapists with a doctoral degree or equivalent training.

For application and information write to: Workshop, Wisconsin Psychiatric Institute, Psychotherapy Research Group, 1339 University Avenue, Madison 6, Wisconsin.

CORRECTION.—Heading the caption lines of the article "Murder and Insanity," page 754, of the February issue, the name of the author should be added, "Aeschylus (526-456 B.C.). Eumenides:."

BOOK REVIEWS

NEBRASKA SYMPOSIUM ON MOTIVATION, 1961.

Edited by *Marshall R. Jones*. (Lincoln : University of Nebraska Press, 1961, pp. ix + 210, with indexes. Paper \$3.25, Cloth \$4.25.)

This volume presents the papers and discussions of the 9th annual Nebraska Symposium on Motivation. It is not a book for casual reading for one in search of quick and easy motivational formulations.

In the initial paper on the "Behavioral Regulation of Water-Electrolyte Balance," John L. Falk presents a body of experimental work on the eating behavior and drinking behavior of rats which may disturb the complacency of anyone who has believed that all such behavior was neatly explainable as homeostatic. In summarizing a number of experiments he states: "Both the compensatory and normal acceptance of NaCl solutions seems to be under the direct control of central factors. These central factors are responsive to homeostatic requirements, but apparently are not solely determined by these considerations."

Philip Teitelbaum presents a review and experimental report on the feeding and drinking behavior of rats, after hypothalamic injuries (1) in the ventromedial region (to which he attributes such an effect upon the satiety mechanism as to lead to obesity and then to regulation of body weight at the obese level) and (2) in the lateral region (producing deficits in feeding and drinking from which there may occur partial recovery which follows a pattern of four clear-cut stages).

Carl Pfaffmann reports at length on the sensory and motivating properties of taste.

Perhaps the prospective reader, if psychoanalytically oriented, should be advised that the paper on "A Motivational Interpretation of Extinction," by David Birch, bears no discernible relation to the so-called death instinct. Rather, it is concerned with the reversal learning performance of rats. Experiments do not confirm the expectation that the persistence of a response under non-reward conditions is directly related to the number of prior rewarded trials. Birch is concerned with quantitative behaviorial measurements, in the tradition of Hull; in these experiments he measures latency of response, and presents his results both as reciprocal of latency and as logarithm of latency. He suggests that the superior extinction achieved by the overtrained may be

motivationally explained by the introduction of competing responses activated because of the higher level of frustration experienced by the overtrained (if this reviewer has understood correctly).

The second section of the book is more directly concerned with human motivation. Seymour B. Sarason reports his awareness that human beings cope with problems in development which are distinctively different in content than those faced by experimental animals, and he presents evidence (in the form of illustrative examples) for his assumption of the interrelatedness of the contents of the human problems. He raises but does not answer the question, "How are different problem-solving areas related?"

W. J. McKeachie explores the interrelatedness of student motivation with teaching methods in college learning, particularly in regard to the "feed-back,"—the clarity with which instructors indicate how to obtain good grades. Students differ in how they are influenced by such feed-back. His material is organized according to the ratings of different students in achievement motivation, power motivation and affiliative motivation. The author states that he is "pleased with the outcomes in relation to the original problem of identifying important human motives in education."

This book, and this series of symposia and publications, serve to assemble representative samples of the large amount of experimental work and psychological theory concerning motivation. Most of the reports are not readily assimilable for clinical use; yet studies of motivation have relevance to basic psychiatric problems.

Baltimore, Md.

PSYCHOPATHOLOGIE HEUTE. Professor Dr. med., Dr. phil., Dr. jur. h. c. Kurt Schneider zum 75. Geburtstag gewidmet. Edited by *Heinrich Kranz*. (Stuttgart : Georg Thieme Verlag, 1962, pp. 380. \$12.00.)

This book is a precious birthday gift for Kurt Schneider from forty of his pupils and friends. Statistically speaking, there are thirty German, three Italian, two French, two English, one Belgian, one Portuguese and one Spanish contributor. Among them are thirty-four psychiatrists, one neurologist, one clinical

neurophysiologist, one pediatrician, one philosopher, one psychiatric social worker and a professor of criminal law.

The first essay by Henri Ey (Paris) deals with Kurt Schneider's particular merits in the clinical field; Ey calls him "le plus grand Maître de l'école clinique contemporaine." De Rosa (Heidelberg) develops thoughts concerning psychopathology in respect to history of science. Pauleikhoff (Muenster, Germany) considers psychopathology as an independent science in its own right. Müller-Suur (Goettingen, Germany) discusses the specific event of the schizophrenic from various viewpoints. Weitbrecht (Bonn, Germany), whom this reviewer considers one of the leading German psychiatrists, uses the problem of dementia to explicate how imperative it is to rid oneself of old prejudices and to come to new concepts. E. Schmidt (Heidelberg), the lawyer mentioned above, gives a sound consideration how judge and expert can and should cooperate in criminological problems.

It is not possible here to mention all the contributions. The editor of the volume—Kranz (Mainz)—can be congratulated on the work of love and labor in which he shortly says in his preface that the pupils have worked ahead and with their very progress shown what "psychiatry today" owes to Kurt Schneider. Despite the serious facial expression on the excellent photo that precedes the text, Kurt Schneider appears to be well pleased with the endeavors of his students and friends. To him: *ad multos annos!*

EUGEN KAHN,
Houston, Texas.

DEATH ROW CHAPLAIN. By Byron S. Eshelman with Frank Riley. (Englewood Cliffs, N. J.: Prentice-Hall, 1962, pp. 252, incl. index, illus. \$4.50.)

Chaplain Eshelman's prison experience includes 3 years on Alcatraz Island and 10 years at San Quentin. His collaborator, Frank Riley, is a free-lance writer of considerable experience.

The substance of this book would seem to make credible the statement that Mr. Eshelman "has worked more intimately and at greater length with more men and women awaiting execution than any other person in America."

The author states his own position clearly at the beginning: he is opposed to capital punishment; he regards it as a symptom of a deeper social malady and holds that "When the deeper condition is adequately healed, the

surface symptom will vanish."

At the same time he quotes respectfully J. Edgar Hoover of the F.B.I. "The criminal fears capital punishment. Where there is no shadow of doubt concerning the guilt of the defendant, the public interest demands that capital punishment be invoked where the law so provides." But the chaplain must stick to his *Fach*, and he does so apparently with conviction. He marshals some persuasive reasons, social and biological. In the infliction of capital punishment, he feels, "the Son of Man has been crucified again."

As chaplain he spends much time with individual inmates, especially those awaiting execution on Death Row. An agnostic convict's lack of religion he respects. To others amenable to religious influence he gives guidance. One member of a "prayer therapy group," he mentions, "has since been paroled and is now making better than average grades as a divinity school student."

In his initial assignment to Alcatraz Eshelman came to know Robert Stroud, the "Birdman of Alcatraz," who had committed his first murder at 18. Sentenced to death, he was granted a commutation by the invalid president Woodrow Wilson. Last year at age 70, after 52 years in prison, he was working on writs, still looking hopefully toward parole.

Chaplain Eshelman gives vivid accounts of the lives and crimes of the men on the Row and how they met their death. He relates that in general they were on easier terms with the chaplain than they were with the psychiatrists or psychologists. He describes the ritual of the convicts' last day, including the chaplain's presence at the execution if the condemned man wished him there or did not definitely object to his attendance, as an occasional one did. Sometimes, as suggested by the picture on the dust jacket, the chaplain seemed to have been able to infuse religious faith into the mind of the convict so that with sins forgiven, he could go to his death with prospect of a happy life beyond, in one case for example reunited with the wife he had murdered.

The longest case history in the book is that of Caryl Chessman. The "twelve-year hell" (Chessman's words) he spent on Death Row at San Quentin is the enduring shame of American judicial procedure; Eshelman as a result of 10 years intimate acquaintance with Chessman states categorically: "I believe that the State of California executed the wrong man."

What was remarkable about Caryl Chessman was that during his life on Death Row he

gave himself much of a liberal education. He read law and became expert in his own defense. Eight times his date with the gas chamber had been set; seven times he had been able to beat it off. He was the leader and legal advisor of other convicts on the Row. The chaplain reports that a noted legal expert had said that Chessman was "one of the sharpest and best trained lawyers I've ever met." His I.Q. was 130.

Chessman was resourceful enough to smuggle the mss. for several books off Death Row to his publisher in New York City. The first of these, *Cell 2455, Death Row*, published in 1954, "sold more than half a million copies in the United States and has been translated into a dozen foreign languages." Much of the income from his publications went for legal assistance. The Government did everything it could to prevent him from earning that income and when he did earn it the Government levied a huge income tax. He estimated that he had spent about \$100,000 for his defense and that the State had spent about \$800,000 "trying to jockey me into the gas chamber." It took the State 12 years to succeed.

Chessman was an agnostic and he did not soften at the end.

Chaplain Eshelman sums up his arguments against capital punishment in the last two chapters of his book, titled "Some Clinical Insights" and "A Theological Interpretation." These chapters impress the reviewer as rather an anticlimax. The author speaks of possible assumed rationalization by a criminal of his criminal motives based on "the dangerous smattering of psychology so prevalent in our culture, and so ineptly disseminated by newspaper and magazine 'counselors.'" The author does not impress one as being wholly free from this same tendency. And when he concludes that the killer "is trying to escape from anxiety and fear so that he can be at peace [and that], without being able to define it, he is actually suffering from a profound religious hunger," should he not be a little more discreet in his phraseology? There are other such arguable points in this last chapter, which is really quite a sermon.

However the book was worth the writing. It throws vivid light on the lives of the convicts whose case histories are given, particularly on that of Caryl Chessman whose life had become valuable. The reviewer agrees with the chaplain that it should not have been destroyed. Psychologically he was probably superior to some of those who had authority over him. There is too much forgetting that the law is made for man rather than that man is

made for the law. It is submitted that the ancient dictum "the punishment should fit the crime" should be replaced by a better one: "the punishment should fit the man."

C. B. F.

FOUNDATIONS OF PSYCHOPATHOLOGY. By John C. Nemiah, M.D. Introduction by Kenneth E. Appel, M.D. (New York: Oxford University Press, 1961.)

Here is a book with unusual merit; it is beautifully written, has literary quality and shows the important use to which a broad cultural background may be put by a teacher of psychiatry. Dr. Nemiah intends the book to be an introduction, but it is much more than that. It introduces psychological medicine to the reader in a way that initiates sympathetic understanding of this major aspect of medical practice. As Professor Kenneth Appel says in his introduction: "This is in many ways a new kind of book in psychiatry. It does not represent the customary working-over of wellworn concepts for presentation to students; nor is it a new textbook of psychoanalysis. There is nothing treadmillish, schematic, or pat about it, nor is it partisan in approach. Clear, accurate, and scholarly, it sketches pathways and byways of explorations into human nature—its vicissitudes and distortions, its blind alleys and tragedies, its pathos and potentials for creative integration.

"... This book is not merely one on psychopathology. It is a sympathetic, clear, understandable portrayal of much that is essential in psychiatry, human nature, its fallings by the way and its rehabilitation."

The book is in four parts. In the first is discussed mind and body, fantasy ("to classify is not to understand") and interviewing ("the importance of being a listener"). Part II takes up three fundamental concepts: psychological conflict, the unconscious and repression, and the childhood roots of emotional disorders. Part III deals with symptom formation and is made vivid by many verbatim reports from patients. In Part IV there are illuminating chapters on defenses, psychological complications of physical illness, the concept of psychosomatic medicine, and the importance of understanding the doctor-patient relationship.

Amid the plethora of publications on psychiatry this book stands out as one which can be recommended to the young physician or student to start him off on the right foot in his understanding of psychiatry in medicine.

S. C.

EXPERIMENTS IN PERSONALITY. Vol. I, Psychogenetics and Psychopharmacology; Vol. II, Psychodynamics and Psychodiagnostics. Edited by *H. J. Eysenck*. (New York: Humanities Press, 1961, pp. xii + 262 and viii + 333. \$16.00.)

These two volumes have been eagerly awaited and will be welcomed. They report a series of important experiments from the Psychological Department of the Institute of Psychiatry, Maudsley Hospital. The experiments reflect the editor's general theory of personality, which is well-known.

The scope of the experiments is almost bewildering in its ambition. Volume I (Part I) deals with Broadhurst's experimental enquiries into the Applications of Biometrical Genetics to the Inheritance of Behaviour. Part II deals with Psychopharmacology, and reports a large number of experimental studies on the effects of stimulant and depressant drugs. A new mathematical model is presented for the classification of drugs according to their psychological effects.

Volume II (Part I), Experiments in Psychodiagnostics, is devoted to a very detailed investigation of thought-disorder in schizophrenia (Payne and Hewlett). Part II, Experiments in Psychodynamics, presents several experiments testing some deductions from Eysenck's dynamic theory of anxiety and hysteria. Part III, Experiments in Psychometrics, examines modern statistical methods useful in the solution of problems of classification, diagnosis and nosology. Most of the methods discussed are those used in the investigations reported in earlier parts of the book.

The editor's Epilogue (The Place of Theory in Psychology) complements his Introduction (which interprets the reasons for and purposes of the total publication), and justifies the importance and systematic significance of "weak" theories in the fields of investigation here under scrutiny.

W. LINE, PH.D.
University of Toronto.

A MANUAL OF NEUROLOGY AND PSYCHIATRY IN OCCUPATIONAL MEDICINE. By *Ralph T. Collins*. (Modern Monographs in Industrial Medicine. New York and London: Grune & Stratton, 1961.)

This monograph grows from the author's many years experience as consulting neurologist and psychiatrist for the Eastman Kodak Company. It does not pretend to supplant the more inclusive textbooks of neurology or psychiatry but attempts to bring into one volume

an outline of such information as might be useful to the industrial physician. In 232 pages the author covers a wide area, relying largely on outlines, tables and charts.

The company with which the author is associated has for a long time been interested in the welfare of its employees for many reasons. Its medical department is well-established employing the services of many specialists other than in neurology and psychiatry. To some outside observers the attitude of this company has been likened to that of a benevolent matriarch. The book reflects that attitude and takes it for granted that psychiatrically and neurologically handicapped employees will under most circumstances be continued in employment. The manual, since it is written by one active in industry, is written with the presumption that all employees, even those ill, are well motivated for employment. The book may not be so applicable to neuropsychiatric problems which may be experienced in a welfare agency, a charity clinic or a union health center.

One major criticism we have of this volume is the tendency to underestimate the sophistication of our non-psychiatric colleagues. Our experience in conducting seminars with non-psychiatric physicians has taught us not to be hesitant in explaining the dynamics of various psychiatric problems. For example, the dynamics of an illness triggered by a promotion are no different from those emotional disorders that follow moving from a crowded apartment to a more luxurious one, the birth of a grandchild or the attainment of a great reward, all of which can result in depressions or other disorders in susceptible persons. The difficulties are not in the new apartment, for example, upon which the patient may focus his attention, but more usually the repressed anger which kept him in the previous frustrating situation without doing anything about it. To simply explain regressions as the desire to become dependent again on those around one (pp. 156) is to emphasize a secondary gain rather than the return, for one reason or another, to a previous stage of adaptation.

As might be expected in a first edition certain errors went unnoticed. Among others: Kernig's sign (pp. 39) is confused with nuchal rigidity in meningismus; in Lasègue, the accent is grave rather than acute; it is Patrick test not sign; and commitment has only one "t" in the center. The tests discussed briefly on page 153 are those of abstract conception rather than intellectual attainment.

Aside from these rather minor errors, Dr. Collins is to be congratulated for compiling a

massive amount of material in condensed form. It is hoped that in future editions he will be less hesitant in showing his psychiatric erudition.

BRAIN AND BEHAVIOR. VOL. 1. Proceedings of the First Conference. Edited by *Mary A. B. Brazier*. (Washington, D. C.: Am. Instit. Biol. Sci., 1961, pp. 433. \$7.75.)

This volume contains the proceedings of the first of a projected series of conferences sponsored by the Brain Research Institute of the University of California in Los Angeles under the general heading "Brain and Behavior." The conference was supported by the National Science Foundation, and the proceedings published by the American Institute of Biological Sciences, with whom Frank Fremont-Smith, who organized similar conferences for the Macy Foundation, is now affiliated. The book is handsome, well printed and illustrated, and well edited. It achieves distinction not only from the high scientific standing of the 27 participants, but also from its truly international character, since nearly half of the participants came from foreign countries, including Poland, Hungary and the U.S.S.R.

Though this conference concentrated its interest on sensory perception, it inevitably involved most of the current basic problems of neurophysiology, where developments of the past two decades, due largely to newer electrophysiological techniques, have been extraordinarily rapid. Those of us who have been educated to believe in the specificity of end-organs and sensory nerves will find their basic assumptions challenged and revised. Sensation can no longer be regarded as the mere product of discrete nerve impulses initiated in the periphery and conducted on specific tracts to the thalamus and cortex to form complex synaptic connections or to link up with higher neurones in the motor complex. Every one of these assumptions must now be questioned or reformulated. The same end-organs can transmit different sensory modalities (Wedell), the fiber-tracts are far less specific than we thought, the non-specific alerting systems can permit or block a sensory perception, descending elements may be essential in perception, and the sensory cortex not only seems no longer to have the strict boundaries we once thought it had, but even the sensory and motor cortex are now intermingled. The supposed unitary nature of the alerting reticular system

is now decomposed by the ingenious pharmacological experiments of Anokhin who suggests there are three distinct subcortical activating mechanisms: 1) to maintain wakefulness, 2) to alert or arouse, and 3) to warn or alarm. Galambos pulls out the last remaining prop of traditional neurological thinking in psychiatry by developing his bold view that the glial structures are important elements in both synaptic relations and in storage of sensory information. "It is possible," Galambos declares, "that several of the complexities of brain function we have been striving with limited success to comprehend through analysis of neuro-neuronal processes alone will become resolved at last when we obtain solid data from experiments on glia function."

The summation by Teuber is erudite and judicious. There is much that seems important in this compact and crowded volume, but I think its main effect on most psychiatrists will be to drive them to the newer neurophysiological texts to discover what has been going on in recent years. The gap between these experimental studies and human behavior is still enormously big, but clinical psychiatrists cannot afford to indulge themselves with points of view based upon an outdated physiology. Even our notions of "chronic brain syndrome" and "organicity" seem very crude if one takes account of the complex subtlety of neural processes as described here. If we cannot emulate our laboratory colleagues in the precision of their data and methods we can at least take notice of their work, and of their expressions of confusion or ignorance. It would be well if more of the physiologists could address themselves to clinical problems and if clinicians could more often test some elements of their hypotheses in the laboratories.

JOSEPH WORTIS, M.D.,
New York, N. Y.

ASYLUM TO COMMUNITY: THE DEVELOPMENT OF THE MENTAL HYGIENE SERVICE IN VICTORIA, AUSTRALIA. By *E. Cunningham Dax, M.D.* (Melbourne: F. W. Cheshire Ltd., for the World Federation for Mental Health, 1623-78th St., New York 21, N. Y., 1961, pp. 230.)

In 1952 Dr. Dax went to Australia from a hospital superintendency in England. His new job was to develop a modern mental health program for the State of Victoria under 1950 legislation which had established a Mental Hygiene Authority for Victoria. Doctors J. R. Rees and Morton Kramer visited Victoria in 1960 and were so impressed by the accom-

plishments of Doctor Dax and his colleagues in the span of 8 years, that they urged him to write up his experiences for the World Federation for Mental Health. Hence this extraordinary book by Doctor Dax, who, in British tradition, is both master of the understatement and sensitive to the broader scene—current and historical—in which his work has been carried forth.

Victoria is the smallest state in Australia proper. It is comparable in size to Minnesota and in population to Connecticut or Maryland. Of its almost 3,000,000 persons, 1,900,000 live in Melbourne and its environs. In 1952 the services and facilities for the mentally ill were in a deplorable state of overcrowding, neglect and disrepair. By 1960 these conditions in the institutions had been, for the most part, corrected by staff increases, new construction, remodeling of some old structures and abandonment of others. Professional training programs and new research opportunities had now begun to bring many more young people into the mental health field. Volunteer programs in the institutions and in new community clinic and mental health services were proving extraordinarily successful.

The philosophy expressed by Doctor Dax's title, *Asylum to Community*, can be seen in action in his descriptions of a "Psychiatric Unit," and the "Personal Emergency Advice Service." A "Psychiatric Unit" is the headquarters of the regional psychiatric and mental health services. It is adjacent to a general hospital, may purchase services from it, but is not a part of it, thus differing from the usual psychiatric wards and clinic services in general hospitals. Although a "Psychiatric Unit" has many functions, Dr. Dax highlights the following: public relations and mental health education; consultation services to schools, public welfare, public health, general practitioners, police, clergy and others; the staffing of emergency services, outpatient clinics for adults and children, a day hospital with a small inpatient facility, and community rehabilitation services for formerly hospitalized patients.

The Personal Emergency Advice Service opened in April 1960. Over 100 trained volunteers are available to man the three telephones located in a Melbourne clinic. The phone number is listed on the first page of the Melbourne directory. Callers can remain anonymous. During the first year of operation almost 2000 calls were handled. The volunteers not only give information but are trained to pick out acute emergencies from those that can wait, and to "help persons solve their own difficul-

ties by talking them out." Consultants and clinical services are immediately available as backstops for the volunteers. Doctor Dax stresses the value of this service as an anxiety reducer and as a tool for public education and orientation.

This reviewer is impressed not only with the full involvement of the public but also with the demonstration of the value of having a central mental health authority which can plan and coordinate all mental health services and functions for the state, including preventive services as well as hospital, clinic and consultation services for the mentally ill, the mentally retarded, juvenile offenders, and others. Many of the recommendations of the Joint Commission on Mental Illness and Health can be seen in operation in the Victoria program. The book is recommended to all who are concerned with improvement of our mental health programs. Mental Health Associations could provide a great service by making this book available to legislators and other state officials concerned with or responsible for such services.

WARREN T. VAUGHAN, JR., M.D.,
San Mateo, Calif.

MENTAL HEALTH IN THE METROPOLIS. The Midtown Manhattan Study. By Leo Srole, Thomas S. Langner, Stanley T. Michael, Marvin K. Opler, and Thomas A. C. Rennie. Thomas A. C. Rennie Series in Social Psychiatry, Vol. 1. (New York, Toronto, London: Blakiston Division, McGraw-Hill, 1962, \$9.95.)

Classical psychiatry, having been concerned with individual pathology and malaise for the longest time, finds itself drawn more and more into a variety of functions within the community and called upon for the purpose of interpreting, for public education, preventive services and community leadership. Such experiences prompted the late Thomas A. C. Rennie to assemble a staff of sociologists and psychiatrists to study the mentality and discontents of a circumscribed area, Mid-Manhattan.

This reviewer introduces the terms "malaise" and "discontent" advisedly because the authors in their search for a definition of being well and the deviations from this status have given up the clinical nosological foundations, i.e., the absence or presence of diagnosable pathology. They feel that social functioning and smooth adjustment to social life should be the matrix from which concepts of mental health may be derived. Several years ago Marie

Jahoda, analyzing current (sociological) concepts of positive mental health, left the reader with the feeling he had passed by a long line of beautifully arranged scrap heaps. Not one of these concepts could finally hold its own. The same objection must, on principle, also be raised against *Mental Health in the Metropolis*.

The book, written to satisfy both the specialist and the general reader, is somewhat too top heavy with statistics for the latter, and not sufficiently detailed for the former type of reader.

Having assembled all the objections, this reviewer may say that this a highly worthwhile book, one that opens up vistas and asks questions that remain sensible even if answers are not given or may be disputed. "If the Midtown Study in any way illuminates the proposition that emotional blights might germinate at points of encysted socio-cultural dysfunctions, then it will have served the vision of Rennie and his colleagues."

Moreover, there is, from the pen of Leo Srole (Chapt. 5, 6 and 7), a community portrait that, as Srole modestly says, "perhaps would be better drawn through the novelist's or playwright's special flair for conveying character in action." This reviewer does not hesitate to call these chapters the most dramatic and tangible picture of New York he has ever read. Those who have cursed New York and those who have learned to love it are quoted. "The real advantage of living in New York is that all its residents ascend to heaven directly after their deaths, having served their full term in purgatory right on Manhattan Island." Steinbeck left the Whore of Babylon only to come back and experience mystically that he was no longer a stranger, that he had become a New Yorker. "Since the New York child has breathed exhaust fumes all his life, he can endure anywhere . . . he wouldn't swap New York for all the fresh air in the West." On the planting of trees in the streets of Manhattan some editorialist remarks: "The Indians may yet be persuaded to take it back." "New York is the world with every vice and blemish and beauty . . . What more could you ask?"

As the book is being quoted frequently, it should be brought out clearly that there are no definite results. Particularly, the popular blame that living in New York is tantamount to living in a constant tension, if not foreshortening one's life, is not confirmed by the Mid-Manhattan Study.

W. G. ELIASBERG, M.D.,
New York, N. Y.

ATLAS III. ILLUSTRATIONS OF THE NERVOUS SYSTEM. By Louis Hausman, M.D. (Springfield, Ill.: C C Thomas, 1961, pp. 168. \$9.50.)

This Atlas, along with the previously published Atlases I and II, is planned to be used with the author's textbook *Clinical Neuroanatomy, Neurophysiology and Neurology, with a Method of Brain Reconstruction*, published in 1958.

Atlas III, seen apart from the rest of the series, stresses the nerve-pathways and their functional significance portrayed in diagrams of great clarity, many of which have been drawn by Miss Mary Lorenc. In the more specialized fields of study diagrams have been reproduced from modern "classical" papers to illustrate the fundamental principles of such subjects as cerebrospinal fluid pressures, electroencephalography, arteriography, venography, ventriculography, intervertebral disc herniation and the results of cortical stimulation in the study of epilepsy.

There is no index, but the use of this Atlas as a reference book is assisted by a detailed table of contents.

ERIC A. LINELL, M.D.,
Toronto, Canada.

FIRST INTERNATIONAL CONFERENCE ON CONGENITAL MALFORMATIONS. (Philadelphia: J. B. Lippincott Co., 1961, pp. 314. \$7.50.)

This volume presents the papers and discussions at the First International Conference on Congenital Malformations, which took place in London, 18-22 July 1960. The papers present a very wide coverage of this important subject, and constitute an authoritative and important survey of this new field of investigation.

ASHLEY MONTAGU, Ph.D.,
Princeton, N. J.

NEUROLOGICAL FOUNDATIONS OF HUMAN BEHAVIOR. By C. Judson Herrick. Introduction by Paul G. Roope. (New York: Hafner Publishing Co., 1962, pp. 334. \$9.50.)

Neurological Foundations of Human Behavior, by the founder of the American school of neurology, the late C. Judson Herrick, is a classical work, first published in 1924, and out of print for some years. It is good to have this fundamental book available again. Good wine needs no bush, and the present volume has an established and imperishable reputation which requires no gilding. It must, however, be said, that the volume is as readable and as stimu-

lating as any book published within the last 40 years, and throughout is infused with the personality of a man who was at once both a great investigator and a great humanist.

A classic is by definition a book that is either out of print or unread or both. Well, *Neurological Foundations of Human Behavior* is back in print. It is an advantage which should not be overlooked.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

GENERAL PATHOLOGY. Edited by Sir Howard Florey. (Philadelphia and London : W. B. Saunders Co., 1962.)

The 3rd edition of this well-established text book of general pathology has brought in a remarkable innovation. Electron microscopy has become an integral part of the tools employed by the pathologist. The author, himself a well-known electron microscopist, has used his own researches in the field of inflammation and in the study of mucin secretion as a basis for rewriting the chapters on these two subjects. The electron micrographs which accompany these chapters are so excellent that they can hardly be surpassed, and they provide the student with a totally new dimension in the study of basic pathology.

The remainder of the book, although fundamentally altered in some parts, remains essentially the same as in previous editions. One may level only one criticism against this book and that is its extent and thoroughness which render it somewhat undigestible to the undergraduate, and which may even present a hard lump to swallow for the postgraduate student.

Thus in essence this is a textbook for the specialist in the field of pathology, and should be treated by any other medical man as a reference book only.

JAN W. STEINER, M.D.,
University of Toronto.

BEHAVIOR OF THE ORGANISMS. By Herbert S. Jennings. Introduction by Donald D. Jensen. (Bloomington : Indiana Univ. Press, 1962, pp. 366. \$7.50.)

Behavior of the Lower Organisms is one of the classics of biology, by one of its greatest practitioners, Herbert S. Jennings. It was first published by Columbia University Press in 1906. It is curious that nowhere in this reprint, though it contains an interesting introduction by Dr. Donald Jensen, is this fact mentioned. There are many things to be said about this volume. In the first place, it remains as inter-

esting, as stimulating, and as sound as it ever was and always will remain. It is a seminal work for all who have any interest in the nature and meaning and evolution of behavior. In the second place, it is of great importance in the study of the development of the science of behavior. Among other things, it was the work which most influenced John Broadus Watson in the development of his own thinking, although he was the reviewer who, in 1907, in the *Psychological Bulletin*, wrote a highly critical review of the book. It is not to be wondered at that when, subsequently, Watson came to embrace Jennings' views he should have been loath to acknowledge their paternity. Dr. Jensen tells this story in his excellent introduction which, however, as I have already indicated, leaves bibliographically something to be desired.

The book is reproduced exactly as it was originally published, except that the type size is somewhat smaller. This is a great boon, because one can quote from this edition, as if it were from the original, word for word, and page-by-page. It is a book that should be read and in the library and in active use by all students of behavior.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

THE WIDENING WORLD OF CHILDHOOD. By Lois Barclay Murphy, et al. (New York : Basic Books, 1962, pp. 399. \$10.00.)

In our abnormal culture we have grown so preoccupied with the abnormal that the normal is likely to be lost by the way. The amount of research, for example, that has been on the normal behavioral development of the child is far outrun by that on the development of the abnormal child. A new and original work on the development of the normal child's behavior is therefore welcome. Adults, alas, too often fail to remember what it was like to be a child, and to realize that it is much more difficult to be a child than it is to be an adult. One of the most serious difficulties in the path of normal development for the child, one of the most intransigent obstacles to be overcome, is the adult. Adults expect children to be better than they are themselves. The child has to cope with expectations which are often conflicting. His world is full of awesome occurrences, or at least, occurrences that seem so to him; it is filled with frustrations, temptations, and confusions.

"Swept with confused alarms of struggle and of flight, Where ignorant armies clash by night."

How does he cope with all these problems? The answer to that question, based on detailed observation of 32 normal children, is the subject of this book. Because the team of observers have carried out their observations with intelligence, sensitivity, and imagination, this book constitutes an invaluable case-history report of the manner in which the normal child manages to cope with his environment and establish some sort of mastery over it on his way to that ever-widening experience which will lead him from childhood to maturity.

PROGRESS IN NEUROLOGY AND PSYCHIATRY.
Vol. XVII. E. A. Spiegel, M.D. (Ed.).
(New York: Grune & Stratton, 1962, pp.
xiv + 607. \$12.75.)

This annual series is one of the best compilations of its sort of which this reviewer is aware in the whole of medical literature. Spiegel has a distinguished editorial board of assistants, and there are more than 60 contributors to the 35 chapters of subspecialties into which the four main subjects, basic sciences, neurology, neurosurgery and psychiatry, are broken down. Nearly 5,000 articles were reviewed, covering the principal Continental languages besides the literature in English. The text notes nearly 4,000 of these, which are indexed as reference lists after the appropriate chapters; and the references in the most important of these papers cover many articles which there was not space enough to mention.

It is impossible to assess authoritatively the individual papers in a compilation of this sort without virtually duplicating the work of the original researchers; the collection is encyclopedic, and, as in all collections of this type, including book reviews, the papers range from the bare reportorial type to critical evaluations of therapeutic means and techniques. Where there is critical evaluation, this reviewer would not in all cases endorse the conclusions without qualification. For example, he disagrees with the following statements by Frederick T. Kapp, M.D., and Louis A. Gottschalk, M.D. at the conclusion of their excellent review of drug therapy:

"From the evidence available, we believe that the use of major tranquilizers and anti-depressants is symptomatic. . . . Truly, drugs can influence human behavior. But ideas and

people exercise a greater influence. No drug can produce true peace of mind." But the student can use this comprehensive annual review to survey the literature himself and draw his own conclusions. The reviewer believes that no psychiatric library and no private practitioner should be without this important reference work.

SOURCE BOOK OF MEDICAL HISTORY. Compiled with notes by Logan Clendening. (New York: Dover Publications, 1960, pp. + 685. Softbound. \$2.75.)

This well-made edition is an unabridged and unaltered reprint of the work first published in 1942, in which Dr. Clendening, Professor of the History of Medicine at the University of Kansas, brought together 624 papers representing discoveries and significant original work in medicine over a period of 4000 years. The material consists of complete texts, abstracts of longer works or adequate selections therefrom. Introductions to the various topics are provided, together with short biographies of the authors.

The editor takes advantage of the chronological arrangement of the material to include selections from contemporary lay literature to reflect the views of medical life of the successive periods. Here are quotations from Homer, Aristophanes, Plato, Thucydides, Aristotle; also from the Arabian Nights, Chaucer and Leonardo; from Moliere, Le Sage, Macaulay, Thackeray and Dickens.

This new edition of the *Source Book* is dedicated to the memory of Logan Clendening (1884-1945).

It is a thoroughly comprehensive and unique type of medical history, beginning with the Egyptian papyri and ending with Roentgen's papers "On a New Kind of Ray." Many of the documents here included have not previously been available in English. The assembling of the material was the work of years. Dr. Clendening's early death prevented what might have been a later edition or supplementary volume covering the "Firsts" of recent years. That will be the task of a future historian. It is fortunate that this valuable work is again available in this re-issue.

PSYCHO-ANATOMY OF A DISASTER :
A LONG TERM STUDY OF POST-TRAUMATIC NEUROSES IN
SURVIVORS OF A MARINE EXPLOSION¹

ROBERT L. LEOPOLD, M.D., AND HAROLD DILLON, M.D.²

Early on the snowy morning of March 7, 1957, the *Mission San Francisco*, a gasoline tanker, collided with the *Elna II*, a freighter, in the Delaware River, near Newcastle, Delaware. Although the mission's tanks were empty of gasoline, they had not been freed of gas fumes, which, when mixed with air, become highly explosive. Sparks generated by the collision caused a series of explosions of such intensity that the sides of the *Mission* were blown out, the entire midship housing sank immediately, and the captain, all 3 deck officers, 5 crew men and the pilot were killed instantly. The engineers and crew who were in the stern of the vessel were badly tossed about and shaken. These men, deprived of leadership by the loss of the captain and mates, and surrounded by flames both on the ship and on the surface of the water, somehow made their way on deck, lowered life boats, and abandoned ship. Thirty-five men of a complement of 45 aboard the *Mission* survived and were taken ashore by various rescue boats. The *Elna*, although badly burned, did not sink, and all 23 of her crew survived. Some were able to remain aboard ship, and others were taken ashore.

Immediately following the disaster, the authors were requested by a firm of Philadelphia attorneys,³ representing the interests of the National Maritime Union, to examine 27 survivors of the *Mission* crew. Seventeen were seen on the day following the collision, the remainder within periods ranging from 48 hours to 13 days. Of these 27, 25 were

re-examined in the authors' offices after periods varying from roughly 3½ to 4½ years. In addition, in 1961, 9 more survivors (including 5 from the *Elna* crew) were examined.

Thus a unique opportunity was presented to study in almost pure culture the natural history of the post-traumatic states and to search for data pertinent to the psychological effects of sudden, life-endangering trauma. The situation was unusual in that it permitted observation of both the short and the long term effects. Three other special factors made it potentially useful: 1. Since the circumstances of the accident were relatively homogeneous for all those who survived it, the nature of the accident could be regarded as a constant, and the individual responses as variables. 2. Since, for various reasons, no systematic psychotherapy was available for these patients, the processes of emotional adjustment to disaster were observable without the potentially ameliorating effects of therapy. 3. The element of litigation anxiety was considerably lessened in these cases because of the unique position of seamen with regard to compensation.⁴

⁴ Because of the nature of sea work and the hazards involved, the seaman surrenders his personal liberty for the life of his contract on his vessel. Consequently, the remedies for injury which are available to him are broader and more realistic than they are in common civil practice. A seaman is entitled to maintenance and cure in connection with any illness or injury which manifests itself during or is sustained in the vessel's service. It is only necessary for him to show that it was suffered during service and not because of it. On proper certification from his ship owner, the seaman can be treated at any Public Health or U. S. Marine Hospital. If necessary, he can seek other or specialized treatment. If hospitalization is not necessary, the ship owner is required to pay, in addition to the cost of medical care, a daily rate determined by union contract during the period that the seaman can be benefited by medical care and attention while under outpatient care. In addition, the seaman, if he can show that the vessel was un-

³ Messrs. Freedman, Landy and Lorry.

A diligent search of the literature of the past two decades failed to reveal any studies significantly similar to the one reported here. In both the medical and social science literature there is a staggering amount of material devoted to the subject of disaster. However, in the vast bulk of the literature, disaster, to the best of the authors' knowledge, refers to a sudden catastrophe which strikes an established social community, involves nearly all its people, and seriously disrupts its normal functions and facilities as the effects of the catastrophe reverberate within that community over a period of time. By comparison, only a small part of the literature deals with disaster in microcosm, and very little of that reports the psychological aspects of such disasters. Among the few papers of this kind are those of Cobb and Lindemann(1), Lindemann(2), and Adler(3, 4), concerning Boston's Coconut Grove fire in 1942. These reports differ significantly from ours in that the group studied represents a different socio-cultural level. Many women were involved and total family groups were disrupted. The effects of horror and fright in themselves were somewhat more complicated by the problems in personal and social relationships which involved conflict and guilt.

Among the many studies which provide a potentially useful theoretical framework for the study of post-disaster phenomena, special mention should be made here of those of Tyhurst(5, 6) and Wolfenstein(7), and of the two selections of papers edited by Chapman(8) and Demerath and Wallace(9).

Background Data. Ages at the time of the accident of the 36 men seen ranged from 18 to 55, with 90% in the 26 to 50 bracket. Two were over 50 and 3 were under 26. Thirteen were single, 22 were married, and 1 was divorced. Two of the married men were separated from their wives. Seventeen men had children.

The educational status of the group was generally low. Of 8 men who had attended maritime academies, only 2 were high

school graduates. The total of high school graduates was 5. Twelve men had attended high school from 1 to 3 years, with no further formal schooling. Of 15 men who had received only elementary school education, 9 had gone no further than the 7th or 8th grade. One man had received no formal schooling.

The majority were veterans of long service at sea: 13 had served more than 15 years; 13 had served from 11 to 15 years; none had been at sea less than a year. To a majority of the men, likewise, conditions of danger and threat were not unknown. Eighteen had served in the Merchant Marine during war years, and an additional 7 had seen military combat during war years (5 of them in the Navy). A number of those who had been in the Merchant Marine during war years had also served in the Navy during that time.

Personal and family histories, so far as could be determined, contained little significant material relative to the psychological conditions which followed the disaster. In spite of careful questioning, only one harrowing personal wartime experience could be elicited: a former Navy man had been involved in a bomb explosion in 1944 which had killed 222 sailors, whom he had helped to bury at sea, and he had suffered from an anxiety condition ever since. Three other patients, however, reported the loss of close relatives in World War II action, one of them having lost a brother and 2 cousins in tanker disasters. Two patients reported prior ship accidents in which they had not been injured physically, but which had caused them severe nervous shock. Three patients admitted to prior psychiatric treatment: one had been treated by a psychiatrist for headaches and poor memory; one had been hospitalized for depression; and the third had been hospitalized with a diagnosis of chronic schizophrenic reaction.

Thirty patients said they were moderate drinkers, 5 said they were non-drinkers, and 1 admitted to chronic alcoholism at the time of the accident. The majority said they smoked cigarettes in moderation. One patient, it may be noted, reported that his father had been a heavy drinker, and had suffered a "nervous breakdown." Another reported the death of a brother by suicide,

seaworthy, or can show any negligence in connection with his illness or injury, can recover compensatory damages as a cumulative right to maintenance and cure.

and a third patient a broken home and a cruel stepfather in his background.

Short Term Effects. For convenience in subsequent reference, the 27 patients who were seen in 1957 (25 of whom were re-examined in 1960/61) have been labeled Group 27; the 9 patients seen only in 1961 have been labeled Group 9. With reference to Group 9, the limitations of patient memory and the lack of objective evidence were obvious restrictive factors in obtaining data concerning conditions existing in 1957. Nevertheless, it was felt that such data had sufficient validity to warrant inclusion in our final totals in spite of some unavoidable skewing.

A rather surprising paucity of physical injury was found. Concussion clearly was present in 6 cases from Group 27 and 3 from Group 9. There were no fractures of weight-bearing bones. Fourteen men had abrasions, lacerations, and superficial contusions. One man had a number of small first degree burns. There was considerable early muscular soreness which disappeared quickly. More significant were the numerous gastrointestinal complaints for which no structural cause could be found.

TABLE 1
Psychological Complaints Immediately Following the Disaster

	NO. OF INSTANCES REPORTED BY GROUP 27 (EXAMINED IN 1957)	NO. OF INSTANCES REPORTED BY GROUP 9 (EXAMINED IN 1960/61)	TOTALS
Mood and affect disturbances	23	14	37
Sleep disturbances	11	6	17
Somatic reactions:			
Gastrointestinal	13	10	23
Other	5	6	11
Intellectual deficits	3	0	3
No psychological complaints reported	6	0	6

Table 1 catalogues the psychological complaints reported present immediately following the disaster by the 36 patients. It should be emphasized that instances rather than patients are listed here. Virtually without exception, complaints were multiple. The

37 instances of mood and affect disturbance, for example, represent the complaints of 26 patients. Predominant in this category were complaints of nervousness, tension, anxiety and general upset. Less frequent were complaints of restlessness, depression, excessive preoccupation with the details of the accident, and phobic reactions. Most numerous among the somatic reactions were gastrointestinal manifestations, usually multiple. These were reported by 12 patients. Other complaints reflecting somatic reactions included coldness and sweating, decreased appetite and tremors of the hands and body.

In 6 cases no psychological complaints were present. It must be noted that all of these came from Group 27. It is possible, of course, that no immediate psychological effects were felt subjectively by some of the patients in Group 9, but this cannot be reported with any accuracy in view of the lapse of time.

Objective evidence of psychological disturbance in Group 27 in general confirmed the complaints of the patients. Most of the patients seemed, in spite of their complaints, to be functioning at a fairly efficient level. However, a few appeared to be overwhelmed totally by the experience they had so recently lived through. Of 5 hospitalized patients, only 1 was admitted purely for physical considerations. Psychiatric considerations figured in the admission of the other 4; one was so depressed as to suggest the risk of suicide; one exhibited a panic reaction so acute that it was feared he might become psychotic; one, despite only a moderate amount of tension, was hospitalized because of a past history of serious mental illness; and the fourth had to be hospitalized because of the severity of his gastrointestinal manifestations.

Long Term Effects. The amount of psychological deterioration that took place between 1957 and 1960/61 was impressive, particularly in view of the relatively small amount of residual physical disability seen in 1960/61. The interim medical histories in themselves attested to the extent of the emotional suffering these men had endured. It is estimated that at least 26 had received some form of help for complaints of a psychiatric nature during the interim, at least 12 of them as hospital inpatients. Of the 26,

at least 10 had suffered from severe gastrointestinal manifestations. Psychiatric treatment appeared to have consisted largely of confinement and sedation. The few instances of psychotherapy reported were apparently limited to brief and infrequent interviews. In giving credence to these figures, one must bear in mind the low educational level of these patients in general and the lapse of time. Furthermore, the somewhat confused stories of many of the patients defy reduction to statistics. It is felt, however, that the estimates are conservative, and that there was probably considerably more treatment for psychological illness than was reported.

The somatic involvements reported in 1960/61, more numerous than those for 1957, were largely musculo-skeletal, the majority involving the muscles of the back and neck. Although considerable muscle spasm was found, the presence of neurological or bony disease could not be confirmed, and it was felt that the majority of these men had somatic reactions involving symbolically significant parts of their bodies. These findings were not disabling in the majority of cases. It must be noted here that one patient who had pre-existing Buerger's disease had had a leg amputation since the accident. Another patient was known to have had choreoretinitis prior to the accident. Nevertheless, he had had minimal visual difficulty all his life until shortly after the accident, when he had become totally blind. The mechanism by which this blindness was produced is unclear. A third patient had in the interim suffered a carcinoma of the bowel for which he had had a transverse colostomy, with an apparently satisfactory recovery.

TABLE 2
Psychological Complaints Reported in 1960/61

	NO. OF INSTANCES
Mood and affect disturbances	73
Sleep disturbances	28
Somatic reactions:	
Gastrointestinal	20
Other	51
Intellectual deficits	5
Sexual debility	6
No psychological complaints reported	1

Table 2 catalogues the psychological complaints presented by the 34 men examined in 1960/61. Here again, the figures represent instances rather than patients, and complaints were multiple in virtually all cases. Mood and affect disturbances increased from 37 reported by 26 patients in 1957, to 73 reported by 33 patients, in 1960/61. Complaints in this category were similar to those reported in 1957, but there was a marked increase in complaints of restlessness, depression, and phobic reactions. New complaints also appeared: feelings of isolation, of being watched, of hostility and distrust toward other workers. The sleep disturbances were reported by 22 patients as compared with 15 in 1957. The persistence of gastrointestinal manifestations is noteworthy. After 3½ to 4½ years, the proportion remains essentially the same as in 1957. The other somatic reactions included 20 complaints of headaches. In 1957, headaches were presumed to be the result of cerebral concussion. On this basis, they would have been expected to disappear after 3½ to 4½ years. But in 1960/61, well over half of the 34 patients examined complained of continuous and sometimes disabling headaches. It may be noted also that whereas in 1957 6 patients appeared to have no subjective psychological complaints, in 1960/61 there was only 1 such patient. Even in this case, we felt that a considerable portion of the patient's back disability could be attributed to a somatic reaction.

TABLE 3
Dates of Post-Accident Return to Sea Work of 34 Men Seen in 1960/61

Within one week	2
More than a week, less than 3 months	20
More than 3 months, up to 12 months	5
More than 2 years	1
Returned to sea, date not available	2
Never returned to sea	4
Total	34

The post-accident employment records of the men seen in 1960/61 attests poignantly to the long term psychological effects of this disaster. Table 3 shows the time lapses between the accident and the return to sea employment. It is true that approximately two-thirds returned within 3 months, and

that only 4 never returned at all. But Table 4, which summarizes the post-employment status of these men in 1960/61, shows a far gloomier picture :

TABLE 4

Analysis of Post-Accident Employment Status of 34 Men
Seen in 1960/61

Never returned to sea work	4
Returned to sea, but were forced to give it up entirely	12
Returned to sea, but work only sporadically	6
Known to be at sea with reasonable regularity	12
Total	34

Of the 4 men who never returned to sea, 2 were frankly incapacitated for work at sea by psychiatric problems, another was the blind patient mentioned above, and the fourth had a disabling back disorder which was felt to be functional in nature. Of the 12 men who returned to sea but who were unable to continue, all but 2 were psychiatric casualties. These 2 were the patients referred to earlier who had, respectively, an amputation and a colostomy.

All 18 men who continued to work at sea were greatly disturbed emotionally, 6 of them to the extent that they were unable to work as regularly as before the accident. All 18 were tense, anxious, nervous and fearful aboard ship. They indicated that going to sea was a matter of necessity. Six men said they definitely would not ship on tankers again in spite of the more lucrative nature of this type of work. Even those who still shipped on tankers, whether regularly or occasionally, said they preferred other ships, with the exception of 1 man who said that it made no difference; he was equally miserable on all ships. This same man, incidentally, was also the only one of the 18 who said that he would rather be at sea than on land: on land he felt like a "worn-out bastard"; while at sea, he at least had some sense of usefulness.

The majority of these men were seasoned veterans of the sea, and it should be emphasized that they were uniformly not able to earn comparable wages ashore. Nevertheless, the psychological difficulties of serving at sea were so compelling that of 22 men who showed deviations from their normal

employment patterns, 19 were considered essentially psychiatric casualties.

Correlations. A simple method was devised to produce a single numerical score for each patient which would express quantitatively the psychological change which took place between 1957 and 1960/61, and which could be used to correlate psychological change with other factors. Using both subjective complaints and objective observations, the examiners, working separately and then checking each other, scored each patient on individual aspects of psychological dysfunction for 1957 and for 1960/61. The scale used ranged from 0 (absence of dysfunction) to 3 (maximal dysfunction). The rare discrepancies between the examiners' scores were discussed and compromised. Scores were totalled for each year. If the 1960/61 total was larger than the 1957 total, the difference was expressed as a negative score showing the degree of psychological regression which had taken place in the interim (the larger the score, the greater the regression). If the 1960/61 total was smaller than the 1957, the difference, conversely, became a positive score showing the degree of psychological progress (the larger the score, the greater the progress). A zero score was regarded as showing no change.

It is recognized that the restrictions which made it difficult, with reference to the 9 men who were seen only in 1961, to assay conditions present in 1957, also made it difficult to assign psychological scores to these 9 men. But the authors felt that the scores in these cases had sufficient validity to warrant inclusion in the correlation studies. The authors acknowledge also that the samples used in these studies were too small for statistical validity but they consider the results significant in that they at least indicate trends.

Of the 34 men seen and scored in 1960/61, 24 had negative or regressive scores, 7 had positive or progressive scores, and 3 had zero scores showing no psychological change. In view of the preponderance of regressive scores (71%) attention is focused on them in the ensuing brief discussion of correlations.

Correlation of scores with age groups in the general population indicated that 46%

of the men who were age 35 or under at the time of the accident had regressive scores, as compared with 86% of those who were age 36 or over at that time. It is to be noted also that the larger negative scores, which reflect the greater degree of psychological deterioration were found more frequently in the older age bracket than in the younger. For example, the largest negative score recorded for those who were age 35 or under was -7, while for those who were age 36 or over, the largest negative score recorded was -12.

Studies, which need not be detailed here, were undertaken to establish the relationship between the pre-accident factors of 1. Education; 2. Marital status; and 3. Military combat and/or wartime Merchant Marine service. They indicated that regardless of educational level, marital status (with or without children), and regardless of whether or not the patients had seen combat duty in military service or wartime Merchant Marine service, there was a greater concentration of regressive scores, and larger individual regressive scores, among the men who were age 36 or over at the time of the accident than among those who were age 35 or under. It is difficult to escape the impression that age, in this study, represented a more significant determinant of psychological deterioration than any of the above three factors.

The relationship between the psychological scores and the post-employment status is somewhat more complicated and not always entirely clear. The group of 4 men (see Table 4) who never returned to sea showed no regressive scores. As a matter of fact, 3 showed progressive scores, one had a plus 14, the highest positive score, and one a zero score. Two factors might be operative here. One is age, since all 4 were 35 or under. The other is the very fact of distance from the psychological risks implied in returning to sea.

It was noted that the highest incidence of regression appeared in the group of 12 men who returned to sea, but were forced to leave it, and in the group of 6 men who returned to sea, but were able to work only sporadically (see Table 4). The significance of this relationship is unclear. It is a fact that the older men returned to sea in larger numbers than the younger men, probably

because the sea constituted the one trade they knew, and they felt they were too old to change trades. The older men in this study, as indicated previously, appeared to be more prone to psychological deterioration than the younger. Age, therefore, may be an important factor in the high incidence of regression in these groups. Another explanation may lie in the fact that these men forced themselves to return to the sea they feared so strongly and suffered further psychological damage as a result.

Only slightly lower was the incidence of regression among the 12 men who were working at sea with reasonable regularity (see Table 4). Here again, most of these men were in the 36 or over age bracket, and the same reasoning applies. The fact that these men continued to work at sea in spite of their psychological damage may be related to certain complex factors of motivation, including the compelling one of financial need.

DISCUSSION

One objective of this study was to derive from the data some useful theoretical formulations with regard to the short term and long term psychological effects of sudden life-endangering trauma. The very nature of the material presented here precludes any intimate knowledge of the individual psychodynamic factors involved, and no detailed psychodynamic formulation will be attempted. Certain conclusions do appear to derive from the data. Limited though their education was, and granting that as a group these men were not particularly sensitive or intuitive, the fact remains that they were largely seasoned seamen, and that many had considerable tanker experience. Also, in the manner of seamen, they had formed a close attachment to life on a ship. Yet, neither intellectual awareness of the potential dangers they faced, particularly in terms of explosions, nor emotional attachment to the sea was sufficient to be of value to these men when catastrophe overtook them. One must wonder what prevented prior knowledge from being of protective value. It appears that repeated performance of a dangerous occupation dulls the capacity for anticipation, fearful or otherwise, of disaster. Riding in

an automobile on a modern highway is a case in point. Familiarity apparently breeds in the organism a loss of the capacity to defend itself.

Anticipatory anxiety, even if momentary, permits mobilization of resources. But such anxiety becomes inoperative when realistically dangerous situations seem safe because of repeated exposures without concomitant injury. When injury does occur, the victim is unprepared to cope with the resultant alterations of self.

When these men, accustomed as they were to discipline and direction, were left leaderless by the death of all the ship's deck officers, panic might well have been expected to develop. But perversely, the men did not panic. After an initial period of confusion, they conducted themselves with considerable competence. The reasons for the failure of panic to develop are not entirely clear. It should be noted that seamen are required to participate regularly in fire and abandon-ship drills.⁵ The repetitive nature of the drills may have served to permit relatively automatic functioning without panic. On the other hand, one may speculate that the situation was so sudden and so overwhelming as to paralyze the ability of the ego to react. Furthermore, the urgent reality demands may have forced the utilization of all available energy in the service of survival.

The short term effects of this disaster were in the majority of cases appropriate to the circumstances. The salient phenomenon reported here is the severity of the long term reactions. These men were unable either to repress their feelings, or to work through them. Indeed, the anxiety seemed to reverberate constantly so that it became gradually worse rather than better over the period studied. This was particularly true of the older men, those, unfortunately, whose economic need to return to sea was most compelling. Thus they continuously re-exposed themselves to the dangers which had proved so damaging. The knowledge that "it had happened" generated and perpetuated the fear that "it will happen."

A potential danger which has been dis-

missed lightly or ignored before conversion to actuality subsequently appears constant and terrifying. Repression does not appear possible. This same failure of repression has been noted by the authors among survivors of the Nazi concentration camps. If repression does not occur in a reasonable time, the prognosis is poor, since past danger is constantly perceived as a current peril.

Another, though somewhat overlapping, objective of this study was to derive from the data support for earlier hypotheses of the authors (10-12). They have maintained that the nature of the accident (and particularly its suddenness, which gives the ego no time to prepare its defenses) is a more significant determinant of the post-traumatic states than the pre-accident personality. If the nature of the accident be regarded as involving both a change in the external environment and a change in the internal environment, then the nature of this disaster may be considered essentially the same for all survivors. Certainly all were subjected to the same sudden shift from a safe situation to a dangerous one; the individual circumstances differed only minimally in terms of personal injury and loss of personal property, and were identical as regards loss of leadership. Thus, it is reasonably accurate to state that the nature of the accident was a constant factor. Yet these men differed greatly in all background factors except service at sea. Even their education, limited as it was for the group as a whole, varied considerably within these limitations. But as the long term examinations proceeded, the almost monotonous similarity of the psychological patterns was striking. Despite little or no contact with each other, the men told stories so much alike they appeared almost to have been rehearsed simultaneously. The conclusion is almost inescapable that the common factor here is the accident itself.

The data derived from this study seem to support another prior hypothesis: that psychological damage incurred in life-threatening trauma, if untreated, tends to grow worse with time. As noted earlier, these men received no systematic interim psychotherapy. Conversely, the authors' experience in other cases supports their hy-

⁵ Title 46, Code of Federal Regulations, Section 167, 65.

pothesis that such damage is mitigated by appropriate psychotherapy. Other writers, including Courville(13), Merrill(14), Müller and Naumann(15), and Cobb and Lindemann(1), also affirm this view.

The authors have maintained that litigation and compensation worries are not basic factors, either on the conscious or the unconscious level, in producing post-traumatic psychological damage. As stated previously, these patients were assured more realistic compensation than is usual in civilian practice. It should be noted, likewise, that many of those who abandoned the sea took up less remunerative and less prestigious occupations; that to most of them the sea represented a way of life as well as a means of earning a living. Yet, without the prime factor of monetary gain, these men exhibited psychological damage patterns comparable to those so often described as litigation anxiety, compensation neurosis, and in other pejorative terms.

The authors feel that the psychiatric community as a whole has failed to recognize the significance of the nature of the accident itself, and particularly its suddenness, in the development of the post-traumatic states. For reasons not entirely clear, it appears more usual to regard the pre-accident personality as a major factor, and to relegate the accident itself to the role of a mere triggering circumstance which sets off an illness considered almost certain to have occurred in any case. This approach discards the tremendous potential, from both the treatment and the research standpoint, which is available if one instead regards the post-traumatic psychological states as diagnostic categories in themselves. Most frequently, these states are best categorized as post-traumatic neuroses; occasionally, one must use the category of the post-traumatic psychoses. These categories are unique in the cognizance they give to the role of the accident itself in producing a discrete illness, which, in all likelihood, would not have occurred had there been no accident.

By their acceptance of such discreteness, these categories recognize that crisis is not amenable to the usual coping techniques. Caplan(16) states that crises per se usually last no longer than 4 to 6 weeks, and clinical

experience substantiates this. However, when all coping techniques have been paralyzed, the only solution becomes regression. In the cases reported here, even regression, because of the fear of repetition of the overwhelmingly dangerously perceived accident, does not snuff out the fire of anxiety.

The important question here, from the psychiatric standpoint, is why the normal coping techniques are inoperative. The psychiatric community will not find out by dismissing the accident as merely an incidental factor. Nor can it adequately treat the post-traumatic psychiatric casualty unless it finds out first what this accident in itself meant to this individual; unless it regards the post-traumatic psychological state as a separate entity which represents the failure of this individual's mechanisms for defending himself.

Historically, prejudices have existed in some segments of the legal community which have clouded the unbiased evaluation of the post-traumatic psychological states. In view of the special interests involved, it is difficult to see how they can be dispelled. However, it is to be hoped that the psychiatric community, through enlightened treatment, research, and the maintenance of an objective and disinterested position, will help to better the lot of the much misunderstood and much maligned victim of post-traumatic psychological damage.

SUMMARY

This study reports the immediate psychological effects of a maritime explosion on 36 survivors, and the long term effects on 34 who were seen 3½ to 4½ years later. All were experienced seamen. The circumstances of the accident were virtually identical for all. None received any systematic interim psychotherapy. All were guaranteed realistic compensation. Immediate effects in the majority of cases were appropriate to the circumstances, but long term investigation indicated appreciable deterioration in 71%, most frequent and most marked in the age group 36 and over. The long term psychological pictures were strikingly similar for all subjects.

It was formulated from the data that repeated exposure to a potential danger

apparently deprives the organism of its capacity to defend itself; when the danger has been converted to an actuality, it subsequently is perceived as a constant peril which is not amenable to repression, and the resultant reverberating anxiety accounts for the severity of the long term reactions.

The data also supported the authors' previously stated hypotheses that the nature of the accident itself is a more significant determinant of post-traumatic psychological illness than the pre-accident personality; that such illness, if untreated, tends to worsen with time; and that litigation worries are a minor factor in producing the illness.

It is suggested that the post-traumatic psychological states be considered diagnostic categories in themselves. This approach, because it shifts emphasis from the pre-accident personality to the accident itself, and recognizes that post-traumatic psychological damage is a discrete illness representing the failure of the individual's defense mechanisms, will best serve understanding and treatment of that illness.

CHILD-PARENT SEPARATION AS A THERAPEUTIC PROCEDURE¹

J. G. HOWELLS, M.D., D.P.M.²

There are limitations upon the usefulness of psychotherapy. Even if it were established that when it is correctly applied, it is always effective, it is doubtful whether it can always be utilised because of the lack of opportunity or the facilities. However, the child is in an emotional environment which affects him, for good or ill, every moment of the day. It can be overlooked that when denied the opportunity to employ psychotherapy to help child or parent, it is often possible to change this emotional environment so that at least relief is given to the child and, under favourable conditions, even recuperation follows. An adverse emotional climate for children is often the product of emotionally handicapped parents. To bring about a change in this climate will, sometimes, involve making a break in the physical link between the child and the parents.

Prevalent opinion, however, tends to be against using separation procedures as therapy. A statement in an authoritative publication by the British Ministry of Health (1), which was written to encourage the family doctor to take an interest in the Mental Health Services, gives the following warning: "On the purely psychological side there is evidence that separation from the parent, or parent substitute before the age of five may have serious effect on the emotional growth of children and may form the basis of neurotic reactions in later life."

In this statement two postulates are implied: 1. That child-parent separation is always harmful under the age of five and causes the child to lack the ingredients essential for its emotional growth, *i.e.*, separation is synonymous with deprivation of the right care; 2. That separation experiences may lead to mental ill-health later on.

Faced with this and similar statements,

there is a reluctance to use separation procedures, and indeed great efforts are made to maintain children with their parents, whatever the cost to the children.

Responsible authorities still often support the adage that "A bad natural home is better than any other home." This point of view fails to distinguish between parents themselves and the quality of child care or parenting (mothering and fathering) which they may or may not be able to provide. It also assumes that physical separation of the child from its parent must lead to a deprivation of proper care, thus regarding separation and deprivation as synonymous.

The object of this paper is to show that the above point of view is not well founded. The belief that separation and deprivation are synonymous is fallacious, and it has led to ill-defined postulates being formulated, which in turn have nullified investigation. Furthermore, there is no investigation that conclusively demonstrates that separation experiences are one of the prime causes of mental ill-health. The view expressed here is that the circumstances attending the separation are the most important factor in determining whether or not the child is deprived of the right care, rather than the separation itself. The right care for a child can sometimes be most advantageously supplied apart from the parents, and some of the ways by which this can be arranged will be described.

Definitions. Much of the confusion about "separation" and "deprivation" springs from the fact that the two words are used interdependently, and it would seem to be essential to have a clear definition of each.

"Separation" of child and parent, by common usage, means that the child is physically apart from its parents.

"Deprivation" is a term which indicates that a loss is suffered and when applied to the child it is used in the following two senses: 1. When the child suffers the *loss of its parent*, or permanent parent substitute. This denotes physical separation of parent

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Dept. of Child and Family Psychiatry, Ipswich and East Suffolk Hospital, Ipswich, England.

and child. To prevent confusion with the term "separation," this usage should be avoided. 2. When the child is deprived of the necessary care for its emotional growth, and so suffers the *loss of parenting*, i.e., qualities including love, affection and security. This form of deprivation can occur with the parent, or apart from the parent.

"Separation," then, involves the physical loss of the parent. "Deprivation" involves the loss of parenting normally, but not necessarily, supplied by parents. Thus the quality offered to the child, parenting, is differentiated from the object, parent, which offers it. To illustrate, one element in parenting, namely mothering, is often found in the natural mother, but it may be absent, or it may be found in another female figure. It may well be that it is more important for a child to have *a* mother than *the* mother.

Investigations. The confusion caused by lack of definition of terms will be illustrated by referring to the contribution of two distinguished researchers in this field.

Amongst other fundamental issues appertaining to the infant and mother, Bowlby, our leading investigator in the United Kingdom, has paid attention to the effects of separation. His first investigation concerned the high incidence of separation experiences in a group of 44 juvenile thieves, and this high incidence, Bowlby(2) maintained, had a casual connection with their disturbance. However, less attention was paid to the possible effects of the deprivation of the right care. From the case histories it appears that both before and after the separation experience these children suffered a loss of the right kind of care. This investigation did not eliminate the variable of deprivation, and it would seem difficult therefore to draw valid conclusions about the effect of separation per se. It will also be noticed that those children whose experience of separation was a happy one would be unlikely to attend Bowlby's clinic and therefore unlikely to be included in the investigation.

His second and larger investigation entitled "The Effects of Mother-Child Separation"(3), compared a group of sanatorium children with a control group of school children. In 5 of 28 items on a teacher report form, the sanatorium children showed

traits which indicated maladjustment. The differences were not as great as had been expected. The limited positive findings of the investigation, however, appear to be nullified by the fact that the effects said to be due to the separation alone cannot be distinguished from those effects due to other factors, such as deprivation of the right care in a sanatorium. The lack of definition of the concepts employed may have resulted in the defective formulation of the investigation. Although the investigation, as the title states, is concerned with separation, the use of this term and of the word "deprived" are ambiguous as, for example, in a paragraph that contains "children who for any reason are deprived of the continuous care and attention of a mother," and the use in the same paragraph of "deprived" to mean physical separation.

In a more recent paper(4), it is apparent that Bowlby still does not find it necessary to differentiate between separation and deprivation. "For many of the cases in which there has been no episode of actual separation . . . there is often evidence that there has, nevertheless, been separation of another and more or less serious kind. Rejection, loss of love . . . and similar situations all have a common factor—loss by the child of a parent to love and to attach himself to. If the concept of loss of object is extended to cover loss of love these cases no longer constituted exceptions." It would seem unwarranted to mix quite different elements of experience, namely, loss of object and loss of love, in this way. One is separation experience, from the object, parent, the other is a deprivation of the quality of love, according to the normal usage of the terms.

Goldfarb's work(5) has sometimes been quoted as showing the ill-effects of separation. However, his main studies have been comparisons between groups of separated children. He has shown conclusively that separated children flourish according to the quality of care they are given following the separation. In one separation situation they may be deprived of adequate care, as for example, in an institution, whilst in another situation, for example, a foster-home, the care may be adequate. He has shown how children removed from the first situation will improve when placed in the second.

His work would appear to demonstrate that the heart of the matter is not the mere fact of the child being separated from its parents, but whether or not the child is deprived of the right care.

Investigations which attempt to show that mental ill-health springs from separation experiences in childhood have been reviewed by Gregory (6), and treated by him with caution. These are no more satisfactory in making a distinction between separation and the other variables that may be responsible for the changes noted. These variables include traumatic experiences before separation, traumatic experiences resulting from separation, traumatic experiences between the time of separation experience and the investigation.

Another Investigation. Statements made about effects of separation experiences were so contrary to our clinical work that some years ago an investigation (7-9) was undertaken to test some of the formulations.

A group of emotionally disturbed children and a control group of healthy children were compared with respect to their separation experiences when under 5 years of age. Every separation experience which lasted 24 hours or longer in both groups was recorded. The information was collected shortly after the child's fifth birthday while the parents' memory was likely to be accurate. The first 5 years were investigated, as the protagonists of the separation viewpoint regard this as the most vulnerable age-group.

The findings showed that the pattern of separation experiences was strikingly similar in the two groups. It was also shown that the incidence of separation in the two groups was equally low, since among 74 children there was only 1 separation lasting more than 1 month during the first year and only 5, lasting 3 days. In both groups, two-thirds of the children under 2 years of age had not been separated from their mothers for more than 2 days. It was concluded that although separation may at the time cause upset to the child, it does not, in most cases, lead to mental ill-health.

The two groups were also compared for the effects of separation due to hospital care and to non-hospital care. Under hos-

pital care, there were 26 of 92 occasions of separation and the majority of these appeared harmful to the children. With non-hospital care there were 62 of 92 occasions of separation, and only a minority of these proved harmful. These findings suggest that the conditions applying before, during, and after the separation are more important in determining whether or not there will be harmful effects than the fact of separation in itself. The quality of the care received rather than the separation is the really important factor. Separation is not synonymous with deprivation.

As a result of the investigation and our clinical experience we now have sufficient confidence to concentrate on removing deprivation when it occurs whether in the presence or absence of the parents. When deprivation was caused by the parents, we formulated ways by which separation could be utilised to reduce trauma, but, of course, we applied the safeguard that separation must not be allowed to cause deprivation; separation must supply what is lacking in the parents' care.

THERAPEUTIC USES OF SEPARATION

Before turning to the therapeutic use of separation, it may be as well to draw attention to its *prophylactic* value. Short periods of separation for children under the care of familiar friends, relatives, or neighbours assures the child that living with strangers need not be unpleasant and that the parents can be relied upon to reappear after being away from them for a short time. Such children, of course, accept more readily unexpected periods of separation from the parents, like those due to admission to hospital. So widespread and exaggerated has been the propaganda about the dangers of separation, that many parents are now fearful of leaving their children under any circumstances, for however short a period. This amounts to a virtual enslavement of the parents and brings an artificiality to the lives of both parents and children. A new syndrome is upon us, anxiety about "separation anxiety."

Either complete or partial separation can be utilised therapeutically.

The most *complete* separation is the assumption of parental rights by another

family. Less complete, simply because it can be reversed more easily, is the placement of a child in a foster-home. Another less complete separation procedure is the use of hostels for maladjusted children. These hostels provide a great intensity of contact between staff and children, do not undertake schooling facilities themselves and tend to have short holiday periods. They are therefore particularly valuable when a great intensity of parental care is required. Special boarding schools again involve a complete separation from the parents. Here schooling facilities and parental care are supplied under the same roof. They sometimes suffer the disadvantage of being educationally orientated and of having long holidays. Inpatient care, in a psychiatric ward for children, involves not only the application of diagnostic and therapeutic procedures within the ward, but also separation from the family. Usually children admitted to inpatient units have a degree of disturbance which is beyond the therapeutic facilities of the agencies previously mentioned.

Partial separation procedures allow the child to live at home, but they arrange his life in such a way that there is a minimum of contact between the disturbed parents and himself. This can be organised within the home by the use of a home-help to look after the children, while both parents go out to work, or in wealthier families by employing a nanny for the children. Mothers, however, must be guided not to select a nanny in their own image. A partial break between parents and children can also be effected by measures which allow others to give special care to the child, outside the home, during the day. These facilities include day foster care, nursery schools for maladjusted children, day schools for maladjusted children, day hospitals and therapeutic clubs. More detail will be given about the use of day foster care and of therapeutic clubs.

Day foster care(10) is the planned, temporary separation of an emotionally deprived child from his parents during the day, in order to supply him with the right emotional care. This can be effected in at least three ways. First, the attendance of the child at a special day nursery whose staff

are carefully selected for their ability to supply the positive parenting which is absent from the home. During the separation the child is, at it were, in a power house of affection. The second method is to arrange for the child to stay during the day in a selected foster home. A third way is for a small number of mothers to band together to form a nursery club, whereby for one day a week, each mother in turn looks after all the children. Such groups are very helpful, but they should not have more than one or two disturbed children within them.

Therapeutic clubs supply positive emotional care for children during those hours after school when the child would otherwise be in a hostile and negative emotional climate. They supply similar care during week-ends and the long holiday periods. Their principal condition of membership is that the child is very difficult and unacceptable to orthodox clubs. The clubs actively create warm relationships between their staff and the children and the staff encourage the children to accept parenting. A high ratio of staff to children is required. Club activities are planned to bring staff and children continuously together by the employment of creative endeavours.

It will be apparent that an essential condition of success in all these procedures is the *selection* of the right staff. In outlining the qualities required in such staff, it is possible to do no better than to turn to history. Modern life does not have a monopoly of wisdom; science often amounts to nothing more than systemising a rediscovered truth. Thomas Phaïre(11) in the first English book on paediatrics in 1545 advised as follows in the selection of a wet nurse :

Ye must be well aduised in takyng of a nource, not of ill complexion and of worse maners : but suche as shalbe sobre, honeste and chaste, well fourmed, amyable and chearfull, so that she may accustome the infant vnto mirth, no dronkarde, vicious nor sluttyshe, for suche corrupteth the nature of the chylde.

PSYCHOTIC MOTHERS AND THEIR CHILDREN : JOINT ADMISSION TO AN ADULT PSYCHIATRIC HOSPITAL¹

HENRY U. GRUNEBAUM, M.D., AND JUSTIN L. WEISS, PH.D.²

Mental hospitals in many parts of the world have become involved in a dramatic change, in both philosophy and practice, toward a more humanitarian view of emotional disorders and their treatment. We are now increasingly aware of the importance of the social and psychological context within which people develop and recover from behavior disturbances.

For the adult in our society, the major elements in this environment are those of family and of work. Hospitals have made great strides in providing patients with opportunities to maintain or regain contact with work and family. Sheltered workshops, hospital industries, part-time out-placement and group discussions of work experiences have become widespread. Similarly, families are brought into closer contact with the patient and the hospital by means of group and individual psychotherapy or casework, improved visiting arrangements, and day care programs which permit the patient to return to his home and family at night and on weekends. These developments appear to be effective because the patient has the opportunity to discuss his life experiences in a supportive and therapeutic relationship. He can learn and test out new ways of behaving in situations which are of enduring importance to him.

In the case of the young mother, her family is her work. However, as a matter of course, mothers requiring hospitalization for mental illness have been separated from their infants and young children. This practice is based upon three principal considerations : 1. *The responsibilities of the hospital.* It is believed that an adult mental hospital is an unsuitable place for a child. It is assumed that special staff and facilities would be required, that the child's presence would be extremely disruptive to other patients, and that it would be impossible to protect

the child from psychological or physical dangers. 2. *The therapeutic needs of the mother.* It is generally held that the mother with a so-called "post-partum" psychosis or other severe emotional disturbance must be free of the responsibility of caring for her child, who may be perceived as the source of her difficulties and is often the object of hostile and destructive wishes. 3. *The effects of a psychotic mother upon the child.* This is a more long-range concern which implies that the mother-child relationship may be adversely influenced by the mother's disturbance, leading to undesirable effects upon the personality of the child.

Recent reports from England, however, raise serious questions concerning the validity of these views. Douglas(1) in 1956 observed that mothers with post-partum psychotic reactions were not likely to relapse if they were given an opportunity to care for their babies in the hospital. This report of 6 patients treated successfully on the "neurosis ward" of the West Middlesex Hospital illustrates dramatically the effectiveness of permitting the mother to assume increasing responsibility for the child in the context of psychotherapeutic and institutional support. The work of Main(2) suggests that it is similarly beneficial for mothers with neurotic depression to have their children with them in the hospital. More recently there have been several such admissions to the McLean Hospital(3).

Encouraged by these reports, we began in the fall of 1960 to admit infants and young children to the adult wards of the Massachusetts Mental Health Center, where they have been cared for by their psychotic mothers. Our first case, which has been reported elsewhere(4), proceeded with success. Much was learned about the problems engendered by such joint admissions and how to deal with them. As a result of this initial experience, we admitted 11 other mother-child pairs over the next year. The ages of the children at the time of admission ranged from 1 to 18 months, and they have

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Massachusetts Mental Health Center.

remained in the hospital for as long as 9 months.

In this paper we shall first summarize briefly several of these cases and discuss the management of various administrative and therapeutic problems. We shall then attempt to clarify some of the complex issues involved and to suggest certain tentative guides to the selection of suitable patients.

Case Summaries

The first mother was a 22-year-old woman who had given birth on the day of her graduation from college. She was extremely disappointed that she could not pursue graduate studies as planned, and felt guilty because she saw herself as an inadequate mother who was unable to love her infant son. She gradually became increasingly depressed and withdrawn and developed ideas of reference during the next year. After a 2-month period in another hospital she was admitted to the Massachusetts Mental Health Center with the diagnosis of schizophrenia. She seemed to make little progress in her first 2 months maintaining that she had little feeling for her son, now 14 months old, and thought that he could be cared for better by his father and a nurse at home. It occurred to us that having her son at home increased her feelings of guilt and gave her the opportunity to avoid the feelings which would arise if she had to care for him herself. Therefore, we suggested to her that if she cared for him in the hospital, she could then work more directly in therapy on her difficulties in learning to be a mother. She found the idea appealing, and although she raised many practical objections decided it was worth trying.

The ward staff knew the patient well and had had ample time to prepare for the baby and discuss their own feelings about caring for the first child in the hospital. The patient had working relationships both with her therapist and her administrator, who had training in pediatrics and child psychiatry. She therefore felt, as we did, that her needs as well as those of the baby would be considered. In addition, her husband, who was very competitive with his wife, sought psychotherapy for himself. The patient changed rapidly upon the baby's arrival. Almost at once she began to express both angry and pleasurable feelings toward him, as well as toward her husband. With the support of the staff and a positive response from her son, she came to feel much more secure as a mother. She was discharged much

improved 2 months later, and on our last follow-up was doing well and expecting a second child.

The next case is that of a 22-year-old woman in a confused and deluded state, admitted from another hospital where she had been violent and uncommunicative. Because of our enthusiasm about the success of our first case, she was told that we would expect her to care for her 3-week-old child in the hospital as soon as possible. She seemed to improve almost immediately, and the baby joined her on the ward within the week. However, over the next month she became increasingly helpless and mute. The staff, her husband and her mother were alarmed over the quality of her care for the child, and during her therapist's vacation, the baby was sent home. She remained in the hospital, soon resumed therapy, and gradually improved so that after another 2 months she wanted her baby with her again. This time the patient resumed caring for the child and did so with increasing competence and pleasure. She was discharged improved 2 months later.

It is clear that when the patient agreed initially to care for the baby in the hospital, it was not her own decision but primarily a result of our enthusiasm and urging. Because this had occurred so early in the hospitalization, the patient had not yet formed a good relationship with anyone on the staff with whom she could share her feelings about the admission of the child. It is our impression that the second admission was more successful because she made the decision herself and also because she now had a working relationship with her physician.

Certain other features of this case are worthy of comment. The patient's husband and mother were seen by a staff psychiatrist and a social worker respectively. The husband was under much strain because his family disapproved of the marriage, and the mother had the responsibility of caring for the baby when the patient could not. Without these continuing relationships with the hospital, the patient's family would have had no direct channel for communicating their concerns about the first admission, and it is unlikely that they would have permitted her to bring her child back again.

The nurses were under considerable pressure the first time the baby came in because of the patient's inability to care for

it, and the second time because of a brief period of manic hyperactivity when the patient avoided the baby. Without regular staff consultations, these emotionally trying periods could not have been weathered. It was necessary to share impressions of the patient, thoughts as to the reasons for her behavior, and suggestions for helping her. Our difficulties were increased when we failed to work sufficiently closely as a team.

Our third case illustrates other types of joint-admission difficulties.

A 24-year-old married woman became depressed following the birth of her first child, a son. She had strong masculine strivings and had been successful as a gymnastic teacher. However, she had experienced many losses, including the death of her father and several siblings in childhood before her marriage, and she had been severely depressed at these times. Just prior to her admission she made a serious suicidal attempt by taking an overdose of barbiturates. After an evaluation period, she asked to have her 6-month-old child join her and they spent some time on the day program. Soon she became increasingly depressed and required rehospitalization. She then went through a very stormy period which she attempted suicide again by taking 14 Seconal capsules. She often said that her child was the only good thing in her life, and all who came in contact with her, including the nurses and other patients, agreed that her care of the baby was excellent and that it was her "link to life." She gradually improved with intensive psychotherapy and came to feel better about herself and happier in her marriage.

It was clear that the physicians in charge had to have close contact with the ward staff in order to obtain accurate information about the patient and to deal with staff feelings. A therapeutic-administrative split with very firm management was also of great importance. It may be wondered what would have occurred in this case if the baby had been with its grandmother 1700 miles away, as the family had suggested, and how the patient would have felt if we had indicated by our agreement that we concurred with her belief that she was an unfit mother. She herself said, "If the baby had been away, I wouldn't have had a chance to develop positive feelings for him. I wanted to love him but couldn't, and I felt

very guilty since I did not feel what I was supposed to."

DISCUSSION

In the foregoing brief case summaries we have attempted to convey how we approached our first experiences with joint admissions. Earlier in the paper we indicated that three major considerations are involved in the traditional practice of separating children from their hospitalized psychotic mothers: 1. The responsibilities of the hospital; 2. The therapeutic needs of the mother; and 3. The effects of a psychotic mother upon the child. Drawing upon our first 12 cases, we may now turn to a general discussion of these significant issues.

Our cases substantiate the reports of Douglas and Main(1, 2). It thus appears that in quite different kinds of hospitals even seriously disturbed women can care for their children successfully. It is important that the decision to bring the child to the hospital be concurred in by the patient, without coercion. Members of the immediate family, such as the patient's husband and mother, must be included in the discussion and planning. The hospital staff needs them as informants in completing its evaluation. They are customarily bearing the burden of the child's care at this point, and their feelings about relinquishing—or not relinquishing—this burden to the hospitalized mother will have continuing implications for the success of the joint admission and the mother's recovery.

Only 1 of our first 12 mothers brought her child with her on admission—and that one instance was not anticipated. In all the other cases there was an initial period of careful evaluation, planning and decision making which varied in length from several days to 4 months. During this period the patient begins to adapt to the hospital and to develop a relationship with her therapist and other members of the staff. We have tried to bring in the child when the mother is able to assume some of the responsibility for it and to accept help from the staff when she needs it. No matter how disturbed the mother may be in other areas, we have found that if she is able to participate actively and responsibly in the decision to

have the child come to the hospital, only rarely will she be unable to care for it adequately.

Careful evaluation by the staff acts not only as a check on a sick mother's unwarranted belief that she may be ready to care for her child; it also gives the staff an opportunity to get to know her, before the child arrives, so that they may respond appropriately to her needs and feel comfortable with her caring for the child. The attitudes of the ward personnel are the single most important consideration in attempting a joint admission. The staff must be brought into the venture from the beginning, with much support and sharing of information and feelings. Frequent consultation is mandatory, particularly when there has been little experience with joint admissions. Not only the attitudes of the nurses and attendants but the timing and quality of their interventions are critical factors in determining how well the mother will be supported in her effort to care for her child. They may tend either to take over functions which the patient is able to manage for herself or to leave her entirely to her own devices. The nurses must be concerned not only with the welfare of the patient and the welfare of the child but must share the philosophy that helping the mother to assume this responsibility is therapeutic. Much remains to be learned about teaching the staff when and how to be supportive, to act as resource people or as temporary substitutes (4).

Both the staff and the patients find it hard to imagine that children can live on a mental hospital ward without being endangered or causing impossible inconvenience to all; yet such is the case. When we interviewed the staff and patients on the first ward to admit a baby, we found that their initial feelings of apprehension, envy, and fear for the safety of the child were widespread and strong (5). Although these feelings persisted in some cases, many had changed their views, and the child had come to be an accepted part of ward life. Those patients who had the most destructive feelings and fantasies tended to avoid the baby. Most of the other patients felt that the child's presence was pleasant, and that it encouraged them to respond appropriately.

This is not to say that a baby can be cared for on any ward any place. The ward must be so arranged that a single room is available for the mother and child or the normal ward life will become too disrupted and the patients will come to resent the intrusion. We have also found that some mothers like to have periods of privacy with their children. One mother in our day hospital, which has neither beds nor private rooms, expressed it this way: "Out on the ward, I'm not free to choose how I want to respond . . . if she rushes over to me immediately looks at me or mothering in her . . . you can't do your own thing to cooking public all the time." Access to cooking facilities and a refrigerator are also useful. Most of the other equipment can be brought in by the family.

Medical responsibility for the baby is best delegated to a physician other than the patient's therapist, in order that the baby's needs may be viewed objectively. The staff serves to reduce the anxiety of the mother about the welfare of the baby, and it leaves the mother's therapist free to work with the patient.

Joint admission will usually be successful if 1. There has been a careful preliminary evaluation of the mother and the nature of her illness; 2. A working relationship has been established with her physician and the ward staff; 3. There has been a mutual decision to admit the baby by the staff, the patient, and her family; and 4. There is adequate provision for the physical needs of the child.

A natural reaction to the idea of admitting babies and young children to our adult psychiatric wards is one of grave concern regarding the physical and psychological dangers to the child. The question is of prime significance; we are now engaged in developing methods for the long range investigation of such effects, if indeed it is possible to isolate them. However, our experience with 12 cases has been immensely reassuring. Although many patients play with and baby-sit for the children, there has been not one instance of physical threat, nor is there any overt evidence of immediate psychological harm.

We may now ask whether the mother's recovery from a psychotic reaction depends,

as is often assumed, upon her being separated from her child. The cases we have seen lend very little support to this view. On the other hand, if taking responsibility for the child does not hinder the treatment process, is there any evidence that it makes a positive therapeutic contribution? We have the impression that this has been true in some of our cases, but a clinical impression is not necessarily a fact, even though it is in accord with the laudable aim of keeping mother and child together.

In attempting to understand the different responses of our patients, it should be emphasized that psychotic reactions in the postpartum period do not comprise a single, homogeneous clinical entity. They appear to vary with regard to 1. The prepsychotic personality and developmental history of the patient; 2. The nature and time of onset of the symptoms; 3. The degree to which pregnancy, childbirth and motherhood have been crucial aspects of the precipitating stress; and 4. The course of illness and the response to treatment.

Our preliminary clinical assessment on the first 12 cases suggests that these women may be divided into three somewhat overlapping groups:

1. The patients in the first group have a history of reasonably successful prepsychotic adaptation, particularly at work and school. They appear to come from intact families with whom they retain close ties. Strong masculine strivings and serious conflicts over femininity are prominent. These women tend to become disturbed during the pregnancy, although they may not be psychotic and in need of hospitalization until months after the delivery. The child is usually their first, and they almost always report that they would like to love the child and feel guilty that they cannot. Caring for the child in the hospital helps these mothers to come to terms with their hostility toward it, lessens the guilt aroused by abdicating this responsibility, and offers them the opportunity to develop positive feelings for the child in a neutral and supportive milieu. The joint admission seems particularly useful in these cases since it requires and allows the patient and the treatment to focus directly on the problems central to the illness. These women appear to have

the best prognosis for rapid recovery.

2. In the second group we have also noted essentially good prepsychotic adjustment, but here the principal feature appears to be an underlying sadi-masochistic need which may be manifested in both passive and rebellious relationships. These women come to the hospital complaining of the difficulty in caring for the child, often not their first child. It soon becomes clear, however, that the illness is primarily related to the struggle with their husbands and general dissatisfaction about their marriage. For these women, the opportunity to care for the child in the hospital may be welcomed as a support to their self-esteem as good mothers. The joint admission may be supportive but is not centrally involved in helping the patient with her problems; how she deals with these determines the hospital course.

3. Relatively poor prepsychotic adjustment, with chronic depression and/or psychotic periods, characterizes the third group. They come to the hospital because of the exacerbation of these long standing problems. Their histories often indicate deprivation and abusive treatment in childhood, and their strong needs to be taken care of leave them with little to give their children. Joint admission in these cases has not worked out well, because the child constitutes an additional demand upon an already overburdened mother. Needless to say, these are among the most difficult patients to help with any therapeutic approach.

The last question we should like to raise concerns the effects of the mother's acute psychotic illness upon the child's emotional development. It is our clinical impression that the children on our wards were not harmed by their psychotic mothers, who were, of course, helped by the staff when necessary. However, this impression deals with only a small part of the question; obviously, there are long range implications which must be investigated. It is clear that there are many emotionally disturbed mothers in the community, and that psychotic women with varying degrees of recovery and disability are routinely discharged and return to care for their children at home. The significant issue seems to be this: Will

the long term interests of both the patient and her child be better served by temporary or permanent separation, or by therapeutic assistance to the patient as she functions in her role as a mother?

At present, little is known about the relationship between psychosis and the quality of mothering. Women who are or who have been psychotic may or may not have enduring characteristics which determine how they function as mothers. In one of the few research contributions to this problem, Sobel (6) has recently reported on the children of 8 couples of which *both* mother and father had been hospitalized and diagnosed as schizophrenic. Upon discharge, half of these parents resumed care of their children, while the children of the other couples continued in foster home placement. Sobel observed less satisfactory adjustment of those children who returned to their natural parents. As far as we can determine, however, hospitalization provided these patients with little or no therapeutic opportunity to deal directly with the emotional problems of parenthood. Up to the present time, all but 2 of our mothers whose children had been in the hospital with them have been discharged and returned home. Their effectiveness in resuming full responsibility and their continuing emotional growth appear to depend to a great extent upon what they were able to accomplish during their hospitalizations.

The psychological issues facing the mother and child at the various stages of early childhood have been delineated and discussed recently by Sander (7). He demonstrates how the child confronts the mother with age-specific problems which may re-arouse her unresolved difficulties from the past. At this juncture in her life the mother may be able to arrive at better solutions to these old problems, she may become further entrenched in her existing pattern of defenses, or she may even change in a less adaptive direction. Thus it seems likely that in some cases the emotional disorders of our patients are causally related to their inability to deal with specific issues raised by the development of their children. We are impressed with the unusual opportunity offered by the joint admission procedure to learn about the genesis and the treatment

of disorders of parenthood.

In cases where joint admission might seem appropriate, the practical alternatives must be evaluated in the light of available diagnostic and factual information. From the viewpoint of the child, whose needs vary with age, the effect of separation may be traumatic to a greater or lesser degree. An infant's needs can probably be met by a warm mother substitute, whereas a child beyond 6 months of age is more likely to experience separation from his *own* mother as a painful loss. On the other hand, older children are not so dependent upon their mothers alone, having begun to develop other sustaining emotional relationships and interests. It is of interest in this connection that none of our mothers has asked to have a child over the age of 2 years admitted.

From the point of view of the mother it is important to consider who will assume responsibility for the child in her absence, for she will have strong feelings toward the person who takes her place. A "devoted grandmother" is often regarded ambivalently by the patient, particularly when a poor or hostile relationship with her mother has been a lifelong pattern, and this may lead to feelings of guilt and inadequacy. In addition, it should be noted that close examination by social agencies of foster home placement indicates that it is increasingly difficult to find adequate mother substitutes.

Finally, there are the problems encountered by the mother and child when they resume life together. The child will have to leave the mother substitute and return to the care of his mother, whom he may hardly know. The mother must care for a child from whom she may feel estranged, and the "substitute" may continue as both the mother's support and her rival.

We must recognize that there are cases in which the mother's illness is so severe as to demand separation from her child. Our experience, however, leads us to suggest that the separation should not be for the duration of her hospitalization.

We are still far from adequately answering the question of how admission to an adult mental hospital and care by a psychotic mother affects the child, although our clinical impressions have been favorable. We are now engaged in a pilot study

to establish more precise indications for joint admission, to devise methods for the intensive and systematic observation of mother-child interaction, and to follow the children over an extended period.

SUMMARY

During the past year and a half 12 infants and young children have been cared for by their mothers on the adult wards of the Massachusetts Mental Health Center, in conjunction with the hospital treatment of these mothers for severe emotional disorders. This paper reports our experiences in the admission and management of these cases and discusses the implications of this procedure in terms of the responsibilities of the hospital, the therapeutic needs of the patient, and the effects upon the child of being cared for by a disturbed mother.

The following points have been particularly emphasized: 1. By arranging the joint admission, the hospital supports the patient in her role as a mother, whereas the usual practice of separation confirms her belief that she is harmful or destructive to the child. The staff provides information, structure, increasing responsibility, and non-

punitive models for identification—all of which tend to reduce her feelings of guilt and inadequacy. 2. In a protected setting, the patient can safely explore in treatment her hostile feelings as they arise in day-to-day interactions with the child. 3. Positive feelings toward the child are experienced by the mother and reinforced by the staff and other patients.

It is our experience that joint admissions are practical in selected cases, and that they may make a substantial contribution to the mother's recovery. They also present a unique opportunity for the study of difficulties in the mother-child relationship.

NEW DIRECTIONS IN THE INPATIENT TREATMENT OF PSYCHOTIC CHILDREN IN A TRAINING CENTER¹

JOHN P. KEMPH, M.D., ALBERT C. CAIN, Ph.D., AND STUART M. FINCH, M.D.²

The treatment of inpatient children at the University of Michigan Children's Psychiatric Hospital is provided within the framework of the usual university hospital model. The psychiatric resident is responsible for the psychotherapy and hospital management of each child with the assistance of a senior staff psychiatrist supervisor. The psychiatric resident is the leader of the team of personnel from the various services such as O.T., R.T., play school, remedial education, nursing, ward staff and other medical services such as pediatrics and neurology. Each of these services functions relatively autonomously administratively as well as in the training of their students and personnel, although they receive direction regarding the treatment of the individual children from the residents in charge of each case. This system provides a rich learning experience to trainees in all the inpatient services and has served as an effective therapeutic method in all diagnostic categories—except for those of early infantile autism and symbiotic child psychosis. We were far from satisfied with the treatment results of the first 8 such children treated in our unit.

In each of these 8 cases, several successive therapists received a wealth of experience and training. At the same time, trainees in O.T., R.T., nursing, psychology, and social work were able to have close contact with these children and their parents. The residents in psychiatry learned the potentialities and limitations of each of these services, and gradually became more capable of helping them within their frame of reference to understand their patient, but the children showed only minimal improvement.

Since we had decided that the most valuable type of inpatient unit from the training standpoint was one which con-

tained children of widely varying diagnostic types, including the childhood psychoses, and since we maintained strong commitments to providing optimal service even while primarily being a training center, we actively set out to explore and then remove whatever external obstacles were limiting our therapeutic progress with these psychotic children.

We were increasingly persuaded that the complexity of the multiple transferences of the patient and interlocking countertransferences of the therapist and other members of the team, much as indicated by Ekstein, *et al.* (9), required both further understanding and opportunities for constructive resolution; and that the impact of certain features of the training hospital setting had to be buffered for these children.

Progress of these cases in ego development of autistic and symbiotic psychotic children was found to be particularly heavily dependent upon the general attitudes and specific countertransferences of not merely the child's therapist, but the entire hospital staff. When the staff's initial enthusiasm and devotion is met with only the painfully slow progress of these children, their sporadic deep regressions, and minimal ability to return the love lavished upon them, it can readily give way to therapeutic pessimism, mutual withdrawal, boredom, reciprocal projections of blame for the child's lack of progress, and various undercurrents of countertransference reactions. Similarly the continual rotation of trainees and changes in staff, inevitable in a training center, are highly disruptive both to team functioning and particularly to these children who are so desperately needy of reliable objects.

To cope with these difficulties, a system was gradually evolved that provides continuity of staff, coordination of treatment program, continual stimulation and reinforcement of staff's therapeutic efforts, and which generally diminishes the likelihood of

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² University of Michigan, Ann Arbor, Mich.

unchecked, malignant countertransference developments. This consists primarily of the use of multiple, long-term therapists, and regular group meetings for all personnel having close contact with these patients.

The first step in this new treatment program for autistic and symbiotic psychotic children was to make clear to all personnel that the next group of psychotic children to enter the hospital would be kept in the hospital for a prolonged period on an experimental basis and that a maximal effort would be made to utilize our resources for their improvement. Although it was deemed desirable to form a closely knit group of therapists representing each of the inpatient services in the manner of residential treatment such as exists at Hawthorne Cedar Knolls(2) and the Orthogenic School (5), this program was not imposed on the therapists of these psychotic children. Instead, each of the services themselves requested more assistance from therapists and supervisors, and often requested help from administrative sources to settle the differences of opinion between different services. It became clear that all persons involved in the treatment of these children desired more communication with one another, and needed more than customary support. Out of this evolved more frequent group meetings, and eventually a weekly meeting was set up both to discuss the numerous practical problems which developed in the treatment of these children and to share pertinent theoretical materials.

At first these regularly scheduled group meetings consisted of different members of the group reviewing literature followed by a discussion of the application of this material to our patients. Soon, hostile feelings of the staff toward the patients, and in a benign fashion toward each other, were expressed at first tentatively, and then freely. Although the inpatient director served as the leader of this group, he encouraged the formation of a group in which the group process fostered spontaneous communication and free discussion by individual members with the development of a "group ego." Recent comments by some of the group members have strongly attested both to the group's cohesion and the meaningfulness the group has come

to have for each of its members. Frequently, specific problems of treating or understanding the unusual behavior of these children are discussed and at times creatively solved by the staff group members spontaneously speaking out and building progressively on each other's ideas. But it is obvious that this is more than just a discussion group, its functions including a major therapeutic element. Actually, it fulfills the three criteria listed by Foulkes and Anthony(14) as necessary for group psychotherapy: 1) free floating discussion, 2) analysis of material, and 3) the handling of unconscious content. The uncovering, group acceptance and cathartic expression of negative feelings diminished negative countertransferences toward the patient as well as between the staff members, and allowed the staff members to become mutually supportive as they shared understanding of each other's efforts and sacrifices. But beyond such quasi-therapeutic functions, interest was constantly restimulated; mutual encouragement was provided; awareness of covert aspects of the children's progress was fostered; the staff was prepared for the children's inevitable regressions and plateaus and could view them with perspective; the group in general (and the senior staff members in particular) gave to the members some of the supplies these children are so notably incapable of even minimally returning to those who work with them; and careful group analysis of the children's more perplexing behavior prevented staff falling into the morass of misunderstanding so well described by Money-Kyrle(22). Intense staff countertransferences were reduced and ways discussed to manage and live with such feelings without grossly disrupting the relationship to the psychotic child. Additionally, in all the varied ways known to observers of group interaction, many previously invisible staff problems, antagonisms, competitiveness, therapeutic jealousies, sidetaking, rigidities, *etc.*, became manifestly apparent.

It was observed that in general the more staff energy invested and sustained in a child, the greater his progress. It is much easier for the therapist to invest freely in and substitutively "lend" the child his own ego when he is relieved of massive negative

feelings inevitably aroused by these patients' primitive behavior (*cf.*, 24), and when he is supported by a group with common interests and goals. Such a group can provide much more than individual supervisory sessions in the way of augmenting the total therapeutic effort for the patient.

The treatment of these children was essentially the same in all cases, incorporating Mahler's aims of developing an integrated body image and identity, establishing and advancing the level of object relationships, and the restoration or building of ego functions (20).

Clearly, extensive need gratification for these children was a vital element in their treatment (1), but the timing and dosage of frustrations was also of great import. As we gradually understood and more appropriately relieved ourselves of hostile feelings for these extremely demanding children, we also became more capable of proceeding guiltlessly to frustrate the children minimally where therapeutically appropriate, and objectively evaluate the results. Here it was clear that with the treatment of psychotic children much as has been noted in the field of normal child growth and development (13, 16), gradual frustration as well as gratification is essential to ego development. "Love" was not simply "not enough": at times it was too much. Similarly Weiland and Rudnik (23) describe a case in which they have pressed an autistic child without speech to use speech by frustrating him in gradual doses until he would, as an initial step, name what he wanted. Our uses of carefully timed frustration have gradually been increased, and children who previously had no communicative speech are now not only talking, but also learning in a fairly normal classroom situation. We have also used conditioning procedures, somewhat more informal than Ferster and DeMyer's (11, 12), to get the children to use communicative speech. But it required frequent discussion and much support before a number of staff members could sufficiently use more demanding, frustrating therapeutic measures of unconscious and even conscious sadistic meanings to a point where this newer approach could be effectively employed.

The 4 children in the experimental group are treated by more permanent personnel, thus providing the enduring, long-term objects required by such children for sustained ego-growth. Among both the psychotherapist and other treatment agents there has been a tendency toward use of co-therapists, which spreads out the training opportunity somewhat, buffers the children from some of the impact of their therapists' vacations, illnesses or eventually leaving the hospital, and allows some sharing of the heavy emotional and time burdens of treating these children. At the same time, trainees who are briefly rotating through the services (*e.g.*, student nurses) are welcomed to observe and peripherally interact with these children, but are not assigned to them to the degree that any meaningful relationship will barely develop only to be ended abruptly a few weeks later. Thus the somewhat restricted training use that is made of these cases is primarily in seminars, progress conferences, and case presentations, as well as the children's availability for both informal and formal observation (much used in our setting with nurses, and in the training of medical students). Substantial training goals are still achieved, though some training purposes have had to be subordinated to improve service. Now that the staff group has formed an identity of its own, there is considerable resistance to the admission of new members to the group, which unfortunately further limits the psychiatric residents' and other trainees' knowledge of the treatment program in these cases. We are confident that these and other new problems (such as those occurring between co-therapists) can be worked out.

With regard to the selection of therapists for these children, it was of course found that the ability of therapists to treat such children varied markedly. Some therapists were excellent in their intuitive understanding of psychotic children and poor at treating neurotic children, while others were equally capable with all diagnostic types. Some developed a high degree of interest in these children only to become discouraged by the minimal and somewhat esoteric gains made in treatment. The ego gratification of the therapist is minute, and there-

fore certain therapists cannot tolerate these patients. Probably it is not necessary in the training of psychiatric personnel that they treat such a rare condition when they lack interest or aptitude or perceptiveness for this phase of psychiatry.

The treatment of all 4 children in the experimental group progressed more smoothly and with much greater improvement resulting than any of the initial group had experienced. This improvement is exemplified in the following case description :

Bonnie, an appealing 4-year-old girl, primarily showed features of an autistic psychosis when first seen at the hospital, though the confused history hinted of an earlier symbiotic psychotic state. She was extremely detached, unrelating, and withdrawn, could shut people out of her world entirely. There was minimal communicative speech other than echolalia, gross disorientation in time and space, arm-flapping, grimacing, and absence of pain response ; she was incapable of play activity, extremely fearful, had a mechanical robot-like quality, and her stiff and somber look was broken only occasionally by moments of strange, massive excitation. She had previously tested in the "moderately retarded" range, but the Seguin formboard test and some selected Binet items administered at the hospital bespoke above average intelligence.

The therapeutic regimen initially included the following : give unendingly of the primary affection she had missed, but dose this so it would not be thrust upon her when she could not accept it ; provide major staff objects for identification that would be long term and primarily sources of gratification ; restore a capacity for play and direct it toward use in belated mastery of severe early trauma ; establish ego boundaries and convey a sense of her inner worth ; avoid anything resembling the harshness and restrictions she had previously experienced ; aid the development of compulsive and other neurotic defenses ; teach specific academic skills and variously build up a broad range of ego functions ; encourage spontaneity and attempt to bring joy and expressiveness into the life of this pathetically frozen, melancholic child. All services accepted the challenge with vigor, and many staff members became deeply attached to her (some who have formally left the hospital still return to visit her, give her music lessons, *etc.*, and others state they will not leave until Bonnie no longer needs them).

She gradually gave up her autistic defenses,

initially forming very dependent, clinging, demanding quasi-symbiotic relationships. Communicative if perseverative speech took the fore. Extensive imitating and mirroring of staff and peers alike appeared. Ego skills in all areas increased by tiny tentative steps. She became a bit more expressive, though only rarely enjoying herself. Play began at first in imitation of her therapist, and soon focused exclusively upon feeding scenes, scoldings and punishments, and dire warnings to "stay in bed and be quiet!" Whiny dissatisfaction transformed cautiously into negativism, and testing—all well accepted by staff as signs of progress of self-definition and assertion. Anger as expressed in a context of control was encouraged, and crude but socially acceptable outlets for growing anal-smearing impulses were provided. Bonnie insisted she was first, biggest, smartest, must win and be included in everything, and turned away disintegrating in great hurt and tears if her wishes were less than totally fulfilled.

More recently she has weaned herself somewhat from her major love objects, has more meaningfully internalized them, shows increased separation tolerance, can grudgingly accept sharing and delay. She has turned to peers, participates with them, gropes with learning how to join in, and sometimes initiates group activities, though just as easily withdrawing to isolated, compulsive busy work. She needs far less reassurance, and often welcomes instead of being panicked by change. Her anxiety is both diminished and more appropriate to situations, though still too often resulting in stiff fist-clenching, severe "wiggling," and a plunge back into routines, rules and repetitions. She is generally playful, teasy, even gay and lively a good deal, a "joy to work with" as many monthly reports now describe her, yet she can dip abruptly from zestful creativity to utter dejection. She now is often proud, more confident, rather sassy. She long has shown remarkable alertness, and now is a hungry, and far less grim learner, reading and testing in almost all areas at an age appropriate level, though making excessive use of stunning rote memory powers and revealing severe distortions in abstractive capacities. Piece by piece she is literally learning each affective expression and what kind of inner and external events it is appropriately connected with ; at the same time, she slowly faces some of the profound grief she defends against fully experiencing. Meanwhile, 18 months after entering the hospital, she has moved up through one higher level inpatient group after another.

Throughout her striking progress, the therapeutic team has maintained extremely close contact, informal as well as formal channels of communication kept open and freely used. The therapist's functions extended far beyond direct treatment of Bonnie or guiding and coordinating her hospital management. Where choices were possible, he selected appropriate staff for Bonnie's major activities and shielded her from others; kept her past progress and immediate goals continually in view of staff; stimulated hope for her future and insisted she not be perceived as a "research" or "training" case; staff's positive transferences to him were deliberately elicited and put to Bonnie's use; he spared other staff members from transient discouraging developments regarding her parents and related court actions; encouragement was continually pumped up; "permission" was granted by example and comment for expression of staff's irritations, exasperations, acknowledged desires to over protect Bonnie, *etc.*; covert staff tugs-of-war were often spotted and resolved or Bonnie removed somewhat from the line of fire; and new, fresh staff and experiences were introduced when staff energies were beginning to sputter out.

Just as with Bonnie the other 3 children have shown marked improvement over a prolonged period since the new treatment program began. Perhaps the most striking aspect of this program was that all 4 children improved simultaneously, whereas previously none of the first 8 children had achieved as much growth in a similar time.

To accomplish and sustain this rate of progress at least some of the staff must be literally inspired in their work or in some research relevant to it. Whether this fervor wanes over a period of months or years or not, they eventually become drained of their energy and increasingly develop guilt and hostility in the face of their growing therapeutic impotence with these children. To "protect" such personnel and to maintain the relatively rapid rate of progress in the children there must be an awareness that this situation may develop, and when it cannot be resolved in any other way, arranging for such personnel to reduce their amount of contact with these children and focus their efforts upon a different type of child may be indicated.

The same diagnostic criteria were used for the selection of all the patients for this

study. Some were found to be primarily autistic according to Kanner's description (17, 18) of early infantile autism, with little tolerance for change, intense need for sameness, preoccupation with inanimate objects, an alert and intelligent expression without being attentive, lack of communication with and feeling for the mother, impairment of sensory perception, proprioception and the persistence of primitive reflexes(3), the need to be isolate, *etc.* Others typified Mahler's symbiotic psychosis syndrome(19, 21, 30), or the "state of the need satisfying part object" with regression, agitated temper tantrums and panics, unusual sensitivities, almost catatonic reaction to minor frustrations, and secondary autistic features. Still others could not be clearly designated as either autistic or symbiotic, but were considered clinically to have some of the characteristics of both of these syndromes.

Higher level categories of childhood psychosis, such as the borderline states(15), neurotic, psychopathic types, ego defect and others(3, 4, 10) have been excluded from this study because their treatment, similar to that described by Despert(6) or Ekstein(7-9), has been relatively successful in this hospital even though some of the therapeutic problems inherent in a hospital training center setting of course have their impact on these children too.

SUMMARY

A review is presented of the treatment of 12 autistic and symbiotic psychotic children over a period of years at the University of Michigan Children's Psychiatric Hospital. The paper focuses upon the effects of two contrasting treatment programs and their relation to problems specific to the treatment of these children in a training center. An initial group of 8 young psychotic children treated at the hospital showed relatively little improvement. Close scrutiny of the therapeutic program and course of their treatment revealed a number of potentially surmountable obstacles to these children's ego development. Subsequently, a group of 4 similar children were treated in a new, gradually evolved experimental program, with considerable improvement resulting. The new program included the use of multiple long-term therapists and group meet-

ings for all personnel having close contact with these patients : it provided continuity of staff, coordination of treatment program, continual stimulation and reinforcement of the staff's therapeutic efforts, and generally diminished the likelihood of unchecked, malignant countertransference developments. Regularly scheduled group meetings for relevant personnel are in part educational but of greater significance is the group process which provides staff catharsis frequently and insight occasionally into their real feelings for these children. As a result the staff are less encumbered by negative countertransference. The staff members become mutually supportive when they share understanding of each others' efforts and sacrifices. Improvement in the autistic or symbiotic child is positively correlated with the total amount of the staff's sustained investment in his care, which can be enhanced by a staff "group."

AN EXPERIMENT IN TEACHING FAMILY DYNAMICS¹

ARDEN A. FLINT, JR., M.D., AND MARGARET J. RIOCH, PH.D.²

This paper is concerned with the general subject of teaching family dynamics. Specifically it deals with a course which was given as one aspect of a pilot experiment at the National Institute of Mental Health in training mental health counselors. The rationale for the pilot project as a whole has been described elsewhere(1). It sprang from a recognition of the need for more low cost psychotherapy and was based on the thesis that carefully selected mature people could be taught in the short period of two years to do psychotherapy with limited types of patients, *e.g.*, adolescents and adults who are not psychotic and who do not engage in grossly antisocial behavior. The kind of psychotherapy was conceived as similar to that which is done in community mental hygiene clinics or college counseling centers in which patients are usually seen once a week. The students in the pilot project were 8 married women approximately 40 years of age, all college graduates, with no prior formal experience or training in the mental health field.

The course in family dynamics which was offered to them illustrates the way beginning therapists can be initiated into this complex area. The course stands on its own merits and can be considered independently of the pilot program as a whole.

While the traditional training of psychotherapists includes interviews with patients, group and individual supervision, placement in various community agencies, lecture and reading courses in the areas of personality development, psychodynamic theory and psychopathology, it is usually only as a result of further, often painful experience that the therapist becomes aware of the importance of family interaction and the strength and mutuality of family bonds.

Family therapy is one of the best ways to learn these significant lessons, but the

treatment of disturbed families is challenging and difficult even for experienced therapists. Our problem was to give our beginning students the benefit of experiencing such families without overwhelming them too early with heavy therapeutic responsibility. The structure of the course was designed to solve this problem.

GOALS

Our basic goal was to help our students to perceive the family as something more than the sum of its parts. Each family member contributes threads to the fabric of family life. Its pattern, although adumbrated before the children are born, becomes richer and more differentiated as each child makes his unique contribution. The patient *was* and *is* a continually interacting member of the family, playing a part in its adaptive and maladaptive functioning. He is not a passive "victim" of parental attitudes.

The inexperienced psychotherapist tends to be gullible, to overidentify with his patient, and innocently to accept the patient's perceptions of an event as the whole truth. He may then over-react to his first taste of self deception and become unwilling to believe anything the patient reports. We wanted to help our students find that elusive position between sentimental intimacy and cold distance that seems so desirable and yet so difficult to achieve even for experienced therapists. We wanted to unfetter their empathy and yet maintain their perspective.

Experience is relative, and meaningful to the individual only through his perception of it. The "objective facts" of a family incident, which is a focus of conflict, are essentially unknowable to the observer. Taking the different perceptions of the incident into account is crucial to the understanding of the interlocking family dynamics. The therapist must develop an almost acrobatic skill in moving from one family member to another, seeing the incident through the eyes of each one. We wanted our students to

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² National Institute of Mental Health, Bethesda, Md.

practice performing this feat, and to realize how the therapist becomes temporarily ineffective if he enters the patient's mythology and forgets the relativity of perception.

By considering the family as a whole, students can become aware of the various myths created by individual family members. They can see how shared mythology and complementary neurotic roles interact to perpetuate pathology.

We wanted our students to feel the full impact of the current family drama; to see the child's look of contempt when father cringes under mother's tirade. We wanted them to chronicle the family subsequences of a single significant incident. For example, a boy impulsively runs away from home. During the next few days his well-intentioned, hard working father suffers a flare-up of his old ulcer and becomes increasingly irritable and perfectionistic. His mother, martyred and overprotective, becomes depressed and tortures herself with vague accusations that it is all her fault. When the boy returns, he finds even more reasons for the guilt and rebellion which led to his running away. Conducting individual psychotherapy cannot fully convey the lessons implicit in such events. We wanted to illustrate how individual life patterns can interlock and reinforce the pathology or conversely, permit individuation and growth, and finally, we wanted the students to experience the patterns of *family* resistance as well as *individual* resistance.

Goals similar to this in the training of medical students (2-8, 13, 14, 18) and residents, (9, 10) have been mentioned by others. The course described here differs more in method than in basic philosophy from those in many progressive teaching centers.

METHODS

The course required 4 hours of class time and 4 hours of preparation each week for 2 semesters. It consisted of 6 different parts, each of which is familiar enough by itself; but the integration of these separate parts into one meaningful whole was, so far as we know, unique. This unity permitted the students to bring together the various aspects of their learning into significant *Gestalten*. The fact that all the phases of the course were taught by one instructor, the

principal author, was a facilitating factor. For the purpose of presentation we shall describe each of the 6 units as if it were a separate part. Actually they were overlapping and interdependent.

1. *Tape Recordings of Family Interviews*. The course was initiated by playing tape recordings of family therapy conducted by the instructor. These tapes provided an excellent introduction before patients were available for direct observation. The recordings had the added advantage that they could be edited, interrupted or repeated to focus discussion.

The presentation of the interview with the teacher as therapist began to structure the student-teacher relationship in a manner crucial to our philosophy. The teacher was not set apart as an authority possessing mysterious skill, operating flawlessly in an aseptic relationship with his patients, but was seen by the students as a struggling human being, sometimes floundering, sometimes skillful, sometimes insensitive, sometimes perceptive. A teacher is a model for his students and it was our conviction that a real model was better than an artificial, overidealized one. In addition, the model we wished to encourage was one of a therapist who could risk exposure.

2. *Literature Review Seminar*. This seminar was held biweekly for the first semester. Literature was selected relevant to the following areas which were discussed sequentially: the functions of the family; the marital pair; parent-child interaction; the marital relationship as an environment for the child. Each student reported to the group on assigned articles in the areas of family sociology, psychology, and psychoanalysis. The text used by all students was Ackerman's, *The Psychodynamics of Family Life*.

It is our impression, confirmed by the students, that oral reviews of articles are usually a waste of time. The material thus presented was quickly forgotten sometimes even by the student who presented it. On the other hand, when everyone had read the same article, a lively discussion took place which not only imprinted the material in memory but stimulated further thinking.

3. *Observation of Family Screening Inter-*

views. We initiated a collateral group therapy program specifically for this course. Thirteen high school boys and girls with character disorders or neurotic problems were referred from community sources. We deliberately chose patients in this age group because the troubled adolescent still living at home continues to interact with his family around those unsolved issues which relate to earlier developmental periods(16). Unlike the younger child, however, the adolescent is able to express his concerns verbally which makes him in some ways more easily accessible to adult understanding.

An initial screening appointment was made for the adolescent patient, his parents, and an occasional sibling. All appointments with patients or families were tape recorded and held in interview rooms provided with one-way glass observation windows. Each family group was interviewed by an experienced therapist and the students observed the sessions through the glass. The patient was then interviewed alone by the therapist. The entire student group observed about one half of these interviews.

Following the screening session, the class met to discuss the family. Various students identified with different family members as they recalled their observations and listened to the tape. They made such disparate comments as "That poor boy! How could he live with a mother like that!" and "What do you mean! The poor mother! Can you imagine having a kid like that in *your* house!" Gradually, they began to disentangle themselves and to experience the interacting family as a whole unit. The instructor attempted to be aware of his and the students' anxieties at such times, occasionally controlling, at other times, pointing out group process(4, 7). There seemed to be less anxiety and defensiveness in our group as compared to that reported in medical students in a somewhat analogous situation(3, 5-7). This may relate to our careful selection process, the general maturity level of our students, and the high group morale.

On several occasions a small segment of the tape involving complex family interaction was played repeatedly while the students and instructor diagramed on the

black board the subtle interaction processes which had taken place. In this way, some of the theory became meaningful and was illustrated by concrete example.

The observation of group therapy has been reported by others(9-12) to be a learning experience in which the student becomes actively involved. Observing family sessions has even greater impact. The vividness of the experience etched a picture of the family on the minds of the students which even now, a year later, has not been erased.

In retrospect, it might have been more desirable to have asked each student to watch one particular family member during the entire interview(15), to try to put herself in his place and later to interpret the subjective reality of that family member to the class. The seminar should have been scheduled immediately after the observed family session when emotional involvement was maximal.

4. *Observation of Collateral Group Therapy.* From the 13 families seen in the screening interviews 4 boys and 4 girls were selected for an adolescent therapy group and their parents for a collateral group. Each group had an experienced therapist and a student co-therapist. The course instructor was the therapist in the adolescent group.³ The students observed about one half of the weekly group sessions of both groups for 5 months, each student paying particular attention to one assigned family.

Our 8 families soon became a central communal experience for the student group. Contributing to this communality were the following factors: 1. In each group the student co-therapist permitted multiple student identifications with the 4 group therapists. Disagreements between the co-therapists were shared with the student group. 2. A group therapy consultant⁴ met with the 4 therapists biweekly. The other 6 students were present and contributed to the supervision discussions. As they struggled to understand the patients they gradually perceived the complex family dynamics.

³ Dr. Ruth Newman, Washington School of Psychiatry, Washington, D. C. was the therapist for the parent group.

⁴ Dr. Beryce MacLennan, Consultant, NIMH, Bethesda, Md.

They made such comments as, "Every time Johnny opened his mouth last Tuesday I could hear his father talking." 3. The course instructor reported all phone calls and contacts with or about the families which he had experienced between the therapy appointments. The students were eager to hear about anything that was happening to "their" families.

5. *History Gathering Interviews with Parents in Assigned Families.* After the group therapy had progressed for two months, each student conducted a structured individual interview with the parents of her assigned family. Detailed information concerning the social background of parents, history of the marriage, and the developmental and school history of the adolescent patient was obtained. Their curiosity had been heightened by observing the families in therapy and some of the students spent up to 8 hours in appointments for these interviews. While interviewing the parents they became aware of their countertransference feelings more sharply. This awareness facilitated their ability to put themselves in the place of the therapists and/or other family members, e.g., "Mr. Jones was boring for me, too. Now I understand how his son feels."

6. *Writing and Discussion of Reports.* Each trainee was asked to prepare a written report summarizing the dynamics in the adolescent patient of her assigned family, speculating on the etiology of his pathology and the family functions which it served. Her report was based on her observation of the screening session, of the individual interview with the child, of the child and his parents in group therapy, and on the material obtained in the individual interviews with the parents. Each student presented her paper in a seminar specifically scheduled for her family. These 8 sessions resembled the traditional child diagnostic case conference which has been reported as having significant training value(5-7).

RESULTS

In the opinion of the authors, the students gained new respect for the complexity of human behavior and the importance of unconscious motivation. They saw various complex but understandable patterns in

different families and the unique configuration each family member had developed as part of the whole.

Other instructors noted that during supervisory sessions on individual therapy when a student tended to overidentify with her patient, she often became spontaneously aware of it and was quickly able to see the entire family pattern more objectively.

A gratifying and unexpected result was the impact of the course on the students as a group. All the students felt possessive of the families. The entire group had witnessed the diagnostic process of all of the families in detail and had struggled with the therapists through the initial phases of therapy. The entire student body felt that they were co-therapists. This communal experience with patients is not often present in training programs.

Family members and incidents became an ABC of psychopathology to which each student could refer with the expectation of being understood. One year later, as their training continues, they are gradually replacing this primitive language with the more traditional technical terminology. Both the instructor and the students, however, still find it useful to refer to family members as illustrating psychodynamic theory.

Limitations. The course had several limitations and faults, some of which might easily be corrected.

1. The events occurring in the lives of our family patients were so dramatic and intense that interest focused almost entirely in the present to the neglect of the past.

2. The families were all from the suburban middle class with the result that our students had no experience in this course with other socioeconomic groups.

3. The adolescents were only moderately disturbed and extreme forms of family pathology were not observed.

4. The length of time during which the families were treated and observed was too short. During the 5 months of group therapy, we saw little evidence of significant change in any single patient and thus missed seeing the effect of change on other family members. The chief patterns of resistance in each family could be well illustrated, but only by observing families over a longer time, perhaps 1½ to 2 years, can

the more subtle patterns of mutual provocativeness and interaction be seen. This would give students an opportunity to reevaluate their initial, sometimes erroneous impressions.

5. Articles from the reading syllabus assigned to the student group were not accurately enough timed. Articles might better be selected when we felt a given family illustrated that particular subject.

SUMMARY

The course described in this paper was an important aspect of the first year's work in an experimental program in training psychotherapists. It was unique in that it integrated many different parts into a meaningful, lively, learning experience of family dynamics without burdening the beginning students with too heavy a therapeutic responsibility in this difficult field. The good results were recognized by students and instructors. The success of the program as a whole is a further indication that courses of this kind would be useful in the training of psychotherapists of whatever professional affiliation.

PROGNOSIS IN "PROCESS" AND "NON-PROCESS" SCHIZOPHRENIA¹

JOSEPH H. STEPHENS, M.D., AND CHRISTIAN ASTRUP, M.D.²

In spite of the fact that Bleuler spoke of the group of schizophrenias, there is a tendency to consider schizophrenia a homogenous entity. Many writers, however, have urged the need for greater clarity in the use of the term schizophrenia and Kubie (29) and Kanner (26) have predicted that the term will disappear in the foreseeable future. Szasz (40), who has been particularly critical of current nosology, speaks of the diagnosis schizophrenia as a "panchreston" which only serves to fill a scientific void.

Nevertheless, problems in nosology are not popular today, and the attempt to divide schizophrenia into subgroups has been termed a classificatory game in which similarities in the new subgroups are pointed out to justify the lumping together of the disorders again under the heading schizophrenia. Typical of such current thinking is this statement in Mayer-Gross's textbook (36): "The effort by Kleist and his pupils to split schizophrenia up again into numerous small entities with different syndromes and outcome, must appear, in the absence of any established pathology, as a retrograde step toward the pre-Kraepelinian confusion of the nineteenth century."

The interest in description and classification prevalent in the 19th century has given way in our century to concentration on formulations of individual psychodynamics. As Grinker has noted, most American psychiatry is dynamic psychiatry and the word descriptive has become derogative. As a result, the details of clinical syndromes are little known and the natural history of psychiatric diseases has been neglected (21). There is no reason, however, to assume that the importance of psychodynamics need

be overlooked when attempts are made in clarification of nosological confusion by more accurate clinical definitions. Zilboorg has repeatedly pointed out the fact that the clinical work of Kraepelin, Bleuler, and Freud need not be looked upon as incompatible.

Failure to take into account the possibility of different types of schizophrenic illness with varying prognoses makes it difficult to compare treatment results reported by different investigators. Entire books are written on the psychotherapy of the psychoses without even passing reference to the natural history of different types of illness. As Donnelly has emphasized, the occurrence of the spontaneous remissions in the various forms of mental illness still constitutes a major problem in the evaluation of psychiatric therapies (9). In 1931 Hinsie (22) wrote: "What the psychiatrist needs, before he can place a fair appraisal upon his treatment measures, is a clearer conception of the ordinary nosological factors in this type of disorder. He needs to have an accurate knowledge of the entire course of schizophrenia." Three decades later we find this advice largely ignored by many investigators interested in schizophrenia.

Twenty-five years ago Langfeldt proposed that schizophrenia be divided into at least two groups, a severe "process" group with a poor prognosis, and a "non-process" or "schizophreniform" group with a good prognosis (31). Bellak in 1948 proposed a dichotomy between classic dementia praecox with a poor prognosis and schizophrenia with a favorable prognosis (5). Sullivan had expressed the opinion some years before that dementia praecox and schizophrenia should be considered unrelated syndromes (39). Holmboe and Astrup in 1957 reported different outcomes on follow-up in various forms of schizophrenia (24). A group of American psychologists in 1959 wrote in support of the concept of a process-reactive distinction in schizophrenia (4, 20, 27, 45). Ey, on the

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

The authors wish to express their appreciation to Dr. Barbara Betz who suggested this study and made it possible by her assistance.

basis of individual follow-up studies, reported in 1959 on 5 types of schizophrenia with varying prognoses (12). Leonhard, whose work is virtually unknown in this country, has further divided schizophrenia into numerous subgroups said to have varying prognoses (34, 35). His work, which is almost entirely in German, has been reviewed by Fish (14-16) and Astrup (1, 2).

Method of the Study. We have attempted to prognosticate outcome in a group of patients labeled schizophrenic at the time of discharge from the hospital by diagnostically reclassifying the patients into groups of different clinical syndromes expected to have varying outcomes.

The charts of 178 Henry Phipps Psychiatric Clinic inpatients hospitalized between 1944 and 1954 were used. The discharge diagnoses on all patients had been reviewed and agreed upon by the psychiatrist-in-chief and chief resident at the time of discharge. No patients diagnosed paranoid state, schizoid personality, or latent schizophrenia were included. These same charts had previously been used in studies by Whitehorn and Betz on the relationship between therapist and outcome in schizophrenia (6, 41-43).

Five to 13-year follow-ups were obtained in 143 (80%) of these patients. Most of these follow-ups were obtained by Dr. Betz and all of the evaluations of degree of improvement, both at the time of discharge and on follow-up, were made by her. Follow-up evaluations were based on letters, telephone conversations, and personal contacts with the patients, their physicians, relatives, and hospitals. Patients were graded "recovered," "improved," and "unimproved" both at the time of discharge and on follow-up. All 35 patients rated "recovered" on follow-up were either employed or doing housework without difficulty, and were considered to show no residual symptoms of their psychoses. Of the 36 patients rated "unimproved" on follow-up, all were in psychiatric hospitals except for 4 who were considered to be committable although they were being taken care of at home by relatives. Those 72 remaining patients rated "improved" at the time of follow-up were no longer considered to be overtly psychotic in any way and most of them were

employed or taking care of their homes although they showed residual signs of their past illness and could not be considered entirely recovered.

All 22 patients rated "recovered" at the time of discharge were considered to be without residual evidence of psychosis or significant psychiatric impairment and were expected to return to work or homemaking without difficulty. Those 75 patients rated "unimproved" at discharge were either transferred directly to another hospital or sent home to their families with a recommendation for further treatment, usually in a hospital. The remaining 81 patients rated "improved" at discharge were no longer considered to be overtly psychotic or in need of hospitalization but were felt to show evidence of some residual symptoms requiring treatment in most cases.

Before the follow-up results were known to us, all 178 cases were retrospectively rediagnosed according to the subclassifications of Leonhard and others. The diagnoses were made solely on the basis of data found in the case records of the hospitalization. Cases were then divided, according to the retrospective diagnoses, into 4 groups, P1 and P2 ("process"—81 patients), and N1 and N2 ("non-process"—97 patients), which were predicted to have varying outcomes.

Group P1, predicted to have the poorest

RESULTS

At the time of discharge significantly more "process" than "non-process" patients were rated "unimproved" just as significantly more "non-process" than "process" patients were rated "improved" or "recovered." These results are shown in Figure 1.

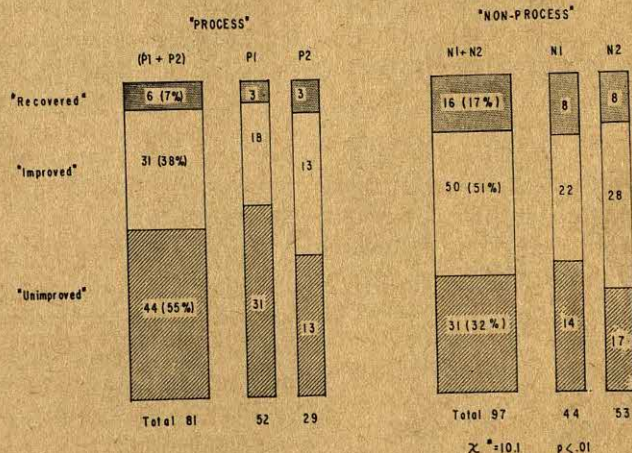

At the time of follow-up only 2 of the "non-process" patients were rated "unimproved" whereas about half of the "process" patients were rated "unimproved." Likewise the "non-process" group had significantly more patients rated both "improved" and "recovered" on follow-up. These results are shown in Figure 2.

On comparison of the condition of the patients on discharge and follow-up the "non-process" patients were found to have improved greatly while the "process" pa-

prognosis, was made up of 9 subgroups of Leonhard's "systematic schizophrenia" and

FIGURE 1.

CONDITION AT DISCHARGE OF 178 PATIENTS

also included "early infantile autism." Group P2, considered less severe, comprised Leonhard's 3 forms of "atypical schizophrenia." Group N1 contained Leonhard's 3 types of "cycloid psychoses" as well as "pseudo-neurotic" and "pseudo-psychopathic schizophrenia" and "depersonalization psychoses." Group N2, predicted to have the best prognosis, was composed of the "reactive psychoses" described in the Scandinavian literature (3, 11, 13, 17, 24, 30-32). The subclassifications with the number of patients in each group are shown in Tables 1 and 2.

tients had not changed appreciably. The results are shown in Figure 3. (Only the 143 patients on whom there are follow-ups used for the comparison.)

A comparison of what happened on follow-up to those "process" and "non-process" patients rated "improved" and "unimproved" is of particular interest. In Figure 4, of all the patients rated "improved" at discharge half of the "process" group was rated "unimproved" on follow-up. As a matter of fact, all "process" patients were in psychiatric hospitals on follow-up whereas only one of the "non-process" patients

FIGURE 2. CONDITION OF 143 PATIENTS AFTER 5 TO 13 YEAR FOLLOW-UP

had deteriorated and was rated "unimproved."

In Figure 5, although about half of the "process" patients rated "unimproved" on discharge had improved on follow-up, all of the "non-process" patients had improved.

groups of schizophrenia. For such a differentiation a knowledge of the characteristics of the subgroups is thus more important than a knowledge of specific characteristics of the more inclusive "process" and "non-process" groups. However, it is impossible in the

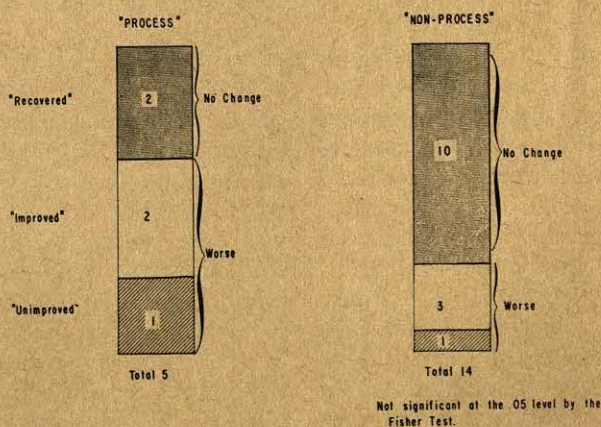

FIGURE 5. CONDITION ON FOLLOW-UP OF PATIENTS RATED "UNIMPROVED" AT DISCHARGE

Interesting, but less significant because of the smaller sample, are the changes on follow-up of those patients rated "recovered" at discharge as shown in Figure 6.

space available to describe each of the more than 20 subgroups. These have all been adequately described in the literature (1-3, 10, 11, 13-17, 19, 23-25, 28, 30-35,

FIGURE 6. CONDITION ON FOLLOW-UP OF PATIENTS RATED "RECOVERED" AT DISCHARGE

The Clinical Differentiation of "Process" and "Non-Process" Schizophrenia. In this study we have differentiated "process" and "non-process" schizophrenia on the basis of different clinical syndromes which for this purpose were considered to be sub-

38). Instead, some of the characteristics found in the "process" and "non-process" groups will be enumerated.

The following traits found predominantly in the "process" group suggest a poor prognosis: 1. Introverted, schizoid per-

sonality prior to psychosis. 2. Chronic schizophrenia in near relatives. 3. Poor premorbid social, work, and sexual adjustment. 4. Insidious onset. 5. Long duration of symptoms. 6. Absence of precipitating factors. 7. Inability of patients to give any sort of reasonable psychological reason for the psychosis. 8. Lack of apparent relationship of psychotic symptoms to past psychological conflict. 9. Intense affective blunting, complete lack of emotional response to all stimuli, with real deadening of emotional life beyond defect of interests and deficiency in initiative. 10. Delusions which appear primary or automatic and unrelated to each other. 11. Delusions of fantastic, extremely bizarre, or cosmic scope with no indication that patient is aware of his absurdity. 12. Affective loading of paranoid delusions (patients talking of delusions with great enthusiasm or irritation). 13. Somatic delusions and hallucinations described in so grotesque a manner that it is impossible to empathize with the patient. 14. Certain auditory hallucinations: a) hearing patient's own thoughts, b) conversing with voices, c) voices commenting on patient's thoughts and movements, and d) voices which come from the patient's own head or body or people in the surroundings. 15. Haptic or tactile hallucinations, especially those involving the sexual organs. 16. Visual hallucinations of mass scenes or murder and torture. 17. Massive feelings of passivity and influence in the presence of clear consciousness. 18. Stereotyped, automatic, grotesque and bizarre movements. 19. Silly giggling and senseless behavior to the point of inability to carry on an ordered conversation. 20. Specific association disturbances: a) neologisms, b) echolalia, c) perseveration, and d) word telescoping. 21. Disturbances of symbolization, *i.e.*, real perceptions given an abnormal significance without rational or emotionally comprehensible reasons. 22. Presence of a defect in higher ethical and social feeling not previously present.

The following traits found predominantly in the "non-process" group suggested good prognosis: 1. Absence of "process" traits enumerated above. 2. Extroverted or cyclothymic personality prior to psychosis. 3. Absence of any gradual personality changes.

4. Presence of non-schizophrenic illness, especially manic-depressive psychosis, in near relatives. 5. Good premorbid work, social, and sexual adjustment. 6. Sudden acute onset. 7. History of previous remission of similar illness. 8. Presence of clearly evident external stress and precipitating factors. 9. Psychotic symptoms, including hallucinations, easily understandable in terms of precipitating factors and past history. 10. Onset associated with marked excitement, elation, perplexity, anxiety, depression, or self-blame. 11. Somatic illness as a precipitating factor. 12. Preservation of affect with considerable emotional reactivity. 13. Vivid expression of personal difficulties by patient with very noticeable distress when traumatic experiences discussed. 14. Delusions of inferiority, guilt, and general hypochondriasis. 15. Realization that depersonalization feelings, if present, are delusional. 16. Presence of delusions that appear secondary to disturbed consciousness, depression, or sensitive personality structure. 17. Lack of domination of clinical picture of paranoid delusions if they are present. 18. Presence of confusion and clouded sensorium. 19. Presence of manic-depressive features. 20. Natural, undistorted movement in hyperkinetic states.

Our findings are in close agreement with those prognostic factors reported by Phillips(37), and Chase and Silverman(8).

CONCLUSION

The relative success in dividing a group of patients into subgroups with varying outcomes depends in part, of course, on the nature of the original group and the criteria by which the diagnosis of schizophrenia was first made. In the group we have studied it was found that the risk of deterioration was very light in the "non-process" patients whereas the prognosis was grave in the "process" group. Nevertheless, although about half of the "process" patients were badly deteriorated on follow-up, we were unable to predict which particular "process" patients would either improve or worsen after discharge. Thus fatalistic pessimism about a particular schizophrenic patient is unwarranted.

We cannot say on the basis of our study whether we are dealing with discrete kinds

of disease processes or different points on a continuum. However, our findings do support, for practical purposes, Bleuler's concept of "groups of schizophrenias" rather than an entity "schizophrenia" (7). Our findings are thus in agreement with those of Freyhan (18) who has urged that we re-examine Bleuler's concepts which are no less pertinent today than 40 years ago.

The persisting notion of "schizophrenia" as an entity can only impede understanding and research. European phenomenological studies, unfortunately little known in this country, may provide some clarification in this confusing field.

DISCUSSION

JOACHIM E. MEYER (München, Germany).—The paper of Drs. Stephens and Astrup deals with a topic of real practical importance. Like the authors I feel that the task of differentiating and subdividing Bleuler's group of the schizophrenias is nowadays often misunderstood as a purely theoretical matter, comparable with the creation of new syndromes out of old well-known diseases. But this is not the case: studies of the outcome and the prognosis of schizophrenia as a whole give little useful information for the clinician. But if we know the course of the various subgroups we are in a much better position to predict the probable outcome of an individual case. This plays a role in the post-clinical rehabilitation but the main importance lies in the fact that a differentiated prognosis enables us to evaluate critically our therapeutic measures. I need not emphasize what that means in these days of rapid progress in pharmacotherapy. It would be very valuable if one could take into account the prognosis of the subgroup to which the single case belongs as a larger basis for the therapeutic plan which is oriented on target symptoms. The knowledge of the great variations in the spontaneous course of the various subgroups of schizophrenia is even more valuable in establishing a reliable judgment about the effectiveness of psychotherapy of schizophrenic patients, because we have to deal here always with a very small number of selected cases, *e.g.*, in Europe the best known case of schizophrenia, treated successfully with psychotherapy alone by Mme. Sechaye, is very much under discussion, because there is no agreement on the diagnosis. The whole value of this observation is questionable because one is uncertain how the course would have been without treatment.

I shall not discuss the methodology of Dr. Stephens and Dr. Astrup in detail. Objections are possible, for instance with regard to the fact that the authors, or rather Dr. Betz, have not interviewed all patients personally. With regard to the frequency of relapses, particularly in non-process schizophrenia, I would like to ask how the authors considered the prognosis in cases with very frequent relapses but without definite deterioration. However, I do not think that these objections will minimize the evidence of their findings to any considerable extent.

In the large study of Astrup and Holmboe amongst 108 cases of non-process schizophrenia—the authors called them reactive psychoses with typical schizophrenic symptoms, according to the Scandinavian nomenclature—45, that is more than a third, later showed a course towards deterioration. The Danish authors Strömberg and Welner had to correct their diagnosis reactive psychosis into schizophrenia—that corresponds more or less with the terms non-process and process schizophrenia—in 30%. Another Norwegian author, Eitinger, had to do the same in 12%. The high concordance between the acute clinical picture, respectively the subgroup and the prognosis in the material of Drs. Stephens and Astrup, is most striking and may be due to an advanced selective procedure regarding the criteria. Another question is why the authors count the pseudo-neurotic schizophrenics in the non-process group. Do not most of the pseudo-neurotic schizophrenics show, what we call, a break in the life line and a definite loss in social adaptation, related to autism?

The value of the differentiation of schizophrenia by Leonhard into 22 subgroups I can not judge sufficiently from my own experience. Henri Ey tried to classify the end stages of 100 schizophrenics according to Kleist and Leonhard. He found that 30% of the cases could be classified under several headings. For the non-chronic cases one has to keep in mind that many patients change in their prevailing clinical features frequently, particularly during the first months of the illness. That increases the difficulties of classifying in such subtle subgroups. On the other hand the relative uniformity and constancy of the symptomatology reached under drug treatment can diminish further the possibility of delineating such groupings.

However the significant difference in the prognosis of process and non-process schizophrenia given by the authors cannot be questioned. It is an important confirmation of the former attempts in the same direction which came to light at the International Congress of Psychiatry in Zürich in 1957. Another point of interest should be mentioned in this connection: the relation between the prognosis and the hereditary factors in both groups. Strömberg and his co-workers found that in the benign schizophreniform psychoses there is a considerable number of the same or of similar mental disorders in the family, while in process schizophrenia there are only very few mental disorders in the family, if at all, but then always with an identical clinical picture and the same unfavourable prognosis.

Quite apart from the question of how to interpret these findings, the results of the prognosis and the hereditary factors in the different subgroups are among the most interesting topics in modern research on schizophrenia. The follow-up studies of Drs. Stephens and Astrup are a considerable contribution to this subject.

Concluding this discussion one could perhaps raise the question whether the terms process and non-process schizophrenia are suitable at this stage of our knowledge to designate them to both groups. With the term process we run the risk of pretending greater knowledge than we have. I may remind you

of the study of Karl Jaspers on process and evolution in mental disorders to demonstrate the extent of the problem involved. Whether one means a clinical, a biological or a psychic process there is no proven ground to attribute this term to one group and to withhold from the other. Perhaps H. Ey is right when he wrote: "What have been regarded as differences in nature are nothing more than differences of degree or of phase in the evolution of the schizophrenic psychosis." Therefore I would suggest that one should designate to both groups terms like nuclear group and marginal forms—terms which are not related to any theoretical concept.

SOME CORRECTIBLE IMAGES OF PSYCHIATRIC PATIENTS, PHYSICIANS AND HOSPITALS¹

MATHEW ROSS, M.D.²

At the centenary meeting of the American Psychiatric Association, Alan Gregg(9) said :

No other speciality of medicine has had a history so strange nor a relation to human thought so intimate as psychiatry. The three most powerful traditions or historical heritages of psychiatry are still as they have been from time immemorial, the horror which mental disease inspires, the power and the subtlety with which psychiatric symptoms influence human relations and the tendency of man to think of spirit as not only separable but already separate from body. These are the inevitable and inveterate handicaps of psychiatry.

If we are going to move ahead in psychiatry it seems to me necessary for us to make a special effort to explore, understand, and correct as appropriate those images of the psychiatric patient, hospital and physician which come to our attention. I believe that there is no single image of American psychiatrists, patients, or facilities, but that these images vary from person to person, and place to place, as well as from time to time. Because of these circumstances, this effort makes no pretense of complete coverage but rather, perhaps, through the selections I have made of other men's words, will indicate my admittedly prejudiced views of some recent and glaring instances of correctible images.

We might begin our survey in the area of research, and the funds and persons who make it possible. If we are to do our best for those who are mentally ill, it is necessary that we have sufficient and continuing financial support. When we come to examine the citizens' contributions to health causes we immediately wonder how favorable our image may be. For example(12), in 1957, the American Cancer Society

raised about \$30 per person for cancer victims, the American Heart Association, about \$2 per victim, the Arthritis Association, about 30¢ per patient, the National Association for Mental Health, about 5¢ per patient. Compare this with the \$3,000 per victim raised by the National Foundation for Poliomyelitis.

What is there about psychiatry's image which produces this discrepancy? Perhaps we can cast some light upon this by an examination of a vivid example of attitudes towards psychiatric research which were demonstrated recently in relation to some basic research sponsored by the National Institute of Mental Health at the University of Wisconsin. Such distinguished newspapers as the *Washington Post* and the *New York Times* carried the story under such headlines as: "One Million Dollar Monkey Love Research Arouses Byrd"(18), and "U. S. Aides Defend Monkey Research"(11). The news items went on to report: "Senator Harry F. Byrd, Democrat of Virginia, reported with fiscal indignation yesterday that the Government plans to spend \$1,201,925 to see why baby monkeys love their mothers." Representative William H. Harsha, Republican of Ohio, commented that "If this profound research should reveal that the baby monkey detests or has no affection for its mother, I'm wondering how many millions more will have to be spent in psychiatric treatment for the baby monkey." Extensive coverage of this particular item is in sharp contrast to the space given to a comment by Editor Graham Dushane(6) of *Science*, the official publication of the American Association for the Advancement of Science, in which he said,

Comparative Research teaches us much that we can learn in no other way . . . subhuman primates, as the Congressmen should know, offer unusual advantages for research. Interesting in their own right and fully worthy of scientific investigation, they occupy the unique position of being the animals most similar to men in physiology and in mental capacity.

¹ A modified version of the paper was presented as the Academic Lecture, Mississippi Psychiat. Assoc., April, 1962, Jackson, Miss.

² Formerly, Medical Director, American Psychiatric Association, Washington, D. C.

Their bodies and brains are far more like ours than are those of any other animals. Hence, they react to physical stresses, to disease, to psychic disturbances, in much the same way that we do. It was not caprice that led us to use a chimpanzee for our first sub-orbital test shots. The brilliant achievement of Colonel Glenn last week owes something to what was learned from Ham's flight. Prior to the work of Professor Harlow and others, hunger, thirst, pain and so on were thought to be the primary motivations of behavior. Harlow has shown us experimentally that monkeys have—as had long been suspected from man—motivations not reducible to those primary ones: drives to explore, to manipulate, to see, to hear, and to experience affection. Furthermore, his work has had an effect on learning theory: monkeys learn how to learn; they have an accretion of learning. To give another example, monkeys reared in isolation are emotionally crippled; those brought up by artificial "substitute mothers" seem for a time to be normal, but when adult they are unable to act like mothers toward their offspring. Monkeys have still another advantage as research subject. They can be studied throughout their lives—they grow up in two to three years—and can be kept in a controlled environment and subjected to planned experiments. Studies of this kind provide new insights into human behavior that could be obtained in no other way. Would the Congressmen suggest that we carry out such studies on human beings? Or do they perhaps think it unimportant to try to understand behavior? Dangerous to study motivation?

Or if we had read the *Harper's Magazine* piece by the president of the Markle Foundation, John M. Russell(15), "Medical Research: Choked by Dollars," we would have found another means of correcting the Congressional image:

Twenty years ago, for example, Hodgkin and Huxley made a study of that lowly, ugly beast of the sea—the squid—which led eventually to a better understanding of heart disease. Neither of these men was particularly interested in the heart, yet their work on the nerve fiber of the squid has cast light on what takes place when the heart beat is recorded in an electrocardiogram. For fifty years Newton Harvey conducted a world-wide search for and study of fireflies and glowworms. His work on fluorescence has resulted in better knowledge of cells and how they grow nor-

mally and abnormally and may one day provide the vital clue to understanding cancer. Fleming's work with molds led to the discovery of penicillin—which has done more to prevent mental retardation than any single development in modern medicine through its successful use in the treatment and prevention of congenital syphilis. Certainly no layman would associate studies of squid, fireflies, and molds with heart disease, cancer, and mental health. And yet this type of study is the foundation upon which all other research rests. If we, the public, forget this fact and in our impatience fail to do our share to support it, we endanger the whole research structure and hence delay the development of the medical cures we so hopefully pray for.

Therein perhaps lie some clues as to how we can approach the public with the necessity for the support of research.

And yet our own psychiatric research people are not always favorably impressed with their own work. A glimpse into Colin M. Smith's(16), "The Unscientific Basis of Psychiatry" is perhaps revealing:

It would seem odd that psychiatrists, who are themselves so familiar with the manifestations of wish-fulfillment, should fall victims to it, yet it is difficult to believe that this had not happened when we reflect on the history of many psychiatric treatments. Even our most successful treatment—shock therapy—can scarcely be said to have had the systematic, controlled and thorough investigation which its importance merits, while the results of evaluation of psychotherapy have sometimes been surprising.

The author cites a study which revealed that

only four out of 36 American and 16 out of 36 British papers had used controls . . . it would not, perhaps, be going too far to say that the road to hell is paved with no controls . . . psychiatry is in danger of becoming a foetid quagmire of anecdotalism. In this respect, it is not so very different from other branches of medicine; other specialties, however, have the enormous advantage of having objective tests which can serve as a final court of appeal. These were lacking, by and large, a century ago when the field of clinical medicine was just as full of vague, arbitrary, and dogmatic decisions as in Psychiatry today.

While we are on this subject of psychiatric research, I would direct your at-

tention to an item by Earl Ubell(17), the science editor of the *New York Herald Tribune* :

... a study of neurotics conducted at the University of Leeds, England ... served as both a shock and reminder of how tenuous is the evidence on which theory and practice of psychology and psychiatry rest. The investigation revealed that neurotics—those patients with relatively mild mental disturbances—could get better without any treatment at an amazing rate. Two-thirds of the untreated patients recovered or improved within three years.

Such a rate of recovery is almost identical to that reported by psychiatrists and psychologists who have treated patients by a technique known as psychotherapy. In case a treatment gives the same result as no-treatment, one would find it quite difficult to say, on scientific grounds, that the treatment was effective.

Of course, the issue is not quite so simple. In the first place there are many different forms of psychotherapy. From that administered to a patient lying on a couch and spewing out his dreams, thoughts and actions to give a Freudian analyst clues to his deep, unconscious motivations, psychotherapy ranges to the kind of guidance that a social worker gives a distressed client in a face-to-face interview.

If we turn for the moment to the public's attitude toward hospitals in general, we find that a study(8) "The Public Looks At Hospitals" conducted under the auspices of the National Opinion Research Center of the University of Chicago says :

that the bulk of the American public now holds positive attitudes toward hospitals (that is to say, non-psychiatric hospitals). There is almost no evidence of the fears that once existed. The public's widespread satisfaction with hospitals and its confidence in them is mirrored in its evaluation of local hospital facilities and of its own hospital experiences. While people are critical of the cost of hospitalization, and a significant minority is critical of local hospital facilities and of some aspects of hospital experience, these reactions seem to be mild. Few people are downright eager to be hospitalized and many may be reluctant to be, but few are so strongly motivated that they refuse hospitalization. Little seems to remain of the old stereotype of the hospital as a place from which no one returns.

Contrast that, however, with the statement(16) :

Mental hospitals have been, and often unfortunately still are, appalling places. It is ridiculous that in a society such as ours such conditions should exist today. They must cease, and mental hospitals must become first-rate hospitals. When this happens an ugly dichotomy in our profession may disappear. I refer to the fact that we are now developing two classes in our profession : the general hospital psychiatrist and the mental hospital psychiatrist. When some years ago I asked a very bright, experienced and well qualified general hospital psychiatrist why he had never entered a mental hospital, he replied, "I feel I'm working at the coalface of psychiatry here." To my mind there can be no question of working at the coalface of psychiatry anywhere until we find some coal, and that is at least as likely to happen in the mental hospital as in the general one.

Private psychiatric hospitals do not escape scathing criticism :

Beyond their avowed purposes, public and private institutions have little in common. The responsibility of the private hospital ceases when the patient or his family is unable to pay the bill. After a patient's financial resources are exhausted, in practically all cases, he is discharged or transferred to a public hospital. Pay or get out is the rule.

One private psychiatric hospital observer (4) says,

The private psychiatric hospital has been looked on as providing essentially individual medical services for a small, selected group on the basis of financial ability, and thus beyond the financial capacity of the average citizen. Hostility, envy, and isolation, become the accompaniments.

The private psychiatric hospital setting has been described by a research team at Yale (10) :

The patients are accommodated in physical settings which appear to range from luxurious cottages on skillfully landscaped country estates to dismal, decaying old mansions that are almost as poorly maintained as the state hospital.

There is no point in belaboring this negative image of the psychiatric hospital and

I would turn to the critic-at-large column by Brooks Atkinson(2) written in the *New York Times*, February 23rd, 1962 :

For even a private hospital is a public institution of a unique kind. Although it is ignored by people as long as they are in good health, it becomes an intimate part of their lives when they or members of the family need it. If the personality of the hospital is callous, their misery is compounded by many intangible evasions ; and every patient becomes an island of despair in a sea of loneliness.

How different is this from the comments by Dana Farnsworth(7) at the 1960 Mental Hospital Institute :

Few of the personnel in mental hospitals seem to feel that parents or other relatives matter. Others that are not relatives but do have a legitimate concern for the patient's welfare are also passed around from person to person. Friendliness is of little moment, even in situations in which patients are not involved. Some doctors are so preoccupied with the dynamics of the patient's illnesses that they have little time for the small amenities and common courtesies that mean so much to patients and relatives. Patients are tossed back and forth between therapists and administrators. There is little evidence of humanity, love, or personal concern for patients. Patients are not aware of what they may reasonably expect in hospitals. Conditions in admitting rooms are depressing. Referring physicians are so seldom given reports of their patients' progress. Patients are shorn of their personal dignity as well as most of their possessions when admitted to a mental hospital. Most doctors are courteous but other staff members often give one quite a hard time.

Farnsworth went on to say that his initial reaction to these criticisms was that they were unfair. That he could not avoid the stubborn fact that many persons believe these and even worse things about mental hospitals. What was even more embarrassing to him was that in many state hospitals these and even worse conditions do exist, and that in the very best hospitals some of these conditions exist for at least part of the time.

And now a word or two about our patients. How do they cast their image ?

You are about to see the most shameful, the most wasteful, thing in the country today. People who are sick and miserable just live to vegetate. Partly no one knows what to do for them. Mostly, nobody is even trying. They lie on the floor or they sit. They don't do much else. Most of them don't even have shoes to wear, and many of them haven't been outdoors in years. Maybe it's not too late for some of them. Maybe we can help. But remember this : they are human beings, just like you and me. They have their hopes, aspirations, their fears. They are not monsters. They have their problems, just as you and I have, only theirs are magnified.

You'll see them now. You will smell the foul air they must breathe all day. You will see the rotten chairs they use and the rags they wear. As citizens of this country, I want you to know that I hold each one of you personally responsible for this thing(13).

These are the words of a college student who has been working as a volunteer attendant in a mental hospital. And he used these words to introduce other student volunteers to the back wards of a state mental hospital.

Perhaps a letter from a patient in one of America's oldest and most respected hospitals tells us more eloquently than any, how psychiatric patients see us and themselves(14) :

Psychiatry is mediocre or poor because the doctors are overburdened. Rehabilitation and research hardly manage to crawl at snail's pace. Room and board and diversions have improved but the alleviation of human misery, particularly of mind, heart and spirit, shows no appreciable gains. Daily environment and routine after a year causes each day to seem the same, regardless of any diversions. Time seems to stand still, drag interminably, or take flight. Either way, it causes a feeling of irretrievable loss. One realizes he is aging, and the older he becomes while in the institution the more difficult, if not impossible, it will be if he is fortunate enough to obtain release, to secure a livelihood and adjust to the rapidly changing times of a critical era in our country's history. Many patients have to stay in a mental hospital for the remainder of their lives because they are outcasts, rejected, poor, aged, forsaken and forgotten and without any means or kin whatever.

One sees an elderly patient drop dead upon the floor amid the stench and din of a roach

ridden ward, or die gradually after weeks, months or years of debilitating ailments, and one can't help asking himself, "Will that be me?" In the dead or dying patient, he sees himself after the passage of several years or decades.

I am ugly, of meager education, poor voice, no home, wife and family, rejected by kin, have little money, no livelihood, no freedom and independence, no normal life. I am nothing, except in the eyes of God. I must make do with what I have—an able mind and the knowledge of suffering. What I can do to help others and bring happiness I do, and I consider myself rich.

I can see that my bleak plight here is rendering my efforts futile, daily my lot becomes more lonely and desperate. I can only hope my suffering will not be in vain—but will mean courage, solace, help and hope for others. The bitter cry of anguish you hear is not mine alone, but that of all who are stranded and abandoned.

The Joint Commission on Mental Illness and Health in its final report, *Action for Mental Health*(1) tells us about public attitudes toward the mentally ill :

One reason the public does not react desirably is that the mentally ill lack appeal. They eventually become a nuisance to other people and are generally treated as such. In contrast, it is the special view of the mental health worker that people should understand and accept the mentally ill and do something about their plight. People do seem to feel sorry for them ; but in the balance, they do not feel as sorry as they do relieved to have out of the way persons whose behavior disturbs and offends them.

While there are some who feel that there is less rejection of the mentally ill and the mentally defective than formerly, we cannot but heed Rene Dubos(5) writing in his *Mirage of Health* :

Like all quantitative statements pertaining to human affairs . . . enumeration of disturbed persons in psychiatric beds gives but a distorted impression of the change in the incidence of mental diseases in modern times—The village fool who used to be an accepted member of any rural setting, the semi-senile oldster who was expected to spend his last years rocking on the porch of the family homestead, and even the timid soul who escaped competition by retiring into a sheltered home atmosphere are likely now to become

inmates of mental institutions because they cannot find a safe place in the crowded high-pressure environment of modern life. Thus, the problem of our time may be less an actual increase in the numbers of mental defectives than a decrease in the tolerance of society for them.

And as I bring my remarks to a close, I present you with a young psychiatrist's view of his profession(3) :

Ideas need the backing of institutions and firm social approval if they are to result in practical application. Yet I see pharisaic temples being built everywhere in psychiatry ; pick up our journals and you will see meetings listed almost every week of the year and pages filled with the abstracts of papers presented at them. These demand precious time in attendance and reading, and such time is squandered all too readily these days. Who of us, even scanting sleep, can keep up with this monthly tidal wave of minute repetitive studies? And who among us doesn't smile or shrug as he skims the pages, and suddenly leap with hunger at the lonely monograph that really says something? As psychiatrists we need to be in touch not only with out patients but with the entire range of human activity. We need time to see a play or read a poem, yet daily we sit tied to our chairs, listening and talking for hours on end. While this is surely a problem for all professions, it is particularly deadening for one which deals so intimately with people and which requires that its members themselves be alive and alert.

It seems to me that psychiatric institutions and societies too soon become bureaucracies, emphasizing form, detail, and compliance. They also breed the idea that legislation or grants of money for expansion of laboratories and buildings will provide answers where true knowledge is lacking. Whereas we desperately need more money for facilities and training for treatment programs, there can be a vicious circle of more dollars for more specialized projects producing more articles about less and less, and it may be that some projects are contrived to attract money and expand institutions rather than to form any spontaneous intellectual drive. We argue longer and harder about incidentals, such as whether our patients sit up or lie down ; whether we should accept or reject their gifts or answer their letters, how our offices should be decorated ; or how we should talk to patients when they arrive or leave. We debate

for hours about the difference between psychoanalysis and psychotherapy; about the advantages of seeing a person twice a week or three times a week, about whether we should give medications to people, and if so, in what way. For the plain fact is that as we draw near the bureaucratic and the institutionalized, we draw near quibbling. Maybe it is too late, and much of this cannot be stopped. But it may be pleasantly nostalgic, if not instructive, to recall Darwin sailing on the *Beagle*, or Freud writing spirited letters of discovery to a close friend, of Sir Alexander Fleming stumbling upon a mold of penicillin in his laboratory—all in so simple and creative a fashion, and all with so little red tape and money.

But is this young man hopeless, and has he an answer for us? I quote:

We cannot solve many problems, and there are the world and the stars to dwarf us and give us some humor about ourselves. But we can hope that, with some of the feeling of what Martin Buber calls "I-Thou" quietly and lovingly nurtured in some of our patients, there may be more friendliness about us. This would be no small happening, and it is for this that we must work. Alert against dryness and the stale, smiling with others and occasionally at ourselves, we can read and study; but maybe wince, shout, cry, and love, too. Really, there is much less to say than to affirm by living. I would hope that we would dare to accept ourselves fully and offer ourselves freely to a quizzical and apprehensive time and to uneasy and restless people.

So often it seems to me that psychiatry's images reflect a rigidity and a clinging to the *status quo* that I wonder if the time will ever come when we will trust ourselves enough to place our trust in others as well.

As a member of the Joint Commission on Mental Illness and Health I find myself in thorough agreement with the sentiment that we must rise above our self-preservative functions as members of different professions, social classes, and economic philosophies and illuminate the means of working together out of mutual respect for our fellow man. Can anyone quarrel with the notion that we each have a responsibility that is common to all—our responsibility as citizens of a democratic nation founded out of faith in the uniqueness, integrity and dignity of human life?

I will conclude as I began by quoting Alan Gregg(9) at the the centenary meeting of the American Psychiatric Association:

Yours has been a long struggle waged with patient heroism, none the less admirable for being at times perhaps despondent and bewildered. Nor is it as yet a battle fully won. So-called mental diseases are still regarded by mankind with fear, aversion and ostracism, and society still pays the inexorable penalties of him who fights and runs away, and so might fight another day.

OBSERVATIONS ON THE NATURAL HISTORY OF HYSTERIA

SAMUEL B. GUZE, M.D., AND MICHAEL J. PERLEY, M.D.¹

Among the most pressing problems in psychiatry is the need to establish valid and generally accepted diagnostic categories. As stated in a recent GAP report, "The problem is not merely the establishment of clearer definitions of diagnostic entities and their communication to psychiatrists and other physicians, but it also involves agreement upon a nomenclature which will be maintained without change over a prolonged period"(1). Grinker and his colleagues(2) have recently discussed this question, particularly as it applies to depressions, from essentially the same point of view. Ultimately, psychiatrists and other physicians will accept and maintain diagnostic categories if their validity has been established.

A diagnosis may be looked upon as a prediction. It may predict which etiologic factors will be found causing the disorder; it may predict what will be found when the pathogenesis and pathologic processes underlying the symptoms are studied; it may predict what will be the prognosis of the disorder under various conditions of treatment or lack of it; and it may predict what kinds of disorders will be found in the close relatives of the patients with a particular disorder.

At the present time, for most psychiatric illnesses, little is known about etiology and pathogenesis so that the validity of a diagnostic category generally depends upon demonstrating that patients with a particular diagnosis have a fairly uniform course (in response to treatment or the lack of it) or that certain characteristic disorders will be found in their close relatives.

We have been interested in studying hysteria in order to establish diagnostic criteria that will meet such standards of validity. Turning to the literature, it is apparent that a major source of difficulty is caused by a semantic issue. Some authors(3-7) use the terms hysteria and conversion reaction in-

terchangeably to refer only to individual symptoms that may be seen in a wide variety of disorders. These authors emphasize the varied clinical pictures seen in patients who present conversion symptoms, and one investigator(7) even suggests that perhaps the term hysteria be dropped because hysterical symptoms may be seen in so many different conditions. Other authors use the term hysteria(8-10) to refer to a distinct syndrome with characteristic symptoms and suggest that hysteria is a valid, recognizable, clinical entity.

In attempting to clarify the issue, we have found it useful to retain both terms, conversion reaction and hysteria, but to assign separate meanings to each. We prefer to use the term conversion reaction (or symptom) in a solely descriptive manner to refer to a category of symptoms which usually includes unexplained blindness, diplopia, aphonia, urinary retention, paralyses, anesthesia, unsteady gait, fits, trances, amnesia, etc. This list is not exhaustive but includes the most striking examples of this group of symptoms. Unexplained in this context means that clinical examinations, x-rays and laboratory tests are all normal.

Conversion symptoms may be seen in hysteria. By hysteria we mean a *syndrome* described initially in 1849 by Briquet(8), characterized again in 1909 by Savill(9), and more recently redefined in a controlled study by Purtell, *et al.*(10), in 1951. These investigators delineated a clinical picture which starts early in life; occurs primarily, if not exclusively, in women; and is characterized by recurrent symptoms in many different organ systems. Included in the clinical history of such patients are: dramatically described symptoms, many and varied pains, menstrual disorders, sexual maladjustment, headaches, anxiety symptoms, frequent conversion reactions, excessive hospitalizations and excessive operations. A histrionic manner or attention-getting and manipulative behavior are common in this disorder though the diagnosis is not based, in the absence of the medical history,

¹ Dept. of Psychiatry and Neurology, Washington University School of Medicine, St. Louis, Mo.

primarily upon the personality characteristics. Hysteria, as here defined, is a syndrome with a number of characteristic features, of which conversion symptoms are only one important part.

Accepting the usefulness of this differentiation between conversion reaction and hysteria, we have been engaged in a series of studies designed to clarify the nature of hysteria in terms of its diagnostic criteria, natural history, prognosis, and response to treatment.

A recent report from this department(11) described a follow-up study of a group of patients who were diagnosed as suffering from hysteria as defined above. The records of all patients seen in one section of the psychiatry clinic during an 18-month period were reviewed. There were 46 patients in whom the diagnosis of hysteria had been made or seriously suspected. Of this number, 39 (85%) were found and interviewed 6 to 8 years later. One patient had died, 1 patient refused to grant an interview, 3 patients had moved to distant states, and 2 patients could not be located. Each patient's record was re-evaluated and re-diagnosed in terms of how well the clinical pictures conformed to the detailed diagnostic criteria for hysteria enumerated in the previous report. In general, the criteria provided for including patients with a very varied, polysymptomatic disorder including multiple pains, menstrual difficulty, sexual problems, conversion symptoms, *etc.*

At the time of follow-up, the patients were studied by means of a structured, detailed psychiatric interview. The criteria for the follow-up diagnosis as well as the characteristics of the interview are described in the previous report. The follow-up interview was conducted without knowledge of any specific information of the past history except that the patient had experienced an illness for which the diagnosis of hysteria had been made or suspected. The purpose of the follow-up interview was to make a psychiatric diagnosis, where possible, based upon the entire history available from the patient at the time of follow-up without regard for the information available in the old clinic record. Specifically, the question asked was: if the diagnosis of hysteria is based upon certain specified criteria, will

the same diagnosis be apparent at follow-up or will some other illness be evident which might account for the symptoms present at the initial examination?

The results showed that when the diagnosis of hysteria is based upon the presence of the clinical picture already described, there is a 90% probability that the same diagnosis will be applicable 6 to 8 years later and that no other disorder will have become manifest to explain part or all of the original symptoms. Further, the results indicated that when the diagnosis of hysteria is rejected because of failure to fulfill the defined criteria, other illnesses that can explain some or all of the original complaints will become apparent in a significant portion of the cases. It was concluded, therefore, that hysteria, as here defined, is a distinct recognizable syndrome, which is very similar in its manifestations from patient to patient and which can be recognized by ordinary clinical examination. This uniformity of clinical picture is in striking contrast to the very varied clinical pictures seen when the term hysteria is used as a synonym for conversion reaction(3-7).

The previous report(11), as already noted, was concerned primarily with the follow-up diagnosis. This follow-up diagnosis was based upon the entire medical and psychiatric history obtained from the patient only at follow-up. In this paper the clinical course of patients with hysteria during the 6- to 8-year period following the initial diagnosis will be reviewed. In particular, what happens to the characteristic features of this illness after the diagnosis has been made will be described. Such information may enlarge our knowledge of the natural history of hysteria and contribute to attempts to establish valid criteria for its diagnosis. It is important to know, for example, whether hysteria is a disorder with exacerbations and remissions or whether it is a chronic, non-remitting condition.

In the previous study(11) 25 patients, all women, were found who fulfilled the diagnostic criteria in terms of the original clinical picture as well as at follow-up. The clinical course of these 25 patients will furnish the material for this report. Their records were reviewed and only relevant clin-

ical features that occurred subsequent to the initial psychiatric evaluation were noted, regardless of whether such features were present or absent at the initial examination.

The clinical manifestations that are most characteristic of the disorder were reviewed. They included continued medical consultation, hospitalizations, headaches, abdominal and other pains, vomiting, menstrual disorders, sexual and marital difficulties, conversion symptoms, suicide attempts, and overall state of health. In addition, experiences with EST and psychotherapy were noted.

Medical Care. Twenty-three or 92% of the sample continued to consult physicians during the period of follow-up. Furthermore, 5 women or 20% consulted osteopaths and 10 or 40% consulted chiropractors. We do not have complete data concerning frequency of consultation for all the women but, in general, these patients saw many physicians repeatedly during the 6-8 years.

Hospitalizations. Of the 25 women, only 5 or 20% had not been hospitalized at all during these years. Thus 20 women or 80% were hospitalized for some condition (other than normal pregnancy). Fourteen women, 56%, had been hospitalized 27 times in a general hospital for non-surgical conditions exclusive of normal deliveries. Twelve women, 48%, had been hospitalized 21 times for an operation. Four women, 16%, had been hospitalized 5 times in a psychiatric hospital. There were, thus, 53 hospitalizations for the 25 women for a rate of 2.1 hospitalizations per patient for the 6-8 years of follow-up. Three of the 4 women who had been hospitalized in mental hospitals had also been hospitalized in general hospitals for both surgical and non-surgical conditions. These 3 women had had 5 surgical hospitalizations and 5 non-surgical hospitalizations. The fourth woman who had been hospitalized in a psychiatric hospital had not had other hospitalizations during these years.

Headache, Abdominal and Other Pains, and Vomiting. These symptoms were scored as positive only if the patient reported that they led to consulting a physician, required medication, or were disabling to the extent that they interfered with normal ac-

tivities. Fourteen or 56% of the patients suffered from headaches, 18 or 72% from abdominal pains, 16 or 64% from back pains, and 18 or 72% from other pains such as joint pain, extremity pain or chest pain. Six or 24% of the patients suffered from vomiting spells. Twenty-two or 88% complained of some pain other than headache, 19 or 76% complained of two or more pains other than headache, and 12 or 48% complained of 3 or more pains other than headache. There were only 2 patients or 8% who denied headaches, other pains and vomiting during these years.

Menstrual Symptoms. Of the 20 women who were not post-menopausal during the entire follow-up period, 16 or 80% complained of menstrual difficulty, chiefly dysmenorrhea with some menstrual irregularity and some excessive bleeding.

Sexual and Marital Adjustment. Three of the women were divorced or separated at the time of the initial psychiatric study and remained in this status throughout the period of follow-up. An additional woman became a widow early in the course of the follow-up period. These 4 women denied having sexual relations during these years. Of the remaining 21 women, 16 complained of sexual indifference and frigidity (11 women) or dyspareunia (9 women). Thus 76% of the women who were experiencing regular sexual relations reported sexual maladjustment.

This sexual difficulty was associated with a high percentage of marital discord. As already noted, 3 women were already divorced or separated at the time of initial evaluation. Ten of the remaining 22 reported considerable marital difficulty during the follow-up period leading to divorce in 5 women (2 women had 2 divorces each) and separation in an additional 2 women. Thus 7 of 22 women (31%) reported marital trouble leading to divorce or separation subsequent to the initial evaluation; and 10 of 25 (40%) were or had been divorced or separated at the time of follow-up.

Conversion Symptoms. Twelve women (48%) reported one or more conversion symptoms during this period; 5 women (25%) reported more than one. There were 16 conversion symptoms reported including diplopia once, aphonia 5 times, blindness 5

times, paralysis once, anesthesia once, and "blackout" spells or "fits" 3 times.

Suicide Attempts. Only 1 woman reported a suicide attempt during this period.

Freedom from Symptoms. Only 1 patient regarded herself as well at the time of follow-up; she claimed to have been well for several years. Her story is difficult to evaluate, however, in view of her repeated unwillingness to cooperate with the study. She was married to her third husband and did not want him to know about her previous marriages. She also apparently did not want him to know about her previous psychiatric difficulties. Her behavior indicated a desire to rush through the interview as rapidly as possible so as to be rid of the interviewer.

Two other patients reported that they were much better than they had been but a detailed inquiry indicated that they were still not symptom-free. It is noteworthy, however, that these 2 patients reported no hospitalizations during this period which supported their statements of feeling better.

The remaining 22 patients continued to be sick without significant change. Their histories indicated that they had not had a symptom-free year during the period of follow-up.

Electroshock Treatments. Two women had received EST during each of 3 psychiatric hospitalizations. These women reported that the EST helped with some of their symptoms only, chiefly depressed feelings and crying spells. It was not possible to evaluate the duration and degree of improvement since the EST had been administered several years before in each case.

Psychotherapy. Only 5 patients were seen in psychotherapeutic interviews more than a few times. Four patients pursued psychotherapeutic efforts for several months and 1 patient for about a year. While all 25 women had been offered psychiatric treatment, few of them accepted its validity and they nearly always discontinued the visits because they believed them to be unnecessary or ineffective.

DISCUSSION

It is apparent that repeated consulting of physicians; repeated hospitalizations and operations; persistent headaches, abdomi-

nal pains, back pains, other pains, and vomiting spells; continuing menstrual disorders and sexual maladjustments; further conversion symptoms; and limited, if any, acceptance of a psychiatric explanation for their symptoms characterized the 6- to 8-year period of these women between their initial psychiatric evaluation and diagnosis and their follow-up evaluation and diagnosis. That is to say, these women continued to experience the typical symptoms of the illness, essentially without remission in all but one case, following the establishment of the psychiatric diagnosis.

These women had been sick for many years: 9 or 36% reported that their illness began before age 20, 20 or 80% were sick before age 26, and only 2 or 8% reported the onset of their illness after age 30. The mean age of these women at the time of the initial psychiatric evaluation was between 40 and 41. Their mean age at the time of follow-up was just under 48. It is thus apparent that this disorder had been present for a long time when they were psychiatrically evaluated initially, and that at the time of follow-up, the mean duration of illness was well over 20 years, while for about a third of the women, the illness had been present for over 30 years by the time of the follow-up interview. There was no indication that these women, with the single exception described above, had ever had a complete remission of their illnesses which lasted as long as one year.

When we combine the findings from the previous study(11) and the results of this investigation the following may be concluded. The clinical picture of hysteria described by the previous authors(8-10) is a recognizable syndrome that may be diagnosed by any physician familiar with the diagnostic criteria. It characteristically is seen in females. It begins early in life—usually before age 20 and nearly always before age 30. It is not a monosymptomatic disorder but rather presents with multiple symptoms in many different organ systems. Among its most striking features are excessive hospitalizations, excessive surgery, many and varied pains, menstrual and sexual problems, conversion symptoms and a long history of ill health. This syndrome runs a chronic course of many years dura-

tion without appreciable remissions. The characteristic, diagnostic symptoms continue to beset the affected patients even after many years of illness. (One patient's illness had begun in her teens and at the time of follow-up, she was 65 and still suffering from the characteristic symptoms.) Even after psychiatric referral, consultation and diagnosis, these patients continue to consult other physicians for the same complaints and continue to be hospitalized and operated upon frequently. Very few of them appear interested in psychotherapy, and most reject a psychiatric approach to their complaints. In fact, refusal to accept a psychiatric approach to their condition appears to be characteristic of the patients with this disorder. Patients who receive a diagnosis of hysteria according to these criteria do not turn out to have other illnesses—psychiatric, neurologic, or medical—that might account for their characteristic symptoms.

The marked variability in clinical picture and prognosis seen when conversion symptoms are taken as the starting point in an investigation, when contrasted to the results of our studies with hysteria, testifies to the usefulness of distinguishing between hysteria, as here defined, a syndrome with a characteristic clinical picture and prognosis and conversion reactions which may be part of the clinical picture of many different disorders.

Our own studies (12) and clinical observations confirm the experience of others that patients with conversion reactions may turn out to have any of a wide range of disorders. We and others have seen such conversion symptoms in the following disorders in addition to hysteria: schizophrenia, sociopathy, drug addiction, alcoholism, drug reactions, dementia, and in patients who are later found to have multiple sclerosis, hyperparathyroidism, porphyria, brain tumor, leukemia, *etc.*

The fact that a follow-up of patients with hysteria did not reveal such a varied outcome and that other disorders that might have caused the original symptoms were not found suggests that there is considerable "practical" value in these diagnostic criteria. Increased precision of diagnosis, in addition to such immediate clinical use-

fulness, should permit resolution of a number of conflicting points of view in the literature. For example, the question as to whether or not hysteria may be seen in males (13) may simply be a matter of definition: hysteria, as here defined, rarely if ever is seen in males, whereas men may certainly suffer from any of the other disorders in which conversion symptoms are seen, such as compensation neurosis, schizophrenia, sociopathy, *etc.*

These studies, then, represent early steps in the process of clarifying this clinical disorder. The diagnostic criteria require further analysis to make them more precise and free from ambiguity. More detailed prospective studies of cohorts of patients diagnosed as suffering from hysteria need to be carried out to verify these results. We are presently in the midst of such a long-term follow-up. Furthermore, we are studying the close relatives of patients with hysteria, looking for the presence of various psychiatric illnesses.

SUMMARY

This study, based upon a 6- to 8-year follow-up of 25 patients, who were diagnosed as suffering from hysteria originally, and again at follow-up, resulted in the following conclusions: 1. Hysteria, as here defined, is a distinct, recognizable syndrome which is very similar in its clinical features from patient to patient; 2. Hysteria is a chronic illness which lasts many years and which is nearly always free from significant remissions; 3. Hysteria is a multisymptomatic syndrome which can and should be distinguished from conversion reactions, which are individual symptoms found in many disorders in addition to hysteria.

ADDICTIVE ASPECTS IN HEAVY CIGARETTE SMOKING¹

PETER H. KNAPP, M.D., CHARLES MICHAEL BLISS, B.A.,
AND HARRIET WELLS, B.A.²

Tobacco consumption, known to civilized man for less than 500 years, has increased dramatically. In the United States alone during the past half century, annual production has leaped from 8.6 to 355 billion cigarettes, a thirty-fold increase *per capita* (19). It has grown, one might say, like a weed. So has the debate about its essential nature—whether it is virtue or vice, blessing or curse, soothing remedy or addictive drug. The encyclopedic review of Larson, Haag, and Silvette investigates the expanding mass of scientific evidence bearing on tobacco in general, as well as the particular controversy about its addictive properties (20).

In part, the latter centers around definition. Tobacco does not invariably lead to progressive physical dependence. Many workers, however (16, 17), argue for a definition of addiction which goes beyond that single characteristic like the one established by the WHO. In brief, this includes: 1. "A state of periodic or chronic intoxication detrimental to the individual and to society produced by repeated consumption of a drug"; 2. "A compulsion to continue taking the drug"; 3. "A tendency to increase the dose"; and 4. "A psychic and sometimes physical dependence on the effects of the drug." So defined, the tobacco "habit" in certain individuals does appear to attain the status of an addiction.³

Nicotine is an active agent (though not

necessarily the only noxious agent in tobacco); it appears to have certain addictive qualities. Tolerance develops to some of its effects—such as nausea, so that it can be consumed in ever greater amounts—but not to other effects, particularly those in the cardiovascular sphere (1, 23, 27, 28, 30, 31, 33). The cardiovascular evidence consistently shows that roughly 20 minutes after smoking, a gradual sympathetic-like constriction of the peripheral vascular bed and acceleration of heart rate develops, then subsides. These effects can be duplicated by parenteral administration of nicotine, not, according to most workers, by sham smoking or by smoking of de-nicotinized preparations.

Some evidence (14) suggests that repeated injections of nicotine can lead to an addictive state. Substitution of low nicotine cigarettes for their regular brand in a prolonged experiment conducted by Finnegin, Larson, and Haag (7) led to clear distress in some subjects, though not in all. Interpersonal variations, suggested by the latter experiment, are of great importance in assessing tobacco usage as a whole. Differences exist in total amount smoked and in whether or not smoking is accompanied by inhalation, which is estimated to increase the nicotine absorption by a factor of 2 or 3. However, among heavy smokers, who have more trouble giving up cigarettes than do light smokers (25), withdrawal effects can be marked. Irritability, sleep disturbance, impaired concentration and memory, anxiety, restlessness and intense craving for tobacco, particularly experienced in the oral and respiratory tracts, as well as distorted time perception have been described (20). Accompanying these symptoms are reported signs of gastro-intestinal instability, profuse sweating, and particularly cardiovascular manifestations, chiefly a fall in pulse rate, by Head (12), Hansel (11), and Larson, *et al.* (20). Our own attention was drawn to these particular effects by personal experience. One of us, formerly a

³ For semantic reasons, other authors would still insist on speaking of "addiction and/or habituation."

heavy smoker, stopped abruptly and noted a drop in pulse from the low 70's to the high 40's in the ensuing 2-day period.

Thus considerable evidence suggests that true physical dependence may develop to tobacco. We undertook to study this by observing a group of heavy cigarette smokers during an imposed state of withdrawal. Our hypothesis was that we would find cardiovascular manifestations which were, broadly speaking, vagotonic. Our exploratory aim was to see whether such physiologic features might fit with other patterns, acute or chronic, suggesting addictive behavior.

METHOD

Two experiments were carried out. Heavy cigarette smokers were defined as individuals smoking more than 2 packages a day for at least 5 years, and inhaling. All subjects were male. They ranged in age from 18 to 54 years. They were screened to exclude hypertension or other gross cardiovascular or medical illness.

The first experiment used 26 paid volunteers from the State Unemployment rolls. They were observed in 5 groups in successive weeks. Each group was under observation for 10 hours a day during a continuous 5-day period. Two of these groups (11 subjects) were controls, allowed to smoke *ad libitum* throughout the 5-day period. Three groups (15 subjects) were asked suddenly to stop smoking for the last 3 days of observation. Pulse rates were taken 6 times daily and blood pressure readings 3 times daily during each 10-hour interval. The experimenters also gave each subject a daily battery of psychomotor tests,⁴ a self-rating mood questionnaire, interviewed them semiformally at the time of testing, and conversed with them informally throughout the test week.

A second experiment was carried out to replicate the cardiovascular findings obtained in the first experiment and to differentiate between withdrawal of nicotine per se and other aspects of the experimental situation. Subjects in this subsequent experi-

ment were 17 unpaid volunteers from the open Neuropsychiatric Service of the Boston VA Hospital. They were studied less intensively, without psychologic testing, the primary focus being on repeated pulse and blood pressure determinations. They were comparable to the earlier subjects in age, socio-economic class, and marital status; none was receiving psychotropic drugs. During 5 continuous days, they were allowed to smoke 2 sets of cigarettes identical in appearance. These had high and low nicotine content respectively (1.75 mg. as against 0.4 mg. in main stream smoke). Roughly one third of the subjects served as controls and smoked high nicotine cigarettes throughout the week. Two thirds smoked low nicotine cigarettes which were substituted, without the subjects' knowledge, at two different intervals during the week.

Subjects were urged to talk freely about any lapses and assured that they would not be punished for them. Five subjects, who had agreed to stop, admitted that during the nights, while away from continuous observation, they had smoked a few cigarettes, the number varying from ½ to 12. Four others reported occasional nocturnal "drugs." Morale and cooperation appeared excellent; strong internal evidence thus suggested that their accounts were accurate. Any lapses, it should be noted, would make our initial hypothesis (of finding abstinence effects) less likely, not more likely, to be confirmed.

RESULTS

1. *Cardiovascular.* In the first experiment control and experimental subjects showed no significant differences (by "t" test) at the start of the study, on so-called "basal" days, but there was a striking difference between the two groups on the last 3, or "test," days. The mean pulse rate actually rose in the control subjects during the "test" period whereas it showed a perceptible drop in the experimental subjects. At times this was dramatic, nearly 20 beats per minute. Both diastolic and systolic pressures dropped slightly in the controls, and more markedly in the experimental subjects.

Paired data analysis, comparing the differences between each group's levels for

ated at highly significant levels with respect to pulse data ($p < .001$), at significant levels with respect to diastolic blood pressure ($p = .02-.01$), and show a strong trend in the same direction with respect to systolic blood pressure ($p = .1-.05$).

The 17 subjects in the second experiment also were statistically indistinguishable on "basal" days in which they all smoked *ad libitum*. Paired data analysis was carried out as before. The experimental subjects, on "test" or "low nicotine" days, showed a slowing of pulse rates which significantly differentiated them from the controls. Again, despite more variability in the circumstances

blood pressure readings, which declined in both groups but more markedly in the experimental subjects.

2. *Behavioral Results.* These subjects reflected qualities of the populations from which they were drawn, and gave considerable general evidence of personality disturbance, more overtly neurotic in the VA patients, and verging more on delinquency in the unemployed volunteers. Among the latter, four could be classified as present or former alcoholics; two gave evidence of past addiction to other drugs.

The only psychologic test which clearly distinguished between experimental and

control subjects was the self-rating mood scale. The experimental group indicated significantly more often that they were *not* experiencing negative emotions of anxiety, hostility and depression.

In general they showed marked *denial* of concern about any discomfort during the testing, as well as about any dangers connected with tobacco. Latent anxiety, however, was readily mobilized by questioning. Five subjects revealed the fear that they actually had cancer. Many others skirted around the subject of lung disease. Forty percent of them spoke of hoping to avoid such illness by the naive expedient of switching brands. In one group an experimental subject took a puff from a cigarette one night, then became acutely ill and vomited. A minor epidemic started; another subject vomited, and still two others complained of severe nausea.

During their start of abstinence experimental subjects had many complaints referable to the stomach, "emptiness," "gnawing" or "hungry" feelings. These may possibly be related to lack of nicotine, which habitually suppresses gastric activity. At times these sensations were also referred to the lungs. One subject spoke about his lungs being as "empty as the Empire State Building"; another talked about how "open to the outside air" he felt. Experimental subjects also described vague restlessness and discomfort on "test" days. Six of them spoke about time moving slowly. Some subjects also spoke of a feeling of loss. Several carried cigarettes around with them, touched them and smelled them. Some described looking for satisfaction in food. Others referred to the loss in more personal terms. "A cigarette is like a companion," said one; another described his state of abstinence as "like not being able to call on a friend."

These feelings during abstinence seemed relatively mild. Possibly aided by the supportive group situation our subjects gave up smoking with apparent ease for the time being. At the conclusion, however, they usually pocketed their last day's pay and walked away lighting a cigarette.

We obtained some information about special meanings of smoking to given individuals. Several talked about times they

had started or stopped smoking, apparently in response to their relationship to other persons, for example, one man who had given up cigarettes twice "for a girl," only to resume smoking when the relationships had been broken. In addition to the feelings of emptiness and the craving to take something in, many subjects also referred to the satisfaction obtained from various sensory avenues. They described relief of tension from having "something to do with your hands." Our subjects stressed pleasurable aspects of smoking less than their "need" to smoke for relief of tension, even when smoking itself had become for a time unpleasant. Cigarettes might make them "jittery" but they still would feel compelled to smoke them. Similarly, as to the cigarette before breakfast: even while acknowledging that a cigarette under those circumstances "tastes terrible," several said, "It wakes me up."

DISCUSSION

This study dealt with heavy smokers, who may well form a special group or at least occupy a particular position in the range of smokers (6, 20, 24, 25). Additional studies, comparing them with mild smokers or non-smokers, are needed. Furthermore, our subjects were unemployed or hospitalized for neurotic disability. We cannot be sure how characteristic the features they showed may or may not be even of all heavy smokers.

Nevertheless, our findings did confirm in a statistically manageable sample the physiologic effect reported by several other authors as characteristic of the state of acute abstinence. The clear-cut cardiac deceleration, the trend toward drop in blood pressure are consistent with a relative decrease in sympathetic nervous system activity. Although this varied somewhat from individual to individual, it is clearly present in both experiments. The second group, for whom only nicotine dosage was manipulated, served both to replicate the earlier finding and to indicate that it was not a function of the experimental situation but, in fact, related to the pharmacologic action of nicotine.

The finding suggests that its opposite, namely chronic hyperactivity of the sym-

pathetic nervous system, exists in heavy smokers. The resting mean pulse rate levels in the 75-85 per minute range for these men sitting quietly and doing very little for a 5-day period are high normal. Persistent reports suggest an increase in cardiovascular disease among smokers in the British literature(19) and in studies from the United States(10), particularly the recent summary of the combined experience of two large prospective investigations (5). The latter report based on more than 4000 men showed that "heavy cigarette smokers experienced a three-fold increase in the incidence of myocardial infarction and in death from all causes as compared to non-smokers, pipe and cigar smokers and former cigarette smokers." It still may be that both smoking and heart disease reflect a common underlying factor—the possibility raised by Fisher(20), Eysenck(6), Kissen(15), and others with respect to the association between smoking and lung cancer. However, our evidence at least is consistent with the existence of "chronic intoxication" in the heavy smoker, which is harmful to the smoker himself.

Our subjects also showed a compulsion to continue to smoke in increasing amounts. It could be overcome temporarily. The unmasking of anxieties about possible harmful effects may have contributed to some more lasting change in smoking habits among these heavy smokers, a third of whom indicated by a follow-up after 2 weeks that they were smoking "less." More systematic therapeutic effort may accomplish more. Lawton(21) who carried out group therapy with 19 smokers found that over 50% reported abstinence 2 weeks after termination.

Nevertheless, the habit is notoriously persistent and recurrent. One of us could testify to its tenacity. Six and one-half years after total cessation of heavy smoking, cigarettes were still occasionally appearing in stereotyped smoking dreams. These always represented a situation of some social stress and always had a similar content. Profuse smoking was accompanied by many self-reassurances and subjective conviction: "I have never *really* stopped smoking; I have always had a cigarette now and then." This in an individual whose waking hours

are dominated by complete unawareness of any subjective desire to smoke. We agree with Lawton(21) that the smoking habit has roots in the body, which ramify in unconscious strata of the personality.

As to the nature of this obscure dependence we have more questions than answers. To what extent is an addictive element present in other than heavy smokers? What is the relative proportion of "lusty" as opposed to "tense" smokers—to use the phrase of Kahn and Gildea(20). We speculate that pleasure, originally neurologically mediated, comes, in the heavy smoker, under the domination of needs to avoid distress, including distress stemming from social discomfort, faulty relationships, loneliness and depression.

Our physiologic findings perhaps permit one further speculation. An important effect of smoking appears to be sympathomimetic (29). Though addiction is usually thought of as involving drugs that produce euphoria or at least sleep, it can occur, perhaps in a form more easy to overcome, in relation to stimulants. Cocaine is the most extreme example. Less dramatic sympathetic nervous system effects, leading to a "keyed-up" state, can be sought out by many individuals and abetted by a variety of agents. It is interesting that Miller(26) treated 24 smokers with benzedrine sulfate in the acute abstinence period and reported avoidance of withdrawal symptoms. Hansel(11) recommends the same treatment. We were struck by these reports because the state of hyperactivity and continuous arousal which we postulate as part of the desired effect in the heavy smoker is similar to that described by one of us elsewhere in a group of mild but persistent addicts who used amphetamine(16).

These amphetamine devotees had many of the "oral" infantile features described in the general group of addicts(4). The actual sympathomimetic drug, however, seemed to be used largely to defend against the regressive, passive longings for bliss, nirvana or sleep—and rather as Szasz has pointed out also(32), to enable the users to remain active. Many of the same features are observed in smokers. Smoking seldom occurs in clearly regressive outbursts. Indeed, the feature that may make it par-

ticularly hard to eliminate the habit is the fact that it never comes to the type of orgasmic climax described particularly by Chessick(4) in heroin addicts. Instead, the heavy smoker, who is likely to smoke at least 2 or 3 cigarettes hourly throughout his waking life, manages to sustain the 20-minute peak of nicotine action more or less continuously.

A number of authors(20, 29) have suggested that tobacco is both a "tranquilizing" and a "stimulant" drug. Our suggestion is that the relaxing aspects of smoking may come largely from the act itself, the opportunity for motor expression, the deep inhalation, the sucking of something into the lungs passively. The stimulant effect, we suggest, comes more from the actual pharmacologic action of nicotine. The combination permits a certain compromise formation in the act of smoking. Along with the passive, relaxing satisfaction, there is the dim awareness, even anticipation, of an opposite type of effect, of generalized arousal, to follow. In any given subject, or at any given time, one or the other aspect may be uppermost. Both are important in the total picture of continued craving and dependence.

SUMMARY AND CONCLUSIONS

1. Fifteen heavy smokers were observed in a state of sudden abstinence, and contrasted with a comparable group of 11 subjects allowed to smoke *ad libitum*. Cardiac slowing, presumably vagotonic, and a lowering of diastolic blood pressure was found in the experimental group. Other less clear-cut complaints of distress, such as "emptiness," and slow passage of time, seemed related to the state of abstinence. The cardiovascular findings were replicated in a group switched under controlled, single-blind conditions from high nicotine to low nicotine cigarettes.

2. Heavy cigarette smokers thus appear to be true addicts, showing not only social habituation but mild physiologic withdrawal effects.

3. It would appear that the opposite of vagotonic action, namely chronic sympathetic stimulation, is one result of heavy smoking.

4. With appropriate motivation very heavy smoking can be given up, though just

as readily resumed. Concerns about the dangers of smoking, latent but readily mobilized in our population, are effectively masked by denial and related psychic defences. They must be unmasked to understand and treat heavy smoking, if treatment is desired.

5. Clinically, smoking appears to represent a complex learned psychosomatic pattern. Primary pleasure from the habit occurs but appears to become subordinate to secondary use of it to ward off pain, especially anxiety or a sense of loss. Various aspects or layers contribute to the urge: a) the symbolic and personal meaning of smoking to the smoker; b) the numerous sensations accompanying smoking—gustatory, pulmonary, tactile, visual and kinesthetic; c) the impulse to take in and eliminate, interwoven with but not identical with alimentary urges; d) the seeking in heavy smokers of a state of chronic low-grade arousal.

6. Our hypothesis is that the motor act of smoking contributes to the relaxing aspects of the habit, whereas, in compromise, sympathetic nervous arousal is mediated pharmacologically by nicotine.

WHITHER THE DAY HOSPITAL ¹

ARTHUR L. JONES, M.D., G. CORMACK, M.D., AND L. BOW, M.D.²

The field of psychiatric services is undergoing extensive reshaping at present, with a feeling of some optimism and a sense of forward drive as more workers and material resources become available. This reshaping further derives from a reaffirmation by psychiatrists, through growing confidence in their status, of their traditional role as doctors in actively and optimistically intervening to help all types of illness in a variety of ways and places, and from a reawakening of social conscience regarding the patient in relation to his community. An integral part of this re-formation is what has come to be called "the day hospital movement"; *i.e.*, the setting up of units, in hospitals or detached from them, providing a daily programme for psychiatric patients who remain at home at night and weekends (1-3). "Day hospital" is one of several names given to such arrangements—"day centres," "day wards" are others. Their services vary in their focus (Table 1)—to give active treat-

tivities for lonely and isolated patients (like an aftercare club). Many are an offshoot of a hospital but there are a number of other types of liaison and geographic location.

TABLE 2
Day Hospitals, Day Centres, Day Wards
Commonest Locations (Farndale, U.K., 1961)

1. Day patients attending inpatient ward of mental hospital.
2. Detached day hospital, linked with mental hospital.
3. Day patients attending inpatient ward of general hospital.
4. Day hospitals in grounds of mental hospital.
5. Detached psychiatric units (day patients, inpatients, outpatients) linked to general or mental hospital.

Farndale (Table 2), in his recent book (4) outlining the work of 38 day hospitals and centres in Britain, describes 9 different sorts of settings. Such a diversity of organization is confusing to those of us used to thinking of patients being customarily treated in one of *two* settings, *i.e.*, outpatient clinic or inpatient ward. Yet day hospitals have by now sufficient experience that their functions should be determinate. Bierer (5), who started the Marlborough Day Hospital in London in 1947, suggests that *his* type of comprehensive day hospital could put mental hospitals largely out of business. Contrariwise, there are indications from both Britain and North America that not all day hospitals run at their expected capacity if the location is poor or after the initial evangelism of their founders has passed. In an attempt to define the work and use of day hospitals more clearly, we assessed our experience, totalling 10 years, with 3 day centres in Central Ontario.

These day care centres have certain common features. All are supported by the Ontario Government, give service at no cost to the patient, employ the usual staff disciplines full time (Table 3), and cater to psychiatric illness alone (Table 4). The day care programme is for adults only, but children as well as adults are treated as outpatients in two instances. All the centres are

run by full-time psychiatrist directors and are located adjacent to, but independent of, parent psychiatric hospitals which provide some essential services, such as kitchen, laboratory or pharmaceutical supplies; otherwise, these day centres function autonomously in their services to the public.

I opened the first of these centres (6) in early 1958 in downtown Toronto, a metropolis of nearly two million people. It is a branch of the Toronto Psychiatric Hospital, and is installed in a nearby renovated church. This city already possessed, of course, extensive inpatient and outpatient facilities for psychiatric patients, with a waiting list of referrals in most instances. The new day centre was designed to serve during the day persons of both sexes over 18 years of age, affected by psychiatric illness of any sort, but who were not so severely ill or unsupported that night-time special care (in hospital) was necessary. The initial criterion for referral was a psychiatrist's recommendation, but sources of referral were progressively enlarged so that patients were accepted from any source, including self-referrals (Table 5). A screening interview was used when the grounds of referral were doubtful. Still this day centre has not always felt the pressure of a sizeable waiting list. This may be, in part, due to the fact

TABLE 5
Sources of Referral
Day Centre, Toronto

	1958	1959	1961
General practitioners	24%	12%	15%

Clinics	51%	42%	26%
Private psychiatrists	9%	15%	17%

that a day hospital is extensible in form; i.e., it is not bounded by bed space as a hospital, or office space as a clinic. This centre, planned for daily use by 25 adults, has accommodated a maximum of 38 a day and treated 50 per week. Thus while it has been increasingly busy, it has not been loaded with a backlog of referrals as are other units in the city.

Another trend noted was a mounting percentage of chronic sick referred for treatment. These might be patients hospitalized elsewhere repeatedly without stable improvement or attending clinics for many months without the expected progress. For these, the active programme of psychotherapy and physical therapy during short stay as originally designed was not suitable; a longer stay with a more supportive type of care was necessary. Consequently, the stay of patients has increased since 1958, and treatment aspects of aftercare rehabilitation and of social support have needed emphasis. This long-stay trend has been reinforced by a liaison with a Toronto mental hospital, whereby chronic patients of that hospital became patients at the day centre and, once improvement had occurred, were discharged from hospital to live at home while continuing as day patients. The behavioural transition from hospital backward to home took many weeks for these patients.

All patients are followed up as outpatients after terminating day care, and an increasing proportion of psychiatrists' time has been spent in outpatient service. Added to this were patients referred for outpatient consultation as the centre became more widely known. Thus, with the evolutionary experience of 4 years, this day centre, well located in a large city as an offshoot of a psychiatric hospital, has had to meet de-

mands additional to its original design. Catering to 25 adult day patients daily, it has found its services called on in a variety of ways—emergency patients, acute illnesses, halfway house, rehabilitation and support of the chronically sick, outpatient ECT, outpatient consultations. The centre has not found one particular demand to satisfy, but rather a need for expansion of many types of service in this city. An extensive programme of teaching and training also is an essential part of the centre's activities.

The next day care centre has a different history. It opened in mid-1958 in Cobourg, a lakeshore town 70 miles east of Toronto of 10,000 population and circled by a rural area of about 75,000 people. For this town the nearest psychiatric services had been in a general hospital 40 miles to the north, and in a mental hospital, 40 miles to the west. Sited in Cobourg is a mental hospital specializing in the treatment of mentally defective girls. Its superintendent became more and more called on for consultation on psychiatric problems by the local doctors, so that eventually a full-time clinic and day hospital was begun in the superintendent's former home near the hospital and additional staff was enrolled.

The emphasis of this Cobourg day centre, under Dr. Cormack, has been outpatient work and community service. This means contacts with patients seen in the centre itself, with two city general hospitals, with the family doctor; also consultations in the local nursing home and home for the aged and in the jail; also liaison meetings with the Children's Aid Society, schools, public-health nurses and clergy, *etc.* From this material, patients are selected for day care, and about 10 attend daily (contrasted with an average of 15 outpatients seen each day). A night centre was run for a few months initially, but was discontinued as it became a haven for patients with character disorders and no need has been seen to reopen it. About 10% of day patients have had to be hospitalized but there is evidence that a smaller number is sent to hospital than before the centre opened.

The third day centre also began in an area where outpatient services were not immediately available. It is situated in New Toronto, an outskirt of and mainly a dormi-

tory area for Toronto, 8 miles from the city centre. It occupies a remodelled house in the grounds of a large mental hospital, and opened in Jan. 1960.

This New Toronto outpatient clinic and day care centre, led by Dr. Bow, aims, like that at Cobourg, to provide a community mental health service—with most staff time directed toward outpatients, adults and children, both seen at the clinic and reached by liaisons with other agencies in the community. Adjunctive to this work is a day hospital for adults. As at Cobourg, about 10% of all patients seen have received day care by the same staff, and 10% again of the day care patients have needed to be hospitalized (Table 6).

DISCUSSION

These three day centres are similar in design in mainly providing a substitute for inpatient care. We cannot therefore draw on our experience to comment on other types of day hospitals such as those servicing geriatric patients exclusively or day wards in mental hospitals dealing with the rehabilitation of chronic inpatients. However, the day centre in Toronto gradually adopted, on demand and by adaptive intent, a programme for a wide variety of patients ranging from mental hospital inpatients to the acutely ill, from enduring support to brief therapy. Why this demand arose in the one centre and not in the other two is not altogether clear. Factors of case selection and environment are important, but significant too, we think, are the uninte-

grated pattern of services found in most cities and the exclusive full-time attachment of the staff in Toronto to a day centre alone without integral links to an outpatient clinic or an inpatient ward. As mentioned earlier, the Toronto day centre has moved in the direction of the other two centres in providing its own outpatient service.

With an innovation, the initial phase is one of promotion and acceptance, and day hospitals are no exception. But we feel it is now time to question some earlier assumptions. One danger we see is the halo effect of a label—the danger of setting up yet another institution as an end in itself. From our experience it is important to keep in mind that a day hospital should not be purely autonomous but should be linked closely with other services, particularly outpatient clinic and hospital. We see the need for something more than office interviews in many patients. We would also assert that a day hospital, comprehensive as you like, will not replace a hospital. It is probable we could improve on our figures of 10% patients needing hospitalization from a day centre but there will be a limit to this. In particular, some patients previously treated in hospital refuse day hospital care and many families reach their limit of tolerance of the sick relative even for part of the day.

Admittedly many professional workers are unsure of the function of a day hospital and, as the Toronto figures suggest, appear hesitant to accept a day hospital as an alternative to hospital. Psychiatrists, like the public, find hospital an appealing way of isolating the contagion of a disturbed patient. Until a day hospital becomes a first stage in treatment of acute illness, its capacities may not be fully used. Thus the Cobourg day centre, with its intimate and exclusive contact with family doctors and outpatient referral, has been very successful in this regard, while the Toronto centre because of its autonomy has not had the same demand. For this reason, where psychiatric services have achieved greater integration, as in England and Russia, day hospitals have expanded more rapidly. In North America we have tended to value private practice and hospital care most highly, but gradually a flexible welding of

services is occurring and day hospitals will multiply.

In Ontario, a day centre has given a new look to the government psychiatrist. This individual, long regarded as the custodian of irresponsible and inadequate persons, through a day hospital changes his image to that of an outpatient therapist, more closely tied to his community, yet identified with "hospital-like treatment." Greater public acceptance has ensued. Day centres are well accepted by a majority of patients, too, and in many instances are the only sort of treatment accepted.

A remarkable fact is that most day hospitals emphasize group therapies as an integral part of their programme and stress this point more than hospitals or clinics have done. This too occurred independently in the three day centres in Ontario. Influencing this trend, of course, are some current fashions in psychiatric theory and practice, but implicit in the self-selection of the directors for these centres is a search for smaller group identity instead of large hospital wards' diffuseness. The day centres in Cobourg and New Toronto are in former family homes and pride themselves on a homely atmosphere for staff and patients. Group activities, verbal and non-verbal, recreational and educational, are a feature.

Day hospitals owe some of their appeal, to patients and staff, to this focus in therapy—the homely setting, the studied small group interactions, the mutually supportive milieu. The patients are treated as a group where possible and staff roles undergo changes from the traditional ones. This seems particularly applicable in a large city where social relations are often loosely tied, and loneliness for example is a frequent cause of mental breakdown. Promotion of social outlets in and by the community, and a sorting of patients into sheltered workshops, residential hostels and rehabilitation centres may reduce the call on a day hospital's services. A hint of this has occurred in Toronto where the day centre no longer has a social club meeting on the premises but passes patients on to a club run by volunteers of the local Mental Health Association.

In summary, from our experience with three day centres in Ontario we advocate

that day hospitals serve as one element in an integrated mental health service rather than as separate units, and that as an acute treatment service it should be most closely linked with an outpatient clinic. Day hospitals warrant further expansion as a feature attractive and effective in the opinions of patients and staff.

ABSTRACTS

PSYCHIATRY IN AN ARMY GENERAL HOSPITAL

JAY F. TUTTLE, LT. COL., M.C.¹

In the Army psychiatry is an integral part of the professional services of each general hospital. As the dominant service of the department of neurology and psychiatry, it is for all practical purposes on a level with the departments of medicine and surgery. Architecturally it is often quartered as far from headquarters as possible, but this is a relic of past construction and does not truly indicate its status or relationship with the other medical specialties or even with headquarters itself.

This is particularly evident at a specialized treatment center like Valley Forge General Hospital which is devoted chiefly to the care of patients with pulmonary diseases and psychiatric disorders. Here it is one of the major departments of the hospital, accounting for nearly one-third of the hospital census. Although it does not have a formal training program, the hospital's Department of Psychiatry and Neurology is, in fact, the second largest in the U. S. Army. It is the last link in the overseas chain of evacuation of psychiatric patients whose homes are located in the northeastern part of the United States. Locally it receives a few patients from the hospitals and dispensaries in the same area.

Organizationally the Department is divided into the conventional divisions—psychiatry, neurology, psychiatric social work, psychology, and the consultation services. Its personnel are either assigned to the Department directly by the Surgeon General's office or indirectly through the hospital, as in the case of the nurses, corpsmen, and occupational therapists who really belong to other services but are placed in the Department of Psychiatry and Neurology for duty.

The professional personnel are stationed at the hospital for tours of varying length, usually two to four years. These assign-

ments usually take place during the summer. While the social work officers and psychologists are well trained and usually members of the regular army, this is not true of the medical officers on whom the real burden of examining and making disposition of the patients devolves. With the exception of the Chief of the Department who is board qualified in psychiatry, and the Assistant Chief who is board-eligible, most of the other officers have had little formal psychiatric training before coming into the army. Because of the shortage of psychiatrists, some neurologists have been assigned to psychiatric duty in the last year.

The task of training these new medical officers is one of the major responsibilities of the Department. Even though a man has had considerable civilian training, he usually finds his attitudes toward treatment and his orientation toward patients have to be revised sharply in the military setting. He also has a host of administrative and technical details to learn. This is accomplished chiefly through personal supervision and conferences and by the liberal use of civilian consultants² from the nearby Philadelphia area. The consultants are scheduled on a regular monthly basis. Their time is spent usually in case presentations, or in discussion of material of special interest to the staff. While the consultants render valuable assistance in difficult cases and stimulate the discussion of dynamics and other aspects of psychiatry and neurology, one of their most valuable contributions has been their broadening effect on the staff's viewpoint.

Certain other facilities are available for training purposes, such as the Audio-visual Aid Section of the hospital, which can obtain a number of excellent psychiatric

¹ Valley Forge General Hospital, Phoenixville, Pa.

films, and the medical library, which, through its connection with the National Library of Medicine, can obtain photostats of almost any article the staff may desire. Although travel money is limited, staff members may be given administrative leave up to ten days to attend any meeting within their specialty. While the Department does not have a formal research program, the scientific attitude is definitely encouraged, and within the past few years several men have published papers. Funds for research can be obtained from the Research and Development Branch of the Surgeon General's Office in Washington, D. C. if the applicant develops an acceptable research protocol. Since the psychiatric service is part of a general hospital, the medical officers have the advantage of expert consultation in all the other specialties and conferences or seminars in the other branches of medicine.

The psychiatric patients are chiefly young men in their twenties and thirties. Except for the mental disorders of the senium and mental deficiency, which is rarely seen now because of the screening examination at induction, their diagnoses cover the entire gamut of the psychiatric nomenclature. Army regulations discourage the hospitalization of neurotics and individuals with character and behavior disorders, but a large number still do find their way into the hospital, though this figure is much less since the re-establishment of the mental hygiene consultation services following the Korean War. Those who do secure admission are either misdiagnosed or have been acting in such a way that they are threatening to the referring group. Some, of course, are sent for forensic purposes.

The treatment programs at Valley Forge General Hospital (and other army general hospitals as well) are very similar to those in civil life. Tranquilizers are used extensively in treating psychotics and have displaced ECT to some degree. Insulin therapy has been discontinued along with hydrotherapy. Considerable emphasis and time are now spent in developing the concepts of social psychiatry and the therapeutic milieu of the wards. Group therapy is used extensively on all the wards, and seems to help in solving problems in communication

and communication breakdown, decreasing ward unrest and incidents.

Although the Department still has closed and open wards, the previously great concern about security, which was evident in military hospitals generally, has given way to a more relaxed atmosphere. Heavy metal screens, for example, have been removed from the mess hall, and patients are no longer checked for silverware after eating. Most of the closed wards are open part of the day, and the better patients are given ground passes for the day.

Much of this permissive atmosphere is the direct result of the good relationship that the Department of Psychiatry and Neurology has with the rest of the hospital, which has enhanced the hospital community's tolerance for the occasional instance of aberrant behavior of the patients. This relationship does not occur as a matter of course, but has to be actively cultivated. Members of the psychiatric staff have had to sell themselves and psychiatry. They must participate in hospital conferences and attend the various social functions of the hospital and its staff.

Probably the most interesting program that the Department has developed in the past few years has been the work therapy program under the supervision of the occupational therapy section of the Physical Medicine Service. It has been most effective in favorably influencing the hospital community. Depending on the patients' training, mental state, or interests, they have been assigned to all activities in the hospital from the nursing service to engineering. Actually the men themselves have been instrumental in breaking down the stigma that usually is attached to psychiatric patients. After leaving the hospital some have written letters to members of the maintenance staff thanking them for their kindness while they were with them. The program has relieved the boredom of ward routine for the patients and has provided another means for the medical officers to gauge their improvement.

The Department has an active recreation program for all the patients. The Red Cross supervises most of the programs for the closed ward patients. The open ward patients, of course, have the entire facilities

includes the Red Cross building and its of the hospital available to them which entertainment, the theatre, swimming pool, golf course, bowling alley, Post Exchange, and Snack Bar. In addition the Department has a liberal pass and leave system for them.

The average length of hospitalization for all patients is 60 to 70 days. Some psychotic patients may remain longer, but army policy is not to hospitalize members longer than 6 months though this is not a hard and fast rule. The great majority of patients have less than 5 years' service and most of these are recommended for medical discharge, although this is not mandatory. Those who have more service are often returned for a trial of duty if they make a good recovery and are well motivated for duty. Generally, they must have had a good army record and be free of such characterological problems as alcoholism or sexual deviation. Badgley, *et al.*,³ did a recent study on

selected schizophrenics returned to duty and found only about 50% remained on duty for at least two years. He concluded that there were no really good criteria for retention. One of the current problems of army psychiatry is to provide a good follow-up program for schizophrenic patients returned to duty.

Soldiers displaying character and behavior disorders usually are recommended for administrative disposition. The actual discharge is ordered by a non-medical board of officers who may or may not accept the medical officers' recommendations. At the present time most soldiers in this category in the army are eliminated locally at their own posts without ever being hospitalized. Those in the hospital are usually returned to their home post, but some are discharged at the hospital, when they have been assigned to the hospital as members of the holding detachment. Thus the vast majority of patients admitted to psychiatry are recommended for separation from the service.

POST-ABORTION PSYCHIATRIC ILLNESS—A MYTH ?

JEROME M. KUMMER, M.D.¹

American medical literature contains frequent mention of psychiatric illness following abortion (1-7). Up to this time, however, there has been no statistical documentation of such sequelae. A preliminary survey among a group of American psychiatrists revealed that psychiatric illness following abortion occurs either very rarely, or, for the most part, not at all. (The term "abortion" will hereafter refer to induced abortion both criminal and therapeutic.) Attempts to amplify this study were made through surveying the literature in this country and abroad and communicating with psychiatrists in other countries, particularly those

in which prevail more liberal attitudes toward abortion. Further attempts through a review of statistics in the larger American governmental bureaus were fruitless because relevant data had not been gathered.

In 1949, I saw a woman, age 29, pregnant for the fourth time. She had suffered severe schizophrenic reactions following the birth of each child and was hospitalized for about one year each time. It was my opinion that she should have a therapeutic abortion to avoid the risk of another relapse. Considerable difficulty was encountered. The law permitted abortion only to preserve a woman's life. Yet, as I subsequently learned, reputable physicians performed therapeutic abortions in many of our leading hospitals to preserve health.

The case in question aroused my interest in this problem and led to my writing a

¹ Assoc. Clin. Prof., Dept. of Psychiatry, Univ. of Calif., Los Angeles School of Medicine.

Original read before the International Congress of Psychosomatic Medicine and Maternity, Paris, July 11, 1962.

series of articles concerning psychiatric indications for therapeutic abortion(8) as well as the need for modernizing and clarifying laws pertaining to therapeutic abortion (9, 10). In the past decade a number of excellent books have appeared, dealing with the abortion problem in a frank and thorough manner(11-13). At the present time there is a substantial movement in the United States for modification of the laws as recommended by experts representing various disciplines.

Inquiries, as part of a preliminary study, among 32 psychiatrists, all but 4 of them associated with the University of California at Los Angeles School of Medicine, revealed that 75% had never encountered any moderate to severe psychiatric sequelae of abortion. The remaining 25% encountered such sequelae only rarely, the highest figure reported was 6 cases in 15 years of practice. The average length of practice in the group surveyed was slightly over 12 years.

The finding must be contrasted with the substantial incidence of psychiatric illness complicating pregnancy and childbirth(8). Of more than 100,000 female admissions to mental hospitals in the United States between 1916 and 1946, approximately 2% were precipitated during pregnancy or the postpartum period. Similarly, a survey of several studies in Europe and the United States revealed one postpartum psychosis in every 500 births.

A review of European literature tends to discount the claim that abortion leads to frequent psychiatric illness. One notable exception is the study made by Karin Malmfors(14), a social worker in Stockholm, who in 1951 reported 10 cases of impaired mental health in a series of 84 women following legal abortion. While it is true that at least 8 of the 10 were aborted for psychiatric indications, the Malmfors study stands in vivid contrast to one made by Dr. Martin Ekblad in the same city at about the same time.

Ekblad has provided a most comprehensive follow-up study of psychological after-effects in a series of 479 women who were aborted on psychiatric grounds. Only 1% developed any psychiatric impairment in their ability to work. To quote Ekblad(15) :

In the light of their symptoms and their situation at the time of abortion, it is probable that they would have developed equally severe symptoms of insufficiency even if they had not been granted legal abortion. All of these 5 women had had severe manifest neurotic symptoms even before the abortion. It is seldom that these undesirable psychic sequelae [of abortion] are so serious that they may be described as morbid or that they adversely affect the woman's working capacity.

Communication with psychiatrists in various European countries, Israel, and Japan revealed a similar trend of rarely, if ever, encountering moderate to severe psychiatric sequelae of induced abortion. During a recent visit with Dr. Henrik Hoffmeyer, Chief Psychiatrist, Mothers' Aid Society in Copenhagen, I learned that they heard of no psychiatric after-effects of the degree in question among approximately 30,000 legal abortions performed over the past 15 years.

We have a critical situation in the United States wherein it is estimated that over one million illegal abortions (or one out of every 5 pregnancies) occur each year. Most of these are performed by extremely unskilled, unscrupulous individuals, and, it is further estimated, more than 5,000 women die each year as a result of complications (16).

In attempting to deal with this problem we must realistically appraise it as one of utmost complexity, a syndrome of severe underlying social illness, requiring studies and remedies on many levels and from numerous disciplines.

The Kinsey group revealed many interesting findings in their third book(12) (published after Kinsey's death; Dr. Paul Gebhard was senior author), pointing to valuable clues concerning the etiology of abortion. It was found that among unwed women where taboos against illegitimacy were stronger, a much higher rate of abortion occurred. Might one conjecture that abortion is a product of sexual taboos? Another finding of the Kinsey group, confirming observations made earlier by others (17-19), was that abortion is more of a problem of married women who have several children, contrary to the popular notion that it mostly involves illegitimate preg-

nancies. The more pregnancies a woman has had, the more likely she is to seek abortion. It was of great interest to Scandinavian physicians that American diagnostic categories do not include anything even remotely resembling the "worn out mother syndrome," used in the Scandinavian countries as a socio-medical indication for therapeutic abortion. "Can this mean," they might ask, "that you do not have worn out mothers in the United States?"

Also noted by the Kinsey group, and again confirming observations by others, was that induced abortion did not result in the ill effects that had been so generally assumed previously. Statistically their material gave no evidence of any resultant sterility or damage to capacity for achieving orgasm. They found that other physical and psychological after-effects appeared less frequently than had been previously supposed.

If the ill effects of induced abortion have been so grossly exaggerated, we must ask ourselves why. Might the answer be that this is part of the means of enforcing the taboo? The taboo concerning abortion goes far back into antiquity. It has deep roots in the Judaeo-Christian ethic. It is part of the Oath of Hippocrates.

There is no question that abortion represents psychological traumata to the abortee on many levels. Also there would be no denying of the incomparable satisfaction accruing to women from pregnancy, childbirth and motherhood, visualized almost universally as the extreme of fulfillment for the woman who is well enough physically and emotionally.

As with pregnancy and parturition, induced abortion would not be considered the basic cause of any psychiatric sequelae, but rather as a precipitating stress. The type of illness that would occur depends on the premorbid personality and susceptibility of the patient.

Pregnancy and childbirth are the most rapid and dramatic changes, anatomically and physiologically, to occur in the course of normal life processes. The emotional reverberations are of comparable magnitude and, when combined with varying psychological predispositions, lead to the emotional reactions observable in all women. These

reactions are considerably more disabling in persons with a history of earlier emotional and personality disorders, particularly one of overt mental illness.

In considering a patient for therapeutic abortion we must balance the threats of psychological trauma from abortion against that from pregnancy, childbirth, and child-rearing. Apparently pregnancy and parturition exert greater stresses than does induced abortion upon women susceptible to mental illness. The incidence of post-abortion psychiatric illness falls far short of what we have been led to expect, particularly when we consider the number of abortions that take place.

My conclusion from my preliminary investigations would be that abortion, as a precipitating stress towards moderate to severe psychiatric illness, is of only very minor significance, probably similar to any of a number of non-specific factors, such as a disappointment in love, an accident, loss of job, *etc.* This stands in vivid contrast to pregnancy, childbirth and child-rearing, which have been found to be substantially significant stresses in susceptible females.

If abortion, as is often claimed, leads to frequent psychiatric complications, then indeed this should be brought out into the open. If, on the other hand, as my preliminary findings suggest, abortion provides substantial relief and protection for women susceptible to disabling psychiatric illness, then let us expose the myth of post-abortion psychiatric illness and proceed from there!

SUMMARY

No known attempts to document statistically the incidence of post-abortion psychiatric illness have been found in American medical literature, yet many writers describe and discuss this as fairly common after-effects of both therapeutic and criminal abortion.

Preliminary findings of a multi-lateral investigation reveal that psychiatric sequelae of moderate to severe intensity following abortion are very rare, markedly less than the incidence of psychiatric illness related to pregnancy and childbirth.

This study involved surveying a small sample of American psychiatrists, attempt-

ing to gather data from statistical departments of governmental agencies, and surveying psychiatrists from other countries, particularly those where abortion is either liberally available or completely legal.

Comparisons are made to the situation concerning physical after-effects of abortion, which recent studies have shown to have been much exaggerated. Enforcement of the taboo against abortion is considered the basis for the widespread myths in this area and resistance to factual documentation.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinions of the Journal.)

THE EFFECT OF CLOPENTHIXOL ON CHRONIC PSYCHIATRIC PATIENTS¹

T. A. BAN, M.D., K. FERGUSON, M.D., AND H. E. LEHMANN, M.D.²

After the introduction of the phenothiazines and rauwolfia alkaloids in the treatment of psychiatric patients, further research has been directed towards finding other chemicals with antipsychotic properties.

Clopenthiol (Sordinol),³ a chemical synthesis of chlorprothixine and perphenazine, was developed with the aim of producing a compound with stronger antipsychotic properties than chlorprothixine while being at the same time faster acting and less toxic than perphenazine(1).

An uncontrolled clinical trial was carried out over 10 weeks with 20 chronic hospitalized patients. During the trial period 30 to 300 mgs. of clopenthiol were administered daily in three equally divided doses. Special emphasis was laid on the investigation of the effect of the drug on certain psychiatric target symptoms and on possible toxicity.

The patients for this study were selected on the basis of chronicity of illness and failure to respond to previous therapies. Their ages ranged from 20 to 65 (mean 41 years); length of hospitalization ranged from 6 months to 25 years (mean 6 years). The diagnostic distribution consisted of schizophrenias, 13; manic-depressive psychosis (hypomanic), 2; paranoid state, 1; mental deficiency with psychosis, 2; pathological personality, 1; chronic alcoholism (Korsakoff syndrome), 1.

The evaluation was based on clinical observations and on the results of a battery of tests.

RESULTS

Psychiatric: Based on the daily notes of changes observed in the patients' mental state and on the symptom check list, the drug's principal effects were seen in the following areas: in 9 patients improvement was manifested in mental integration as reduction of disorders of thought and perception together with positive behavioral changes; there was also better social contact; the activity (arousal factor) of three patients decreased and four became depressed (affectivity factor). *Psychological*: Based on the Word Association and Conformity Index tests(2) a general improvement was noted in word association time of patients, expressed in mean values from the pre-trial 2.2 seconds to 1.1 seconds in the tenth week. In association time there was a directly proportionate relationship between clinical improvement and decrease of association time in most individual cases. The conformity index did not show any conclusive changes. *Physical*: There was a tendency towards a moderate lowering of blood pressure and also a moderate rise in pulse rate which gradually tended to return to normal. Fourteen patients gained weight during the trial period. *Adverse Reactions*: The following side effects occurred: paroxysmal tachycardia, 1; dry mouth, skin and scalp, 3; facial flushing, 4; extrapyramidal symptoms, 10; depressive mood change, 4; transient drowsiness, 14. Medication had to be discontinued in only one case because of side effects (paroxysmal tachycardia). The majority of the extrapyramidal symptoms occurred in the third week and were controlled with antiparkinsonian medication.

¹ This investigation was supported by a Public Health Service research grant MYP 5202 from the U. S. Department of Health, Education and Welfare.

² Verdun Protestant Hospital, 6875 LaSalle Blvd., Verdun, Quebec.

We are indebted to Mrs. K. Vagi, R.N., for her valuable assistance in these observations.

³ Clopenthiol (Sordinol) was generously supplied by Ayerst, McKenna & Harrison Ltd.

Drowsiness was prominent at the beginning of the trial but diminished during the course of treatment, while the dryness of skin and scalp increased as time passed. *Laboratory Findings*: Liver, kidney function and haemopoietic system tests did not reveal any toxic effect of the drug.

Of the 20 cases, 9 showed clinical improvement (3 marked and 6 moderate), 1 became less controlled, 4 became more depressed and 6 patients remained unchanged.

SUMMARY

In our clinical trial with 20 male chronic patients on a mental hospital ward, clopen-

thixol appeared to have observable antipsychotic properties with relatively little toxicity. The observation that this drug was therapeutically effective in certain chronic schizophrenic patients where previous treatments had failed is in accordance with the findings of other clinical investigators and suggests that clopenthixol may deserve a place among the clinically used antipsychotic compounds.

THE IDENTIFICATION AND TREATMENT OF AN EARLY DEPRIVATION SYNDROME IN ALCOHOLICS BY MEANS OF LSD-25

ERNEST BELDEN, M.A., AND RICHARD HITCHEN, M.D.¹

The original purpose of the exploratory study was to determine the effectiveness of LSD-25² as adjunct to psychotherapy in treating alcoholic patients in a large mental hospital. The general findings were in essential agreement with those of other investigators who have used the drug (1-4) and have been published elsewhere (5).

One of the most intriguing findings of our research was that certain alcoholics have experienced extreme emotional and affectional deprivation at a very early age. In some cases we were able to substantiate such speculations by historical data supplied by members of the patient's family. Individuals who have experienced such psychic trauma, usually the loss of the mother, will attempt to protect themselves against recurrence by means of massive denials for any need for affection and by an almost complete avoidance of affective investment in others (love). This type of armor has many of the qualities found in psychopathic and character-neurotic adjustment. We felt that such individuals

make the most promising subjects for LSD-25 treatment. We were able to work through these long-established defenses by means of an intensely magnified transference, *i.e.*, the intimate exchange of feeling between therapist and patient enhanced by music. This interchange between therapist and patient comes close to the existentialist concept of "encounter" (6) and the results are quite dramatic and far-reaching. The breaching of the patient's defenses often makes it impossible for him to retreat to his previous pathological adjustment of encapsulation, distancing and avoidance.

Once these gains have been achieved by means of LSD therapy they have to be consolidated and exploited by the therapist in regular (non-LSD) sessions.

We might now theorize as to what need alcohol serves in individuals with a desperate, yet covert or denied need for affection, love, and closeness. Is the desire for oblivion, so often expressed by alcoholic patients, a wish to blot out affectionate needs or to re-instate them at the most primitive infantile level? We also wonder what sort of a re-arrangement of personality structure takes place during the "LSD encounter" and why these changes appear to

¹ Napa State Hospital, Imola, Calif.

² LSD-25 (d-lysergic acid diethylamide) was kindly furnished by Mr. H. Althouse, Sandoz Pharmaceuticals.

be of a permanent nature. Why is the patient after LSD therapy able to meet his affectionate needs on a reality level and abandon alcohol which has served as a substitute for so long? Obviously, these questions are in need of further clinical investigation.

We do not want to imply that all or even most alcoholics exhibit the syndrome of affectional deprivation or that they can be cured by means of LSD therapy. Instead, we propose merely a more systematic research approach to this problem which would include careful selection and treatment of subjects which fit the criteria of the identified syndrome. This type of research combined with a follow-up study would throw light on the validity of our speculations.

SUMMARY

A limited research project was undertaken in which LSD was combined with psychotherapy. The results are in essential agreement with those of other investigators, who have used LSD as adjunct to therapy with alcoholic patients. Evidence of the

existence of an emotional deprivation syndrome which responds to the technique developed by the present investigators was found and discussed. This syndrome is consistent with some of the psychoanalytic formulations regarding the origin of psychopathic and character disorders. Treatment may be viewed as similar in nature to an intensive existentialist "encounter." The authors propose a larger, systematic investigation with follow-up studies which might confirm their present tentative findings.

A PRELIMINARY STUDY OF PHENOXYPROPAZINE IN THE TREATMENT OF DEPRESSION

M. R. LEAHY, D.P.M., J. T. ROSE, D.P.M., AND R. PLOWMAN, M.B.¹

Thirty-five depressed female inpatients of a psychiatric unit in a general hospital were selected as suitable for antidepressant drug therapy. All cases were of moderate severity; the average age was 47 years. Seventeen cases had endogenous depression, 18 were reactive depressives. Patients received 5 mgms. of phenoxypropazine (Drazine) b.i.d. for one week, then 10 mgms. b.i.d. for 3 weeks after which observations were discontinued. All patients had, in addition, phenothiazine treatment, the average dose being 50 mgms. of thioridazine (Mellaril) t.i.d., as well as a small nightly dose of barbiturate. Ankle oedema was the only side effect, occurring in 3 elderly patients (average age 68 years) and easily controlled by temporary reduction of dosage

together with an oral diuretic. Patients were assessed at the end of the fourth week, the results being shown in the following table.

	ENDOGENOUS	REACTIVE
Recovered	11	10
Moderate improvement	4	7
No change	2	1

Only 3 cases failed to respond to treatment, whilst 21 patients made a complete recovery. Endogenous and reactive depressions showed no significant difference in response to phenoxypropazine. Cases who responded well showed improvement which began during the first 7-10 days and progressed as treatment continued. No cases of delayed response occurred. A further 11

¹ St. James's Hospital, Leeds, England.

patients, more severely depressed, received phenoxypropazine and EST; no complications were observed and the number of treatments required did not appear to be reduced.

Phenoxypropazine appears to be an effective

antidepressant in cases of moderately severe depression of either endogenous or reactive nature. The results of this pilot investigation are sufficiently encouraging to warrant full-scale controlled clinical trials.

FLUPHENAZINE IN THE TREATMENT OF HOSPITALIZED MENTAL PATIENTS

LEROY E. MOORE, M.D.¹

Between Jan. 1, 1961 and Aug. 25, 1961, all patients from a selected ward of this hospital were treated with fluphenazine² except those with convulsive disorders and those who had refused all previous medications. Originally, the study group included 97 males, manifesting various psychiatric illnesses, predominantly psychotic and chronic. Subsequently 77 additional male patients, who were admitted or transferred to the treatment ward during the study period, were added to the series. Most of these 77 patients were acutely ill, the majority had schizophrenia. The ages of the 174 patients comprising the series ranged from 20 to 80 years.

Fluphenazine was administered orally to each patient, usually in daily doses of 2.5 mg. or 5 mg. Initially, a dose of 2.5 mg. was prescribed for the first two weeks, then uniformly increased to 5 mg., with adjustments in dosage thereafter (1 mg. to 10 mg.), as indicated. Subsequently, patients were usually started on daily doses of 2.5 mg. or 5 mg., though a few patients were given 1 mg. a day and one patient received daily doses of 20 mg. to 40 mg. Patients who exhibited low urinary phenothiazine values³ were subsequently given the medication either by parenteral administration or as an elixir instead of as a tablet. Treatment was continued in individual patients for varying periods up to 8 months.

Initially, the psychiatric status of each patient was evaluated immediately before

treatment with fluphenazine and again at weekly intervals for the first 6 weeks of therapy. Effects of treatment were appraised in each case on the basis of these evaluations together with weekly reports on the patient's behavior by the nurses and attendants on the ward. As the study progressed, patients were evaluated less frequently, usually once each month, but in every case immediately before treatment and again at the completion of the study. In order to facilitate assessment of the findings the results observed in the original 97 patients and those in the added 77 patients were tabulated separately.

Results. Improvement was observed after 1 week of therapy in 30 of the 97 patients originally placed on fluphenazine. As treatment was continued an increasing proportion improved. Of the 79 patients continued on medication for 6 weeks, 44 were improved, 6 were discharged from hospital either markedly improved or in remission, 2 were placed on indefinite leave, and 5 were transferred to other hospitals for continuing treatment. Further, of the 64 patients who received treatment for longer than 6 weeks, some for as long as 8 months, 43 were improved, 4 were placed on indefinite leave, 9 were transferred and 1 was discharged. Similar results were observed in the 77 patients added to the series. After treatment with fluphenazine for periods up to 7 months, 47 of the 77 patients were improved, 5 were placed on leave, 4 were transferred, and 1 was discharged. Improvement in these patients was manifested by favorable changes in affect and attitudes, improved behavior and interpersonal relationships, as well as a decrease or remission

¹ Camarillo State Hospital, Camarillo, Calif.

³ Values below 1+ according to the method of Forrest, *et al.*: *Am. J. Psychiat.*, 114: 931, 1958.

of psychotic symptoms. Treatment was discontinued in patients from both groups who failed to improve as well as in 13 of the 17 patients of the entire series who experienced one or more reactions, as follows: parkinson-like symptoms (13), nervousness (7), insomnia (2), gastrointestinal symptoms (3), vomiting (2) and drowsiness (3).

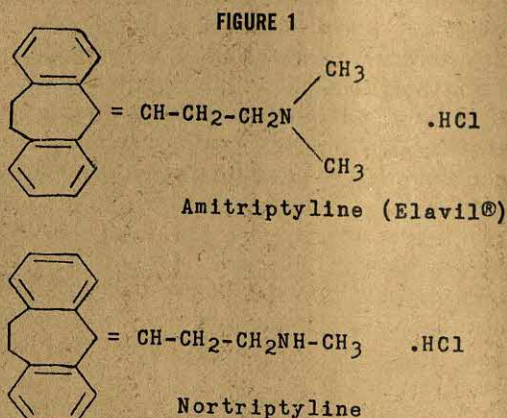

Fluphenazine is effective in the treatment of functional psychiatric disorders. It is effective in low dosage and therefore economical to use; its effect is long-lasting, so that dosage once or twice daily usually suffices; its adaptability for maintenance therapy of patients on an outpatient basis is a definite advantage.

EVALUATION OF NORTRIPTYLINE IN THE TREATMENT OF AFFECTIVE DISORDERS (AND COMPARISON WITH OTHER DRUGS)

JANE E. OLTMAN, M.D., AND SAMUEL FRIEDMAN, M.D.¹

This is a report of our experiences during the last 6 months with nortriptyline (Aventyl)² in the treatment of affective disorders. This compound is 5-(gamma-methylaminopropylidene)dibenzo(a,d)cyclohepta (1,4) diene hydrochloride. Its chemical structure, and its relation to amitriptyline, is as shown in Figure 1.

The drug was administered to 50 female patients suffering from acute or recurrent depressive illnesses. The age incidence was characteristic of patients with depressive states, as follows: 21 to 30—3; 31 to 40—10; 41 to 50—9; 51 to 60—14; 61 to 70—12; and 71 or over—2. Thus, 28 (56%) were over 50 years of age. Diagnostic classification is

indicated in Table 1. Dosage was initiated at a level of 25 mg. t.i.d. or q.i.d., and increased, usually after 7 to 10 days, to 50 mg. t.i.d. Maximum dosage prescribed was 200 mg. daily.

As in previous studies, results were desig-

² Generous supplies of nortriptyline were furnished by Eli Lilly & Co.

nated as satisfactory (A level) in patients who achieved a full remission or much improved state, or as unsatisfactory (B level) in those who failed to improve or exhibited partial improvement only. As indicated in Table 1, 80% of the entire group exhibited an A level of improvement. Thus the final overall results were somewhat superior to those obtained with previous antidepressant drugs, although the difference does not appear to be statistically significant. It may be noted particularly that the results in the manic-depressive group were better than those observed with previous drugs. Speed of action was eminently satisfactory. Initial improvement usually began within 7 to 10 days, and progressed uniformly thereafter. Thus, with respect to temporal factors, the drug compared favorably with imipramine and amitriptyline.

Significant complications were absent. However, side effects, although relatively minor, were frequent. Thirty-eight patients

indicated the presence of one or more side effects, either spontaneously or in response to direct inquiry in this area. Of these, dryness of the mouth was by far the most common, as 26 patients (52%) noted this symptom. In addition, the following were recorded: peculiar ("cotton") taste, 2; dizziness, 6; somnolence, 4; weakness, 3; constipation, 3; sweating, 1; feeling of warmth, 1; mild manic phase, 1. All of these were relatively mild, and tended to disappear after the first week or so. Dryness of the mouth, however, tended to persist. These side effects did not necessitate discontinuation of therapy in any patient. Laboratory data, including alkaline phosphatase and transaminase levels, were normal.

In summary, therefore, it may be concluded that nortriptyline is an effective antidepressant agent. Side effects, particularly dryness of the mouth, are frequent, but not distressing.

DIAZEPAM, A NEW TRANQUILIZER

ARMAND DiFRANCESCO, M.D.¹

During the past 10 years, research in psychopharmacology has increased tremendously and there are now over 65 different drugs available for the treatment of mental illness. While these drugs have had a beneficial and remarkable effect on the emotional states and behaviour of the mentally ill, the variability and degree of effectiveness and side effects have continued the search for better compounds. One of the newest is a benzodiazepine derivative, diazepam (Valium),² with the chemical formula 7-chloro-1-methyl-5-phenyl-3H-1,4-benzodiazepine-2(IH)-one.

We have tested the effectiveness of this drug in the treatment of various mental disorders as seen in a psychiatric outpatient clinic. Diazepam has been described as having approximately 5 times the potency of chlordiazepoxide as a tranquilizer and muscle relaxant. Twenty-six patients of both sexes, between the ages of 7 and 78, were

chosen for the study. The onset and duration of mental illness varied from a few months to 30 years. All patients had received some previous psychiatric treatment including ECT, tranquilizers, antidepressants and psychotherapy with no satisfactory results. Their adjustment ranged from moderate incapacitation to marginal ones. These cases were chosen because they all showed moderate to severe overt anxiety and tension. In addition, 9 patients suffered from reactive depression. Their diagnoses were as follows: 7 chronic anxiety neuroses, 3 obsessive-compulsive neuroses, 1 anxiety hysteria neurosis, 1 schizoid personality, 12 schizophrenia (including 1 chronic catatonic, post-lobotomy), 1 passive-aggressive personality disorder, and 1 adjustment reaction of childhood, neurotic disturbance.

A double blind study was conducted using diazepam and identical placebo. Each patient was started either with diazepam or placebo. In 2 weeks time, their medica-

¹ Monsignor Carr Institute, Buffalo, N. Y.

² Supplied by Roche Laboratories, Nutley, N. J.

tions were switched; this was repeated a second time at the end of 4 weeks. At the end of the sixth week, all were placed on diazepam and continued for a period of 1 to 3 months. No suggestions were made regarding the medication other than that they were required to take it as "part of the treatment program." Patients were interviewed weekly for one hour and given supportive psychotherapy of a minimal nature. Signs, symptoms and current adjustment were noted and recorded. Dosage was started at 2½ to 5 mgm. t.i.d. and increased as necessary. The maximum dosage given was 40 mgm. daily.

From the data obtained, a definite reduction in anxiety and tension was noted when diazepam was taken. No improvement was noted with the placebo and symptoms

usually returned when patients were switched from diazepam to placebo. At the end of the 4-month study, 5 patients showed marked improvement; 17 were moderately improved and 2 had mild reduction of symptomatology. No changes were noted in 2 patients. Side effects occurred in approximately 25% of the cases, consisting chiefly of mild drowsiness, hypotension and nausea. These, however, caused a minimum of discomfort and were easily controlled. Clinically, no serious toxic effects were observed.

Best results were obtained in the neurotic disorders with overt anxiety and tension. Diazepam appears to be an effective tranquilizer with minimum side effects. It deserves further study alone and in combination with other tranquilizers.

TREATMENT OF ENURESIS WITH IMPRAMINE

MARIA A. SALGADO, M.D.,¹ AND OSWALDO KERDEL-VEGAS, M.D.,²

During the last two years there have been clinical notes reporting encouraging results in the treatment of enuretic children (1, 3, 4) and in hospitalized psychotic females ranging from 8 to 16 years of age (2). Recently Dorison, *et al.* (5), reported no significant difference in the rate at which both imipramine and placebo decrease enuresis in adults.

We selected 20 enuretic patients ranging from 4 to 15 years of age from a larger group referred to us for a variety of psychological problems. We administered imipramine following the recommendation of Munster, *et al.* "Patients under 12 years or over 12 but retarded physically, were given 25 mg.; those over 12 years or under 12 but physically precocious were given 50 mg. imipramine" (2). The response to the imipramine was satisfactory from the very first dose. It is interesting to note that although 5 of the 20 patients were mentally retarded, all showed remission of the symp-

tom as long as treatment was continued. The only exception was a female patient with a Laurence-Moon-Biedl syndrome who had diurnal and nocturnal enuresis. We increased the dosage to 25 mg. during the early morning and 50 mg. at bed time. Her diurnal enuresis ceased completely while the rate of nocturnal enuresis decreased sharply.

This treatment is highly recommended because of its lack of side effects, simplicity and the immediate cessation of the condition. We feel that further trial of this treatment on mentally retarded children and adolescents is necessary.

A NEW TOPICAL SPRAY AGENT TO PROTECT PATIENTS ON CHLORPROMAZINE FROM SUNLIGHT

IVAN W. SLETTEN, M.D., RAMON M. FUSARO, M.D.,
AND WALTER J. RUNGE, M.D.¹

Since the introduction of chlorpromazine, it has been well documented that a number of patients on this drug develop a severe sunburn reaction to minimal exposures of sunlight (1, 2). Methods to protect patients have included the use of topical suncreening agents and protective clothing but thus far there has not been a practical, efficient, and consistent means. At the Hastings State Hospital each spring, straw hats are placed by the exit of each cottage and patients are encouraged to use them each time they go outdoors. Patients often forget to wear their hats and the hospital personnel have to warn them to keep on their protective cover.

Recently the Department of Medicine and Division of Dermatology at the University of Minnesota reported a new concept of light protection (3-6). This consists of changing the optical characteristics of the stratum corneum so that 95% of ultraviolet radiation reaching the skin is effectively blocked. Since this filter is part of the stratum corneum it cannot be washed off and wears off as the skin normally exfoliates. The filter is kept at maximal efficiency by reapplication of the mixture every few days to once a week. The topical mixture consists of 0.035% lawsone and 3% dihydroxyacetone in a 50% isopropanol-water solution. The use of chromatographically purified chemicals is mandatory as impurities cause contact dermatitis and instability of the topical mixture.

At the Hastings State Hospital in the spring of 1962, the following procedure and study was initiated:

The physicians and aides on each ward noted those patients who, in previous years, had definitely shown a marked sunburn reaction while on chlorpromazine. These patients were candidates for this study. They were sprayed with the aerosol mixture on all exposed

parts three times a day for two days, every other day for two months, then every four days for one month, and every five days for the last month. The time interval between applications of the spray was not extended further because of lack of sunlight in the autumn.

Forty patients were sprayed with this topical mixture; all were protected if they were adequately sprayed. Four patients who were quite emotionally disturbed and confused were difficult to spray adequately and they showed some sunburn reaction in the areas where they were not properly treated, around the eyes, nose, and under the chin of one; one confused chronic schizophrenic (N. M.) ran outside several hours wearing only underclothes. On areas which had not been sprayed, she became severely sunburned. Besides the 40 patients, 3 additional patients had been asked to be included in the study but they refused to be sprayed. We purposely sprayed one male patient (R. J.) only on his left side. Observers who were not informed as to which side was sprayed were asked which side was sunburned and always indicated the side which had not been sprayed. This same patient was accidentally not sprayed for two weeks; he then began to sunburn. When this patient was sprayed again, he was protected and did not sunburn on prolonged exposure. Another patient (J. L.) sunburned severely for one month before spraying was instituted. He became well protected; later the spray was discontinued when chlorpromazine was temporarily stopped. When chlorpromazine was again started, he sunburned from minimal exposure. He was again sprayed and was completely protected.

CONCLUSIONS

This protective method will be of value in patients taking chlorpromazine. The aerosol spray is simple to apply and need not be applied more than once every five days once the protective filter is induced. It has protected patients who are on chlorpromazine, but whether it will be useful in protecting from other phenothiazine sunburn reaction we are unable to say. We expect that the broad spectral absorption characteristics of this induced topical keratin filter will protect patients who are taking other phenothiazines. Each spraying took

¹ Respectively, Medical Director, Hastings State Hospital, Hastings, Minn. Instructor, Div. of Derm., Research Assoc., Dept. of Medicine, University of Minnesota.

only a few seconds; in our experiment we estimated that the total staff time per patient for the 4 months of the study was 30 minutes. This gave the staff more time to spend with patients as they did not have to seek every few minutes the patients who were on chlorpromazine to see if they were wearing their protective clothes. We found that this protection from sunlight permitted more freedom for the patients since they could participate in outdoor activities during the summer without fear that they would be severely sunburned.

THE DIAGNOSIS OF CEREBRAL ARTERIOSCLEROSIS

J. R. SMYTHIES, M.D.¹

This study was conducted to determine whether, in cases of cerebral arteriosclerosis, the diagnosis made by the clinician was reliable and whether his assessment of 'dementia' on clinical grounds was more or less reliable than the assessment made by the psychologist on a basis of his testing. All cases at the Maudsley Hospital diagnosed as 'cerebral arteriosclerosis' and who had had psychological tests from 1949 to 1957—a total of 44—were followed-up by writing to the general practitioner and to other hospitals, and when the patient was alive by interview. Of the original cases, 26 had died and 5 were in hospital.

1. In 13 cases the original diagnosis was certainly right and all showed, on admission, focal neurological evidence of cerebrovascular disease. Of these dementia was present as follows: marked 2, moderate 4, minor 1, none 6. In these the physician's and psychologist's assessments of 'dementia' were correct in 10 cases. In 3 cases the physician's estimate of 'dementia' was somewhat more accurate than the psychologist's.

2. In 2 cases the diagnosis was probably correct on clinical grounds although signs of focal neurological damage were absent. The two assessors were in agreement.

3. In no less than 11 cases the diagnosis was certainly incorrect. One case was Alzheimer's disease confirmed by post-mortem.

Of the rest 8 were depressive illness, one was hysterical (all of whom subsequently recovered completely), and one an atypical psychosis. Yet in only 3 of these did the physicians and psychologists agree that there was no dementia present. In the others the psychologist's reports were somewhat more accurate than the physician's (if report of 'concreteness' or Goldstein's test are ignored as subsequent work has shown that such findings are to be expected in old people and depressed patients). Yet both assessors reported variable degrees of 'dementia'(3), or reported symptoms commonly associated only with organic disease of the brain(4).

4. In 2 cases an initial diagnosis of depression was subsequently changed to cerebral arteriosclerosis following a stroke. In these 2 cases, too, the psychological tests were slightly more in accordance with the subsequent train of events.

5. In 15 cases the follow-up was too short (3), insufficient information was available (7), or the diagnosis remained in doubt or obscure(5).

CONCLUSIONS

Some points of interest arose out of this study:

1. Some cases of depression(8) were misdiagnosed as suffering from dementia; the impaired powers of concentration and atten-

¹ Maudsley Hospital, London, England.

tion found in depression presumably giving a false impression of impaired memory and of dementia.

2. The reverse mistake was much less common (2 in this series) and one can conclude that only a minority of cases (2 of 15 in this series) of cerebral arteriosclerosis will present without signs of focal neurological damage.

3. The presence or absence of peripheral or retinal arteriosclerosis had no bearing on the state of the cerebral vessels.

4. The small differences between the psychologist's and physician's assessment of dementia is probably of no significance particularly as the psychologists used many tests (e.g., Goldstein's) that are no longer in general use.

ADDICTIVE AND POSSIBLE TOXIC PROPERTIES OF GLUTETHIMIDE

CARL F. ESSIG, M.D.¹

It is now well known that glutethimide (Doriden) can induce physical dependence in man and that the latter may be manifested by a withdrawal syndrome which includes convulsions and/or delirium (1-5). Similar findings have been reported for meprobamate (Miltown) (6-8). It has been suggested that new CNS depressant drugs be tested for their addiction liability in dogs prior to release for use in man (8, 9). The method of chronic intoxication and withdrawal has proven feasible with both barbitol sodium and meprobamate (8, 10, 11) but it has been complicated by death during chronic intoxication of the dogs used in a similar study of glutethimide. Ten dogs were given 51 to 83 mg/kg of glutethimide² by mouth once daily for 3½ weeks. The drug was then given both in the morning and afternoon each day in progressively increasing dosages for periods ranging from 113 to 168 days. Final daily dosages varied from 114 to 424 mg/kg. During the period of chronic intoxication the dogs were obviously somnolent and ataxic (staggering gait). Five of the dogs died during this period at dosages ranging from 300 to 424 mg/kg/day. The 5 remaining dogs were observed for the occurrence of convulsions following abrupt withdrawal of the drug. One of these dogs developed four major convulsions during abstinence after it had received the drug 168 days and the dosage had been increased to 300 mg/kg/day. In

view of glutethimide's demonstrated addiction potential in man the occurrence of abstinence convulsions in the dog assumes belated significance. However, if it had been possible to do adequate addiction studies in the reverse order it is conceivable that some of the cases of human addiction and resultant abstinence syndromes could have been prevented. Moreover, the high death rate in the dogs during chronic intoxication contrasts sharply with that observed in similar studies of barbitol sodium of meprobamate. Carefully controlled chronic toxicity studies of this drug may well be indicated if its use in man is continued.

CASE REPORTS

PAROXYSMAL AURICULAR TACHYCARDIA APPARENTLY RESULTING FROM COMBINED THYROID-IMIPRAMINE TREATMENT

ARTHUR J. PRANGE, Jr., M.D.¹

Since hypothyroidism and depression share certain features, a depressed patient may sometimes receive thyroid extract, and a hypothyroid patient may receive an anti-depressant drug. The significance of this possibility is enhanced if the two types of medication are relatively incompatible, as this case report and animal studies suggest.

A 65-year-old woman was admitted to hospital (Day 1) with vague gastric complaints. Six years earlier she had been diagnosed as hypothyroid.

The patient had an enlarged non-nodular thyroid. She was obese; resting pulse rate was 70; tendon reflexes were sluggish. Radioactive iodine uptake was 5% in 6 hours and 9.9% in 24 hours (borderline low); butanol-extractable iodine was 3.9 gamma % (normal) and cholesterol was 242 mg. % (borderline high).

The patient was given 15 mg. thyroid per day, which was increased to 60 mg. per day.

Five weeks after discharge, the local physician reported the patient was depressed and threatened suicide. On Day 55, she exhibited typical depressive content without motor retardation. A psychiatrist recommended hospitalization and 75 mg. of imipramine daily.

On Day 62 the patient was admitted to a psychiatric center. Her resting pulse rate had increased to 85, and she had lost 12 pounds. Since different examiners were involved, it was impossible to evaluate change in tendon reflexes. No other manifestations of hyperthyroidism were noted.

The patient was observed and given psychotherapy. Thyroid dosage was maintained at 60 mg. per day, while imipramine was increased to 150 mg. per day. The patient gradually improved; on Day 67 BMR was +18; by Day 69 she slept 8 hours each night.

On Day 76 the patient complained of dizziness

and nausea. EKG revealed auricular tachycardia with a rate of 158. Carotid massage restored normal sinus rhythm; but auricular tachycardia recurred twice the same day. The patient was given phenobarbital; thyroid medication was withdrawn; imipramine dosage was maintained at 150 mg. per day. On Day 80 cholesterol was 226 mg. % (normal); on Day 82 BEI was 3.1 gamma % (borderline low).

The patient continued to improve and was discharged on Day 95 with reduced doses of imipramine.

This patient had probably suffered from depression partly manifested by somatic complaints. Initially she may have been slightly hypothyroid; on admission she was likely slightly hyperthyroid, but may have been euthyroid. In hospital the patient received thyroid each day, while possibly she had missed an occasional self-administered dose. If so, hospitalization resulted in an effective increase in thyroid medication.

The evidence for induced hyperthyroidism consists of BMR of +18 and the increase in resting pulse rate. (The patient was neither agitated nor retarded. Weight loss probably should not be cited since weight reduction had been prescribed.) Two laboratory values suggesting normal thyroid function were obtained during psychiatric admission (BEI and cholesterol), but both were obtained during the first week after the discontinuance of thyroid medication and may represent suppression of endogenous thyroid function.

To review, the patient took thyroid for about 50 days before starting imipramine. On the 20th day of combined medication, 11 days after imipramine dosage had been doubled, she experienced auricular tachycardia. Thyroid medication was stopped. The patient had never experienced cardiac irregularity before that time and has experienced none since.

¹ Asst. Prof. of Psychiatry, School of Medicine, University of North Carolina.

This work was supported by NIMH Career Investigator Grant No. MY-1870-C4.

The possibility of thyroid-imipramine interaction warranted animal investigation. It was found that the imipramine LD₅₀ for hyperthyroid mice is 44% of the LD₅₀ for euthyroid mice(1). In another study, hypothyroid mice were found to be more resistant to imipramine death than euthyroid mice(2). Also it is known that in animals prolonged imipramine administration produces loss of thyroid weight and loss of body weight, and that in the cat imipramine potentiates the effect of thyroxin on heart rate(3).

With MAO inhibitors, Carrier and Buday have demonstrated increased toxicity in hyperthyroid rats(4), and Bailey, *et al.*, have noted the poor response to MAO inhibitors of depressed patients also receiving thyroid extract(5). Zile and Lardy have shown decreased liver MAO activity

in thyroid-fed rats(6).

SUMMARY

Auricular tachycardia occurred during combined thyroid-imipramine therapy. Animal studies suggest that the toxicity of both imipramine and MAO inhibitors may be increased in states of hyperthyroidism. The mechanisms involved are under study.

DEVELOPMENT OF PARKINSONISM AFTER GRADUAL REDUCTION OF FLUPHENAZINE DOSAGE

WALTER KRUSE, M.D.¹

Until now it has been assumed generally that the occurrence of extrapyramidal syndromes in patients treated with neuroleptic drugs becomes more frequent the higher the dosage. With slowly increasing dosages the extrapyramidal signs will usually appear within a few weeks, if at all. Where a fairly large dose is given initially, especially if the drug is administered by intramuscular or intravenous injection, acute extrapyramidal reactions usually of the dyskinetic type can be observed within 24 to 48 hours. Other patients develop akathisia as soon as a certain daily dosage has been reached. In cases where the drug is suddenly increased during the course of treatment these reactions, if not already present, may occur soon after the increase.

During the last 18 months while treating more than 100 patients with neuroleptic drugs (mostly fluphenazine) we have observed 3 cases where parkinsonism did not develop until several months after the drug

had been started. Actually, the drug had already been gradually decreased from a maximum of 20-45 mg. daily over several weeks. Only when a daily dosage of 2-5 mg. was reached did the patients develop a parkinsonian reaction. Parkinsonism in these cases disappeared completely after further reduction of the fluphenazine dosage or termination of the treatment.

1. A 22-year-old white male patient who was deluded and hallucinated and showed little expression of affect was first started on fluphenazine on Mar. 13 (2 mg., i.m., t.i.d.). Three days later he was placed on p.o. medication (5 mg. t.i.d.). The dosage was gradually increased until a maximum of 15 mg. t.i.d. was reached on Apr. 16. When, finally, on May 19 a moderate improvement had been accomplished dosage was gradually reduced. On May 28 he received 10 mg. t.i.d., on May 30 10 mg. b.i.d., on June 5 5 mg. t.i.d. and on June 14 5 mg. b.i.d. During all this time no noticeable extrapyramidal signs had been observed. On June 27 dosage was decreased to 5 mg. once daily. The following day the patient exhibited a rather severe parkinsonism

¹ Landeskrankenhaus, Wehnen Post Ofen, West Germany.

which receded completely 3 days after the drug had been discontinued.

2. This 37-year-old white married man, a farm laborer, had entered the hospital because of systematized religious delusions. He was diagnosed as paranoid schizophrenia and had been given the same diagnosis on 2 previous occasions. He was started on 5 mg. of fluphenazine b.i.d. on Oct. 10. There was some initial improvement, but when further progress failed to substantiate the dosage was increased on Nov. 29 to 10 mg. b.i.d. Subsequently, his delusions disappeared gradually. He became more sociable. His improvement continued after the medication had been decreased to 5 mg. b.i.d. on Dec. 28. There was a minor relapse during January, but no change of medication was needed. He improved again and the dosage was further reduced on Feb. 20 to 5 mg. once daily. While there had been no extrapyramidal symptoms during the course of drug treatment so far, on Feb. 21 he showed a rather severe oral syndrome with involuntary protrusion of the tongue, spasm of the masticatory muscles and facial twitching followed by a pronounced parkinson syndrome with gross tremors, muscular rigidity and sialorrhea which subsided within 3 days after further reduction of dosage to 1 mg. b.i.d.

3. Another paranoid schizophrenic, 38 years old, had been ill for several months prior to his admission to the hospital. He was hallucinated in the auditory field and had delusions of persecution. On Jan. 9 he was started on intramuscular fluphenazine (1 mg. t.i.d.). On Jan. 15 he was placed on 5 mg., p.o., b.i.d. The dosage was increased on Jan. 18 to 5 mg. t.i.d. and again on Jan. 24 to 10 mg. b.i.d. There was good improvement, and the dosage was reduced on Feb. 1 to 5 mg. t.i.d. and on Feb. 5 to 5 mg. b.i.d. Because of a slight set-back he was again placed on 5 mg. t.i.d. on Feb. 16, but responded promptly and was therefore reduced again on Mar. 2 to 5 mg. b.i.d. On Mar. 10 he was placed on 5 mg. once daily and on Mar. 16 on 1 mg. b.i.d. Two days later there appeared rather suddenly a moderate but clearly noticeable muscular rigidity, especially of the upper extremities, the typical parkinsonian posture, and slight tremors of the hands. His facial expression was mask-like with the saliva dropping from his mouth. No such signs had been noticed before this date, and there had not been any signs of akathisia or dyskinetic reactions either. The extrapyramidal syndrome vanished within 2 days after the drug had been discontinued.

PSYCHOLOGICAL STRESS AND PETIT MAL VARIANT, A TELEMETER STUDY¹

C. L. YEAGER, M.D., AND A. J. GIANASCOL, M.D.²

The simultaneous study of behavior and telemetered brain waves has not altered appreciably since 1960(1). The latest telemeters, 2.7 cm. in diameter and 0.8 cm. in thickness, transmit the subject's brain waves to a portable, 2-channel frequency modulated receiver and accompanying amplifiers. A 16 mm. sound camera simultaneously records on the film the child and the trace of a small inkwriter built into the camera

assembly. A detailed report of all instrumentation is in press(2).

The child, nearly 7 years old at the time of the filming, was referred to our Children's Service when 4½ years old because of a behavioral regression which followed a head injury at age 3.

He had developed normally except for some minimal gait difficulty in his second year, before his fall.

At age 2 years he fell 25 feet, without apparent loss of consciousness, incurring a fracture of his skull and right femur. Neurological consultation revealed no abnormalities.

He gradually became hyperactive, regressed in toilet training and speech, and by age 3 years he had stopped using any meaningful speech. At age 2½ years minor motor seizures began and continued in clusters of 2 to 6 seizures about every two months despite varied

¹ This is a modified version of a paper "Telemetering of Brain Waves and Behavior Problems," read at the 91st annual session of the California Medical Ass., San Francisco, April 1962. This study was supported in part by State of California Department of Mental Hygiene Grant #60-1-23, "Development of a Technique for and a Pilot Study of Behavior and Brain Waves."

² Respectively, Director, EEG Laboratory, and Chief, Children's Service, Langley Porter Neuropsychiatric Institute, San Francisco, Calif.

anticonvulsive regimens. In addition, he has had a rare grand mal seizure.

He was admitted as an inpatient when 4½ years old. During his 2½ years of hospitalization prior to the filming, he had mastered a few self-care skills but learned at an extremely slow rate, remaining mute except for an occasional word or vocalization. He responded, at times, to verbal instructions.

Physical examination has remained negative except for a questionable Babinski reflex, inconstant throughout numerous neurological and neurosurgical consultations. Repeated pneumoencephalograms have revealed no definitive abnormalities. EEGs have been grossly abnormal and of the hypsarhythmic type.

The following sequences were illustrated by the motion picture film presented at the meeting. One sequence illustrated the relationship between emotional stress and a possible petit mal variant. The therapist handed clay to the child who tossed it into a can. When the supply was exhausted, the child appeared disappointed and stopped his play. Concurrently, a buildup of paroxysmal spike and dome discharges culminated about 4 seconds later in a several-second period during which he was motionless and unresponsive to the therapist's questions. The sequence also illustrated how such a transient petit mal variant might be misinterpreted as "the child's mind wandering for a moment." At other times paroxysmal bursts of less amplitude and shorter duration could not be correlated with either his emotional state or any observable change in behavior. It seemed, however, that during moments of evident pleasure and relaxation such as his sucking on a piece of clay, there was little or no evident paroxysmal activity. Once, as he intently looked at the camera during a period of paroxysmal bursts, the trace returned to a relatively more normal pattern. This is in accord with the experience that some patients can abort the development of a seizure by

focusing their attention on a particular subject or object.

It would be premature to generalize at this point about such data, but the technique augurs to be helpful in the further study of behavior and brain waves.

SUMMARY

The study of behavior and the electroencephalogram has been enhanced by sound motion picture photography and EEG telemetry. The technique led to an unexpected degree of reduction of muscle and electrical artifacts resulting from the elimination of strong electrical fields previously produced by moving electrode wires. The data are permanently available for repeated study and evaluation.

A study of the first film produced using these techniques led to the following observations: 1. In one instance what appeared to be a petit mal variant seemed to follow the child's disappointment. A buildup of paroxysmal activity on the EEG culminated in a momentary lapse in the child's responsiveness. 2. Other paroxysmal dysrhythmias of less amplitude and duration could not be correlated with any apparent change in behavior. 3. During periods of pleasurable activity and relaxation, his EEG returned to a relatively normal appearance. 4. One instance of the child's focusing his attention, apparently aborting a dysrhythmic buildup, was described.

HEPATIC ENCEPHALOPATHY AS A PSYCHIATRIC PROBLEM¹

K. SINGER, D.P.M.²

Hepatic encephalopathy has long been recognized as a complication of the terminal stages of liver disease(1). As its devel-

opment in chronic liver disease is usually associated with deterioration of hepatocellular function as shown by jaundice and fluid retention(2, 3), the diagnosis is usually obvious on clinical examination. But when it occurs in the presence of well-compensated liver disease, its features may dominate the clinical picture(4, 5) and cases

¹ I am indebted to the Honourable Director of Medical and Health Services, Hong Kong, for permission to publish.

² Govt. Psychiatric Specialist, Castle Peak Hospital, N. T., Hong Kong.

have even been initially admitted to psychiatric hospitals (4, 6). Because of their rarity, the ease with which the diagnosis may be missed and the importance of early treatment, two such cases, recently admitted to this hospital, are briefly described. In both, there was paucity of the customary history and physical signs of liver disease.

Case 1. A 40-year-old Chinese man was admitted for psychiatric observation after an episode of violent behaviour. The history could be obtained only from his wife. He had been a seaman, and, $3\frac{1}{2}$ years previously, was hospitalized in England for an unknown illness. Six months later, on his return to Hong Kong, he showed gross personality changes and intellectual impairment and subsequent unsteadiness of gait. As far as could be ascertained, he had never had any manifestations suggestive of liver disease or an operation relevant to it.

On examination, he was grossly confused and violent. He showed evidence of generalized and patchy involvement of the extrapyramidal and pyramidal systems, with parkinsonic facies, hypersalivation, slurred and explosive speech, generalized fine tremor, "flapping" tremor, clumsiness, hypertonia and hyperreflexia in the upper limbs and absent abdominal reflexes. An old linear scar ran along the level of the ninth right rib the major portion of which was missing. There was no sign of liver disease.

Laboratory investigations done shortly thereafter revealed: Hb 11.8 g./100 ml. (80%); r.b.c. 4,740,000; w.b.c. 5,350/c.mm. (neutrophils 62%, lymphocytes 34%, eosinophils 1%, basophils 1%, monocytes 2%); platelets 122,000/c.mm.; albumin 3.6 g./100 ml.; globulin 2.6 g./100 ml. Van den Bergh: direct delayed; indirect 0.7 mg. bilirubin/100 ml. Cholesterol 210 mg./100 ml. (ester 160, free 50). Alkaline phosphatase 20 K.-A. units. Thymol flocculation 4+, thymol turbidity 4, and zinc turbidity 8 units. Urea 40 mg./100 ml. Urine: urobilinogen present in increased amounts; bile pigment and salts absent; uric acid 0.4 g., copper 102/ μ g., and total amino-acid nitrogen 86 mg. in 24 hours. CSF normal. Chest x-ray showed a partial resection of the ninth rib. Skull x-ray normal. EEG grossly abnormal, with a dominant rhythm of 3-4 c/s high voltage waves, widespread and bilaterally synchronous.

Treatment included withdrawal of dietary protein, and oral administration of glucose and aureomycin. He recovered maximally in 3-4

days and was left with mild personality changes.

The history later given by his former doctors and the patient may be summarized: At the onset he had a portacaval anastomosis for an episode of bleeding from oesophageal varices due to portal cirrhosis. The operation was followed by a short period of confusion and two months later he was hospitalized elsewhere for "schizophrenia." At this time he had slight dependent oedema and abdominal distension. During the subsequent 4 years, however, he had no manifestations of liver insufficiency, apart from the encephalopathy.

After 3 months' hospitalisation he was discharged on a low-protein diet. He remained in reasonably good health for one year. Thereafter he was unable to restrict his diet, his condition progressively deteriorated and he had several exacerbations of the encephalopathy.

Case 2. A 49-year-old Chinese farmer was admitted with a history of confusion for one week, culminating in semistupor. During the previous 15 months he had had more than 10 episodes of confusion, each lasting two to three days and accompanied by generalised tremor and unsteadiness of gait. On these occasions he would confine himself to bed and could be aroused only with difficulty. Between episodes he appeared almost well but was unable to cope with his former work. He had never had symptoms of liver disease but had been drinking heavily for the previous 10 years. The drinking was not related in time to the confusional episodes.

On examination, he was lethargic and mute, and shortly after admission became unresponsive to painful stimuli. There was evidence of impairment of extrapyramidal and pyramidal systems. He had a moderately fine tremor of hands on voluntary movement, a suggestion of "flapping" tremor, and sluggish reflexes in the lower limbs and absent abdominal reflexes. There were a few spider angiomas in the upper chest region.

Investigations at the time revealed: Hb 11.7 g./100 ml.; w.b.c. 6,000/c.mm.; polymorphs 4,100/c.mm.; E.S.R. 11 mm./hr. (Westergren); bleeding time 3 and clotting time (Macfarlane and Bigg's modification of the Lee and White method) 4 mins. Van den Bergh direct, negative; total bilirubin 1.2 mg./100 ml. Total protein 6.3, albumin 2.6 and globulin 3.7 g./100 ml. A/G ratio 0.7. Thymol flocculation negative, thymol turbidity 1, and zinc sulphate turbidity 2 units. Alkaline phosphatase 8 K.-A. units. SGOT 18 and SGPT 15 units (Karmen)/100 ml. Total cholesterol 190,

ester 140 and free 40 mg./100 ml. Blood V.D.R.L. positive. Urine, C.S.F. (including V.D.R.L.), x-rays of skull and chest and Barium Swallow for oesophageal varices were all negative. EEG : when stuporose—irregular, symmetrical, generalised 3 c/s waves of 80 μ V ; in lucid intervals—normal. Liver biopsy : cirrhosis.

He was treated with protein-free diet, glucose and neomycin and was much improved on the third day. On discharge he had residual mild intellectual impairment only.

Two cases of hepatic encephalopathy occurring in the presence of well-compensated chronic liver disease and presenting as diagnostic problems are described. The

importance of early recognition and proper treatment of such cases is stressed.

HISTORICAL NOTES

FAMILY CARE OF MENTAL PATIENTS

CYRIL GREENLAND, A.A.P.S.W.¹

During the past year two articles dealing with family care of the mentally ill appeared in this Journal. The first (119: 116, 1962) dealt with the decline of family care in the Belgium village of Gheel; the second (119: 154, 1962) described the growth of family care in Norway. The purpose of the present historical note is to describe briefly the fate of a Japanese "Gheel" in the village of Iwakura near Kyoto.

According to tradition the third daughter of the Emperor Gosanjo, who reigned from 1068 to 1072, developed melancholia in her eighteenth year. After praying night and day to get her well, the Emperor had a divine inspiration. Obeying this he confined his daughter to Daiunji, a temple at Iwakura, where everyday she drank from the holy fountain. It seemed that the water had healing effects on mental illness and soon the Princess was fully restored to health.

This news quickly spread and brought fame to the temple. As a result the mentally ill in great numbers came there to be cured. At first three small inns were constructed to receive them. Later tea-houses, villas and cottages were established to provide accommodation for the ever increasing population. These patients prayed to the principal image, Ekadasamukha (the Goddess of Mercy with eleven faces), drank the waters and bathed in the waterfall until they too were recovered.

In 1884 at the request of their government the people of the village built the first

Iwakura Mental Hospital which had 450 beds. The medical staff supervised the inns and cottages which continued to care for patients. Some of the large inns, by now called health resorts, took in as many as 40 patients, the smaller ones about 15.

Most of the cottages provided family-care for two or three patients. They usually shared the occupation of the households which was mainly out-door employment in the fields, gardens and forests. The attitude of the people of Iwakura to patients was friendly and understanding and their village was regarded as a most suitable place for the care of the mentally ill.

Towards the end of World War II the Iwakura Hospital was taken over by the military and used as an army hospital. Later it became a home for the aged of Kyoto prefecture. As the mental hospital was closed the number of patients in health resorts and cottages decreased. They were completely gone in 1950 when the Government made it illegal to care for the mentally ill except in a hospital. It is not expected that the colony system at Iwakura will be restored.

The present Iwakura Mental Hospital, with 460 beds was built in 1953. It is a well equipped hospital of modern construction. Dr. K. Kubo, the director and psychiatrist-in-chief writes² "Patients on the open-wards have all the freedom; they enjoy walking around the neighborhood and playing ball-games *etc.*, just like most of the Western style hospitals."

² Personal communication.

COMMENTS

SIGNIFICANCE OF THE EARLY 19TH CENTURY CONTROVERSY REGARDING SHOCK THERAPY VS. MILIEU THERAPY

Psychiatrists today differ as regards the relative values of shock therapy and milieu therapy. It is interesting to note that the current dispute is a repetition of one that occurred in the first half of the 19th century.

The start of that century saw the introduction of shock therapy in the form of centrifugation of patients. Cox, who originated the treatment, wrote: "This is a new remedy in the treatment of maniacs, and it is one of very extensive powers and properties, both as a medical and moral mean. . ." (1).

Several pages of description of devices for centrifuging patients are followed, in the third edition of Cox's book, by more than 20 pages of indications for and effects of the treatment. Of particular interest is the comment on anorectic patients:

But there is another class of maniacs, who, bent on suicide and having been prevented from accomplishing their purpose by other means, have effected it by starvation, in spite of every precaution that could be devised; for such cases the swing offers a dernier resort, and effects of which, judiciously regulated, have counteracted the horrible purpose, either from a dread of the repetition of the painful process, or from exciting new ideas and obliterating the old ones. Hence such patients have been induced to take food, and thus life has been preserved.

William S. Hallaran summarized his 3 years' experience in his book, published in 1810. He wrote(2):

In several cases of continued insanity, where I have been induced to call in the aid of the swing as a demiere resource, I have been most agreeably surprised at the unexpected alteration which it had effected after three or four trials. In some, who from an inclination to commit assault, and who through necessity, had been closely confined to solitary apartments, it had so operated, as not only to render them easy of access, but also of kind and gentle

manners, and in the end, of the most willing disposition to aid the servants of the house, in the usual occupations of cleanliness, and in the attendance of others. . .

Prichard reviewed the situation in 1835 in the following words(3):

Darwin, in modern times, made the proposal known. A rotatory couch, in which the patient was to be turned around with rapidity in a horizontal position, was the plan recommended by the last mentioned writer. Dr. Cox, who brought the suggestion into actual use, improved also on the scheme. He used a swinging or rotatory chair, in which the patient remained seated during the operation. Hallaran and Von Hirsch have recommended a ship-bed or hammock. In the hospital of La Charité at Berlin, rotatory machines on both principles are constructed; one for horizontal and the other for perpendicular rotation. The application of this remedy has been still further varied by Dr. Hoven and by Hayner.

That it must be advantageous to a medical practitioner who has the care of maniacs to have within his reach the means of reducing occasionally the morbid activity of such persons by thus lowering the energy of the physical powers, could scarcely admit of doubt. Experience confirms this presumption. Some writers have, indeed, ridiculed the idea of attempting such a remedy, and others have thought it difficult to imagine on what principle it can be of any service; but those practitioners who have put the proposal to the test of experiment have, if I am not mistaken, in most instances been convinced of its utility.

The rotatory swing is also useful as a method of moral restraint. Its effects are so disagreeable that the threat of a repetition has a salutary influence upon turbulent and untractable patients. . .

It is interesting that the beneficial effects of this type of shock therapy were ascribed by Hallaran to its being a form of punishment, whereas Cox emphasized its physiologic effects, including those on the sympathetic nerves. Cox based his conclusions on

the premise that "passion, in a physiologic sense, may be defined as an affection of the nervous system, communicated from the brain to the sympathetic or visceral nerves. . . ." The works of Guislain and of Hirsch illustrate the machines used; it is evident that the most elaborate and best-constructed were made in Germany.

In the meantime, milieu therapy was being employed more and more widely in England and to some extent in the Netherlands; however, German physicians regarded it as valueless. John Conolly, a leading exponent of milieu therapy in England, wrote a book in 1856(4) that described this treatment in words that would sound familiar to modern psychiatrists who have rediscovered this form of treatment.

With remarkable self-satisfaction Conolly described the effects of changes he made at the Middlesex Lunatic Asylum at Hanwell: he discussed such topics as "disuse of mechanical restraints," "the number of attendants increased," "vigilance and moral management substituted for restraint," "want of resources in offices and attendants accustomed to rely upon restraint," "necessity of *forbearance* in the management of lunatics," "no mechanical restraint resorted to for ten years," "reception and treatment of a newly admitted patient," "occupations, etc., in the day time," "evening entertainments," and "necessity of having kind and conscientious attendants." Over 50 pages of text were used to describe the spread of his ideas to other English hospitals.

Conolly noted that "in all asylums the statistical registers show that the recoveries, in the recent cases admitted, are in the first year numerous; that in the second year from the commencement of the malady they are much fewer; and that in the third and subsequent years they become rare." He then claimed, without recourse to published statistics, that in good hospitals "one-half, perhaps two-thirds, of the recent cases recover; whilst not one-third, perhaps not one-fourth, of those recover who are injudiciously treated on the first appearance of the malady." Conolly is modern not only in his views about how to use milieu therapy but also in proclaiming, without relying on data, its superiority over all other forms of

treatment. As might be expected, Conolly sneered at shock therapy and emphasized untoward reactions to it:

We read with almost as much amusement as wonder the respectful acknowledgment of Dr. Hallaran, that Dr. Cox made known to the profession the "safe and effectual remedy" of the circulating swing, the invention of which Dr. Cox "Generously gives the credit of" to Dr. Darwin; this invention being one by means of which the maniacal or melancholic patient, fast bound on a sort of couch, or in a chair, was rotated at various rates up to one hundred gyrations in a minute . . . It is acknowledged that patients once subjected to the swing were ever afterward terrified at the mention of it; that it lowered the pulse and the temperature to such a degree as to alarm the physician; that it occasioned a "disagreeable suffusion of the countenance," frequently leaving an ecchymosis of the eyes; that it acted as an emetic, and as a hypercathartic; but still it was lauded as reducing the unmanageable, and, stranger still, as causing the melancholy to take "a natural interest in the affairs of life." . . . effects mentioned were induced more certainly when the patient was in the erect position. Worse consequences occasionally resulted, I believe, from this barbarous invention; which probably rendered Dr. Hallaran's recommendation, that no "well regulated institution intended for the reception and relief of insane persons" should be unprovided with a machine of that description, ineffectual.

The use of whirling-chairs, baths of surprise, violent affusions over the body, prolonged immersion in water, and all similar devices, are universally condemned.

Although the specific content of the 19th situation in psychiatry at that time and what obtains now is that Conolly was very much under the influence of an intuitive Viennese system of thought, phrenology. Many modern advocates of milieu therapy are under the influence of another system of intuitive ideas that originated in Vienna.

Although the specific content of the 19th century controversy here described differs from the current controversy between those who advocate shock therapy and those who favor milieu therapy, the basic factors in the dispute are obviously the same. It is evident that the controversy arose then, just as it arises now, because neither type of treat-

ment is curative in all types of psychosis ; indeed, neither is demonstrably effective in securing remissions in chronic cases. The controversy here discussed will undoubtedly continue until a successful specific treatment for currently incurable psychoses (analogous to the specific treatments for the formerly incurable syphilitic and pellagrous psychoses) is discovered.

THE HUMAN MIND

I may be obsessed, or suffering from anthropocentric illusions, but I cannot escape the feeling that the human mind and human curiosity are significant in this world—even perhaps in the cosmos of geological time and intergalactic space. With this impression (or illusion) that the mind is the best of us, and the best of biological evolution, I cannot escape (and neither can you !) the feeling of a responsibility to glorify the human mind, take it seriously, even dream about its ultimate flowering into something far beyond the primitive muscle-guider and sensation-recorder with which we started.

—HARLOW SHAPLEY

CORRESPONDENCE

MASS MEDIA EFFECTS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: I hope that American psychiatrists who are concerned with the problem will not be deterred from reading *Television in the Lives of Our Children* by Professor Wilbur Schramm, Jack Lyle, and Edwin B. Parker because of Dr. Fredric Wertham's criticism in the October 1962 issue of the *American Journal of Psychiatry*.

Professor Schramm's research was the most carefully planned and executed, comprehensive and significant study of this question which has thus far been carried out in the United States. Mr. Schramm and his colleagues report their findings with precision and their conclusions with caution. Their discussion of the relevant issues is wide-ranging, incisive and fair-

minded. It carefully presents and analyzes investigative findings and opinions which differ from as well as support their own.

No one, least of all Professor Schramm, claims that we know enough about the impact of television and other mass media on the development of our children. The answer of course must be sought in research. These badly needed investigations should include the clinical evaluation of representative individuals as Dr. Wertham suggests. They cannot, however, ignore the potent contribution of communications theory and research techniques in which Professor Schramm is a pioneer and leading contributor.

Lawrence Zelic Freedman, M.D.,
University of Chicago.

REPLY TO THE FOREGOING

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: The difference between books of the type of Wilbur Schramm's *Television in the Lives of Our Children*, to which Dr. Freedman contributed, and my own clinical studies is, I am afraid, fundamental. To quote *Faust*: "What separates us is reality."

Professor Schramm writes that in respect to television "the term 'effect' is misleading because it suggests that television 'does something' to children." I think it does, and that the term is indispensable. The saturation of children's minds with violence,

brutality and sneering sadism is doing, and has done, unquestionable harm.

It is unfortunate for American children that the shortcomings of methodology in so much of behavioral science research have led to wrong conclusions. It is not enough, as Dr. Freedman suggests, to "include the clinical evaluation of representative individuals." The whole point of view has to be corrected. It is the clinical examinations that must be the foundation, and not questionnaires.

Fredric Wertham, M.D.,
New York, N. Y.

BLEEDING STIGMATA

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY:

SIR: Therese von Kornersreuth died recently at the age of 64. She was a poor tailor's daughter, who had bleeding stigmata at her palms and felt she suffered Christ's agony. She had spent practically

all her life in bed in a small village in Bavaria.

Her stigmata were repeatedly examined and interpreted both by churchmen and physicians. The religious men said, approximately, the distilling retort of the chemist cannot solve problems that belong in the

realm of the mystical. Some Catholic physicians of the time (1931) likewise wrote that scientists must have the courage to admit that there are supernatural revelations. Nobody went far, however, as the editor of the *Münchener Neueste Nachrichten*, Fritz Gerlich, who declared that on account of his training as a historian he must accept the facts about Therese von Kornersreuth as completely verified.

Against these voices, physicians showed that bleedings may be accounted for without resorting to the supernatural. In Karl Jaspers' *Allgemeine Psychopathologie*, (7th

edition, Berlin : Springer Verlag, 1959) a number of authors are listed who wrote on skin stigmata : Kohnstamm and Binner, 1908 ; Heller and Schultz, 1909 ; Pollak, 1938 ; More, 1914 and Rudolph Schindler, 1927. The paper by Schindler deals specifically with the stigmata in the hands of Therese von Kornersreuth and relates them with observations on skin effusions under the influence of various, among them also non-religious, emotions.

W. G. Eliasberg, M.D.,
New York, N. Y.

WAR PSYCHOSIS

Editor, THE AMERICAN JOURNAL OF PSYCHIATRY :

SIR : This letter is prompted by an item in the minutes of a recent meeting of the Executive Committee, referring to a request of a member for the appointment of a committee to study "alternatives to war." I hope an increasing number of our membership have this matter on their minds as a proper subject for study by the American Psychiatric Association. The request was presumably referred to the Committee on International Relations.

You will recall that this was the subject of my presidential address (read at the Richmond meeting in May 1941 and published in the Journal in July 1941), entitled "The Psychiatric Public Health Aspects of War." I had deviated from the usual subject matter of presidential addresses because this subject was closest to my heart and because I considered it a field in which modern psychiatry should play an important role. It was also timely, World War II having begun more than a year previously for many nations, and only months later Pearl Harbor was to bring the United States into the conflict.

My thesis was that as "wars begin in the minds of men," and as psychiatry's main field is the minds of men, in their psychopathological reactions, psychiatrists could not avoid responsibility for study in this field and for attempting to do something about it, in co-operation with all the other

social sciences. The public health aspects of war are, of course, the damage and destruction to the minds and bodies of so many people throughout the world. In that address I called for the appointment of a Committee on International Relations, which was appointed for the first time the following year by my successor, the late Dr. James K. Hall. It was my hope that such a Committee would undertake serious study of the problems involved and would attempt to bring into inter-governmental bodies psychopathological interpretations of international wars (cold and hot) and hopefully find some preventive and psychotherapeutic skills to aid in removing eventually one of the most devastating public health menaces—war. During the intervening 21 years great progress has been made in overcoming mankind's natural enemies—leprosy, tuberculosis and polio, to mention only three—but there is no evidence that any real scientific progress has been made to overcome mankind's worst enemy—man.

I presented a second paper on this subject to the Association, entitled "International Psychiatry in the Post-War World," (published in our Journal in January 1944), in which I extended and enlarged some of the ideas in my earlier paper. Reprints of both papers are available on request.

The purpose of this letter is to challenge again our Association, and its Committee on International Relations, to their full respon-

sibility in the field of international psychopathology in the hope that, even if it is too late to prevent World War III (or is it?), World Wars IV, V, VI, *etc.*, may never occur.

May I conclude by quoting a paragraph from my 1941 address, which I hope will strengthen the response to this challenge:

If events are left only to political leaders and to the emotional reactions of the leaders and the lead, you and I know that in 1965, or some such year, the babies our colleagues are now ushering into the world will suffer and die by the millions in another fratricidal war. The ordinary man, the ordinary woman and

child, pay in blood, tears and taxes for this fearful psychosis, a psychosis essentially preventable, not preventable by us alone, or by any group alone, but by the intelligent co-operation of all bodies in the social sciences, not least of which should be preventive psychiatry . . . Who can foresee the achievements of psychiatry in the next hundred years? When the history of our second century comes to be written, may it be recorded that the American Psychiatric Association was largely responsible for the elimination of the international psychosis—war.

George H. Stevenson, M.D.,
767 Ilalo Street,
Honolulu 13, Hawaii.

PRESENTING A PAPER

In my opinion the reading aloud of a written paper is a cardinal sin, as deplorable as meretricious writing; it is a wicked procedure utterly contemptuous of the audience and unfair to it.

—GEORGE SARTON

NEWS AND NOTES

NEW YORK OFFICE CHANGE OF ADDRESS.—The New York office of the American Psychiatric Association and of the Business Manager of the *American Journal of Psychiatry*, Mr. Austin M. Davies, is now Room 1700, 1270 Avenue of the Americas, New York 20, N. Y. The phone number remains the same, CIRCLE 5-8844.

CANADIAN MENTAL HEALTH ASSOCIATION PLANNING COUNCIL.—The National Scientific Planning Council of the Canadian Mental Health Association announces the establishment of a *Committee on the Law* in relation to psychiatric disorders and services. The Committee comprises physicians and lawyers under the chairmanship of Dr. F. C. R. Chalke, Professor of Psychiatry, University of Ottawa, and will concern itself with the essential requirements to be met by legislation, the changes necessary in the light of changes in patterns of psychiatric care, and with the principles of legislation.

Communications from interested persons are welcome and should be addressed to the Secretary of the Committee, 11½ Spadina Road, Toronto 4, Ontario.

AMERICAN SOCIETY OF CLINICAL HYPNOSIS.—The Society will hold its 6th annual meeting at the Jack Tar Hotel, San Francisco, Calif., Oct. 10-13, 1963.

FEDERAL GRANT-IN-AID PROGRAM.—Dr. Luther L. Terry, Surgeon General of the Public Health Service, announced that \$4.2 million will be made available through the National Institute of Mental Health on a matching basis with each state receiving at least \$50,000.

Dr. Robert H. Felix, Director of NIMH, presented tentative guidelines for the grant-in-aid program, pending formal publication of the guidelines and regulations governing the program.

THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The 1963 schedule of examinations to be given by the Board is: Mar. 30, Apr. 1-2, 1963—New Orleans, La.; Oct. 12, 14-15, 1963—Chicago, Ill.; Dec. 7, 9-10, 1963—New York, N. Y.

The following are new Diplomates certified by the Board at the examinations held in New York, N. Y., Dec. 8-11, 1962.

LYNCHBURG TRAINING SCHOOL LECTURE SERIES.—Feb. 28, 1963—T. R. Johns, M.D., Diseases of the motor unit.

Apr. 18—Miss Eleanor J. Collard, R.N., Psychiatric nursing of the mentally ill and mentally retarded.

May 2—Alanson Hinman, M.D., Reduction of drug therapy in the therapeutic environment.

May 16—Bernard Scher, Ph.D., Diagnosis and treatment of retardation.

June 20—James D. Beaber, Ed.D., Education of exceptional children.

BERKSHIRE FARM INSTITUTE FOR TRAINING AND RESEARCH.—This Institute has been established at Canaan, New York to provide training to persons planning to work in juvenile delinquency, to conduct research, and to disseminate information to interested persons. Field work placement opportunities will be offered for social workers along with internships for psychologists and psychiatrists and training for special teachers, and others in related activities.

The Institute director, George H. Weber, was formerly Chief of the Technical Aid Branch of the U. S. Children's Bureau. Persons interested are invited to communicate with the Director, Berkshire Farm Institute for Training and Research, Canaan, New York.

UNIVERSITY OF MONTREAL TRAINING IN CRIMINOLOGY.—An autonomous department of criminology has been established since June, 1961. The interdisciplinary program is organized for teaching graduates with bachelor's degrees (honours), graduates in social work, sociology, psychology, or law. Requirements: two years residence; a dissertation; supervised externships, leading to a Master's degree in Criminology. In June, 1963, laboratory facilities will be available for training in research. Over thirty students are enrolled in the department, the first of its kind of Canada. There are 10 staff members, 6 of whom are full time.

KORZYBSKI—GENERAL SEMANTICS.—The 25th Anniversary of the Institute of General Semantics will be celebrated at the International Conference, Aug. 13-16, 1963 at New York University.

The 1963 Alfred Korzybski Lecture will be given by the distinguished surgeon and director of physio-biological research for the Navy of France, Dr. Henri Laborit of Paris. Dr. Laborit is a member of the French group that launched the Association Européenne de Semantique Generale. He dedicated to Korzybski his latest book, *De soleil à l'homme—L'organisation énergétique des*

structures vivants. For his work in psychopharmacology he received the Lasker Award in 1957.

CONFERENCES ON CONGENITAL MALFORMATIONS.—The second International Conference on Congenital Malformations sponsored by The National Foundation-March of Dimes will be held in New York City, July 15-19, 1963 at the Americana Hotel.

Scientists from nine nations will present reports of recent advances in the treatment of birth defects.

Speakers at the Conference will include leading geneticists, surgeons, biochemists, pediatricians, immunologists and epidemiologists. Its general chairman will be Dr. Frank L. Horsfall, president and director of Sloan-Kettering Institute for Cancer Research.

AMERICAN ELECTROENCEPHALOGRAPHIC SOCIETY.—The annual meeting of the American EEG Society will take place October 7-9, 1963, at the Jack Tar Hotel, San Francisco, Calif.

CORRECTION.—In the Case Report by Dr. John A. Sours (*Am. J. Psychiat.*, 119: 584, 1962) the last sentence should have read "30 mg. qd" instead of "30 mg. q.i.d."

VETERANS ADMINISTRATION HOSPITAL, COATESVILLE, PA.—The 6th Annual Institute, Psychiatry and Neurology, will be held Tuesday, Apr. 16, 1963. The general topic will be Research Design in Psychiatry.

BOOK REVIEWS

THERAPEUTIC COMMUNICATION. By *Jurgen Ruesch*. (New York : W. W. Norton, 1961, pp. 480. \$6.50.)

Anyone who has maintained even a nodding acquaintance with the psychiatric literature in communication during the past decade will expect that this eighth book by Jurgen Ruesch will, like the others, be historically erudite yet strikingly original, broadly integrative yet topically specific, and ingratiatingly suave yet pertinently challenging.

Piquant passages in point, telescoped but not twisted :

Historical Perspectives : "Three traditions are exemplified in many . . . psychiatric therapies. The Judeo-Christian tradition is upheld by psychoanalysts [who advocate] . . . purity of belief, exclusion of dissenters, adherence to an established methodology . . . dogmatic defense of the established theory [and] redemption of the morally guilty sinner by the Savior . . . The Greco-Roman influence led to the development of . . . men such as Kraepelin, Bleuler, Charcot and Janet [who] tried to derive laws which would do justice to nature-made order [since] man is in nature, subject to its laws, and . . . adaptation is the best solution.

Finally, we have the Anglo-Saxon influence with its belief that man triumphs over nature by daring, exploitation, resourcefulness and industrial production [as represented by] the group therapists, the child psychiatrists and the interaction therapists. It goes without saying that these three basic trends intermingle with one another and eventually will be amalgamated, but many of the controversies and the bitter feuds in psychiatry and psychoanalysis can be traced to these different value systems and views of nature which go deeper than the individual dares to think."

In the next section, Ruesch previews his own eclectic position as follows :

"Therapeutic communication is the get of four grandparents known as psychoanalysis, re-education, logical reasoning and authoritative suggestion. Not being concerned with purity of origin, loyalty to forefathers or other mythological aspects of art and science, the communication therapist is free to use any source to accomplish his ends. To understand the exchange of messages between people, he borrows from social psychology and cybernetics ; to appraise what goes on inside the

individual, he utilizes the psychoanalytic scheme ; to assess pathology and some of the therapeutic processes he draws heavily from clinical psychiatry, and to assess the cultural and social milieu he turns to the social scientist . . . In terms of experience . . . we have a cumulative body of knowledge which recounts the beneficial results of human communication over several thousand years."

Thereafter follows a fairly well-organized and searching re-examination of psychiatric phenomenology, diagnosis, prognosis and therapy in terms of interpersonal communication : non-analogic, verbal, and socio-cultural. Though Ruesch's writing is occasionally cavalier, his opinions sometimes rather dogmatically expressed, and his aphoristic conceptualizations now and then malapropos (e.g., p. 437, "mismanagement of the energy household") the text is on the whole remarkably clear, the clinical orientations sound and the therapeutic directives refreshingly pragmatic. This, then, is a book for the psychiatric connoisseur who, with old aromas in mind, likes to sample new wines in new bottles.

JULES H. MASSERMAN, M.D.,
Chicago, Ill.

EPILEPSY AND RELATED DISORDERS. By *William Gordon Lennox* with the collaboration of *Margaret A. Lennox*. Two Volumes. (Boston, Toronto : Little, Brown, 1960, pp. 1168, 22 tables, 7 plates, 203 figures. \$13.50.)

Dr. William Lennox began a career in epileptology shortly after phenobarbital replaced the bromides. His 38 years as a student of the disease were paralleled by increasingly frequent advancements in knowledge, more important perhaps being the demonstration of electrical rhythms in the brain by Hans Berger in 1929, the ensuing development of electrophysiological understanding of nervous tissue functioning, and the introduction in 1938 of phenytoin sodium (Dilantin), the first in a series of new and effective anti-convulsant drugs. To a science thus growing, Dr. Lennox and his daughter contributed over 200 papers. The two volumes reviewed here constitute a life collection of information and clinical experience on "the falling sickness." The chapters cover history, classification, clinical manifestations, febrile fits, childhood seizures, statistical studies, genetic and twin studies,

diagnosis, psychological and social concomitants, etiology, and clinical management. The authors tell us not to expect an atlas of electroencephalography, a handbook, or a functional anatomy of the brain. These data are supplied elsewhere by other writers. Instead these two volumes are, primarily, a monumental work representing the authors, their laboratory, and their co-workers. A more astringent style, suitable perhaps for the ideal textbook, would not have reflected Dr. Lennox as his colleagues knew him. This final effort is a scholarly, comprehensive study of the disease. The chapter on history-making is masterful. Something like it should be followed by all physicians who undertake to investigate convulsions; for, in the end, epilepsy is a clinical and not a laboratory diagnosis, and all too frequently poor therapy begins with poor history.

The editing is near-perfect. Indeed I can find only one error, and that of no substantial importance, *i.e.*, on page 589 "artificial parthenogenesis" is defined as the cessation of growth of embryos induced by chemical, thermal, electrical, and radiant stimuli. There are a 23-page book list and 41 pages of references (782 references in all). The index is complete.

THOMAS H. LEWIS, M.D.,
Bethesda, Md.

NEUROPHYSIOLOGY. By *Ruch, Patton, Woodbury, and Towe*. (Philadelphia & London : W. B. Saunders Co., 1961, pp. 521.)

The appearance of this volume, which is reprinted from *Medical Physiology and Biophysics* being the latest edition of Howell's *Textbook of Physiology* is symptomatic of the Renaissance in neurological thought. After the tremendous advances in the neurological disciplines at the end of the 19th century there was relative stagnation for a generation, until modern electronic methods provided a new impetus. Associated with this has been the electronic computer, which has provided an analogue to the nervous system, and information theory and cybernetics, which together have raised the hope that brain function may become comprehensible. As a result there has been a revival of interest in neurophysiology, and a demand for modern texts. This volume of 500 pages is offered to meet this demand. It is a comprehensive text which is suitable both for the beginner and the more advanced worker. Although it is assumed that the reader has a working knowledge of neuroanatomy and physical chemistry, the relevant portions of

these basic subjects are outlined so that the text is complete in itself. Because it has been reprinted from a larger text, the space devoted to various aspects of neurophysiology is not perfectly balanced, and there are some gaps, *e.g.*, the regulation of respiration.

It is, however, a satisfactory text of neurophysiology. It is a surprisingly thin volume to have 500 pages, for it has been printed on thin but opaque paper. There are numerous illustrations, mostly line drawings that are clearly reproduced. Where halftones are used a glazed paper is provided. References are provided at the end of each chapter and there is an adequate index.

This volume provides a suitable textbook for the serious student of neurophysiology. It is designed to give the medical practitioner a background for his clinical work, but stays well within physiological territory.

JOHN W. SCOTT, M.D.,
University of Toronto.

THE FACTS OF MENTAL HEALTH AND ILLNESS.
Third Edition. By *K. R. Stallworthy*.
(Christchurch, New Zealand : N. M. Peryer Limited, 1961, pp. 227.)

In the preface to the third edition the author states that the book is based upon a series of popular lectures given to lay audiences. The book is, therefore, intended for the layman. The author agrees that there is danger of oversimplification in a book of this sort, but he feels that he must take this risk. One is surprised to find in the preface the statement, "Any case histories quoted are fictitious; they could all very easily be true, but they have not actually happened within the experience of the author." It is, of course, a common practice to alter and distort many case reports in the scientific literature in order to prevent any identification. Perhaps for popular teaching it is just as well to use fictitious cases.

There are 14 chapters in the book. The first seven deal mainly with the discussion of the normal workings of the mind and the emotional aspects of life including sex. Chapter 7 discusses getting along with oneself and with others. Chapters 8 to 14 discuss treatment of minor and major breakdowns. The last three chapters deal with criminology, physical and mental illness and hospital care. The chapter, "Intelligence and Those Who Lack It," is one of the very best chapters in the book.

On the whole the author does an excellent job in giving us a book that can be recommended for popular reading.

K. M. B.

KLINISCHE PSYCHOPATHOLOGIE. By *Kurt Schneider*. 6th Ed. (Stuttgart: Georg Thieme Verlag, 1962, pp. xii + 170.)

The fifth edition of this remarkable book was reviewed here in Sept. 1960. It is gratifying to see the sixth edition ("improved") appearing already in 1962. This is the work of a psychiatrist whose stature still appears to be growing.

EUGEN KAHN, M.D.,
Houston, Texas.

EMOTIONAL FACTORS IN PULMONARY TUBERCULOSIS. By *David M. Kissen*. (London: Tavistock Publications, 1958, pp. 238. 35 s.)

The research of D. M. Kissen into the psychosomatic aspects of tuberculosis is a demonstration of the high level of objectivity, precision and usefulness which psychosomatic research can attain. Studying groups of examinees in a chest clinic, using a questionnaire and structured interview technique in which all data were recorded and tabulated before the medical examination differentiated the patients with active tuberculosis from the controls, he was able to clearly demonstrate and prove the importance of psychological factors in the etiology, course and tendency to relapse of this disease.

Kissen's long experience as a chest physician combined with careful experimental design and an expert use of statistical analysis, as well as his ability to observe and listen to his subjects, has enabled him to produce a book of outstanding merit. The clarity of the writing and the use of statistical and verbal summaries has made it both easy and stimulating to read. The careful review of the literature and an excellent 5-page synopsis of his research add to the book's value.

Highly and statistically significantly correlated to the presence of the disease, to poor response to treatment and to relapse, he has found what he terms "a break in a love link." This is a loss (or threatened loss) of an important personal relationship in a person "with an inordinate need for affection." It is impossible in a brief review to present the full depth and understanding which Kissen's observations, statistics and case histories bring to this finding. He proceeds from his research data to a practical discussion of the use of the new knowledge in the management of tuberculosis patients.

In summing, a book of marked importance to anyone interested in psychosomatic prob-

lems, in research methodology in this field or in tuberculosis.

LAWRENCE L. LESHAN, PH.D.,
New York, N. Y.

THE PERSON SYMBOL IN CLINICAL MEDICINE: A Correlation of Picture Drawing with Structural Lesions of the Brain. By *Robert Cohn, M.D.* (Springfield, Ill.: Charles C Thomas, 1960, pp. 196, 127 figures. \$10.00.)

This book contains a different approach to the figure drawing test usually employed by psychology and interpreted in terms of the individual's concept of his body image, his personality, and his preoccupations. These studies, in contrast, emerge from a research neurology laboratory, and deal with symbol formation and use as related to the functional organization of the brain. Patients (N=8000) were given meticulous clinical neurological examinations plus electroencephalograms and the draw-a-person test. Postmortem correlations and comparisons with "elite" intellectual persons were made. The author understands the human figure drawings as formal, graphic, acculturated symbols, dependent primarily on visual training and only secondarily on central schemata formulated by other sensory apparatus. The symbol may be a simple "token," or may contain isolated representational elements which modify the basic person symbol or which may have a signature quality. The development of the person-drawing is related most importantly to neurological maturation, and thus may be delayed or distorted. Asymmetrical drawings are associated with hemi-inattention and homonymous field defects. Serial drawings during recovery from structural lesions of the brain, or during progressive deterioration of clinical status, are especially useful. In a critique of earlier studies the author concludes "The entire picture, although in many instances a signature, appears to have little representational attributes that can be precisely correlated with the individual producer. When such correlations are assayed, uncontrolled speculation and vague opinion dominate the work."

Students of F. L. Goodenough (*Measurement of Intelligence by Drawings*, 1926) and K. Machover (*Personality Projection in the Drawing of the Human Figure*, 1952) will be interested in the perspective offered by this work. Neurologists will find in it a valuable tool. All clinicians will treasure the collection of well described cases.

THOMAS H. LEWIS, M.D.,
Bethesda, Md.

MIGRATION AND BELONGING. A STUDY OF MENTAL HEALTH AND PERSONAL ADJUSTMENT IN ISRAEL. By Abraham A. Weinberg, M.D. (The Hague, Netherlands : Martinus Nijhoff, 1961, pp. 402, incl. glossary pp. 14, bibliog. pp. 8, and appendices pp. 122.)

This is a valuable monograph which makes a contribution to our concepts of migration, mental health, adjustment, affiliation, and the function of psychosomatic symptoms.

The author describes a pilot study aimed at developing reliable comparative methods of sociopsychopathological research. Interrelations between mental health and personal adjustment of immigrants in Israel were investigated. The research was carried out among students of an Ulpan, an institution providing intensive Hebrew courses for immigrants.

The procedure consisted of compiling, computing, and discussing data obtained by a depth interview and a written questionnaire. Four main variables were assessed : mental health, general adjustment, psychomatic complaints, and at-home feeling in the Ulpan (equated with affiliation). Relations were computed between these main variables and a score of other variables. A remarkable finding was the frequent existence of a special form of heteroscedastic relation [a property of a scatterdiagram where the variability in the columns is not uniform], where the regression was flat or fairly flat in a good portion of its range, but then rose steeply towards one end. The steep end was more predictable.

This study achieves a clarification of the concept of personal adjustment, contributes significantly to an understanding of the predictability of adjustment, and formulates an operational theory of mental health and personal adjustment.

Mental health is defined as a state : positive mental health is the dynamic steady state of mind, concomitant with free, undisturbed, interpersonal and intrapersonal relations within a primary group of peers, and accordingly with inner security with attendant basic confidence, ensuring gratification of the needs of belonging and self-realization. It is characterized by adequate personal adjustment.

Personal adjustment is defined more as a process : "a psychodynamism for acquiring, preserving and recovering, i.e., regulating, mental health." Among other facets, active and passive forms are delineated.

The research brought into focus *the need for belonging* and its importance as a pre-condition for mental health.

A byproduct of the work is its clarification

of the needs of migrants, so that this can serve as a source for those concerned with their care and direction—a very vital area.

Dr. Weinberg brings to his task a broad knowledge of the pertinent world literature and presents his material in a thoughtful and well-organized form, which permits rapid scanning or thorough study.

PSYCHIATRIC SOCIAL WORK : A TRANSACTIONAL CASE BOOK. By Roy R. Grinker, Sr., Helen MacGregor, Kate Selan, Annette Klein, and Janet Kohrman. (New York : Basic Books, 1961, pp. 338. \$6.50.)

This book is based on an 8-year study in the outpatient clinic of the Division of Psychiatry at the Michael Reese Hospital and Medical Center. The object was to determine what really were the functions of the psychiatric social worker, with special reference to her role in psychotherapy. In Chapter 5, Critique of Psychotherapy and the Social Worker's Participation, psychotherapy is defined according to different points of view ; there is a discussion of who does psychotherapy ; who receives it ; its goals, methods and results. Following a discussion of research in psychotherapy the point of view of the authors is presented.

A seminar or panel consisting of several well trained and experienced psychiatric social workers, several of whom had been analyzed and all of whom had a good knowledge of psychodynamics, met once a week under the direction of Dr. John Spiegel for the first 2 years, and Dr. Roy Grinker, Sr., for the next 6 years. The psychotherapy conducted by the social workers was presented in detail to the seminar group and agreement was reached regarding next steps in treatment. The thinking of the therapists and the seminar group form a significant portion of the report in this book.

Following a section dealing with a Theoretical Framework for Social Work is a discussion of psychotherapy by the social worker under the headings, Intake Exploration, Information and Recommendations, Experiencing and Modifying Complementary Relationships, Complementary Relationships with illustrative extracts from cases.

The authors chose the transactional approach as best suiting the needs of the patients. It is difficult to describe this method to those unfamiliar with the literature on role theory and communication theory. The techniques are described in Chapter 13. It leans heavily

on a changing mutual system of communications between the two participants of the transaction. The communications are expressed verbally, non-verbally by gestures and expressions, and para-lingually.

In transactional treatment attention is focused on the patients' immediate problems, with the attempt to change the stereotyped patterns that have failed in the past, making use of the role theory.

According to the authors, in psychotherapy the therapist and patient have explicit and implicit roles. The explicit roles are conscious and observable. The patient and the therapist must accept these explicit roles—the patient recognizes that he is sick and wishes to be helped, and the therapist is trained and wishes to help. Each also has implicit or unconscious roles. All the transactions occur within the "current life situation." Each participant has an effect on the other whose response in turn feeds back on the first. The patient attempts to perpetuate his neurotic pattern as a stable role. The frustration of this wish by the therapist produces a feedback to the patient. Messages are received and distortions are corrected. The authors, stressing the importance of understanding dynamics according to the psychoanalytic model, are of the opinion that this is not adequate for understanding the immediate transactions operationally within a psychiatric interview.

The complementary relationship is supportive and lasts until little is added through the transaction; it is not an end in itself. When the decision is reached to continue with psychotherapy, the complementary relationship becomes modified and intensive efforts are made to deal with the implicit roles of the patient. The therapist helps the patient to see explicitly what his implicit roles are. The section on Modifying Complementary Relationships deals largely with the detailed therapy of a young non-psychotic female patient. Her therapy and the discussion by the group cover a major portion of the book. The reader is carried along with the therapy step by step and thus becomes familiar with the transactions between therapist and patient as the implicit roles of each are revealed. The discussion of the defensive mechanisms used by the patient to avoid recognizing her implicit roles, especially the need to regress to a dependency situation, are clearly described.

The authors believe that well trained psychiatric social workers are capable of treating the patient as the primary therapists, and one must assume that they refer to the conditions as they exist in Michael Reese Hospital. We

may assume also that the excellent supervision they were able to offer helped to improve the quality of the psychotherapy.

Other aspects of the functions of the psychiatric social worker are discussed in Chapter 11. These include orienting the patient to the services at Michael Reese Psychiatric Department, services available in the community, contact with agencies and schools, and the contacts with the families of patients. History taking is one of her important functions. She also works with patients who are not motivated for therapy, or those who cannot benefit without radical changes being made in the home. These changes are apparently assigned to other social agencies. She works with the delays the patients must accept before they can begin their psychotherapy.

The goals of therapy are difficult to set. The plan must be flexible and changes made as they are indicated. Through the transaction the therapist helps the patient to have a better understanding of the reality he must meet in the group he will live with. He must regain the equilibrium he had before he became ill and understand how he became ill. The authors feel that social workers tend to give too much reassurance in therapy, the result of their working with anxiety in a supportive way in their social work services. Young psychiatrists often permit and encourage excessive quantities of anxiety which can throw the transaction out of equilibrium. One must locate the optimum amount of anxiety that facilitates mental work recall and understanding.

There is a comparison of the transactional approach with classical psychoanalysis, and it is not surprising that there are great differences. Several references are made in the discussion to the prolonged therapy case to differences between the psychotherapy by the therapist trained to do psychoanalytic therapy and the transactional approach which is a more appropriate comparison. Ever since psychoanalysis emerged as a therapy efforts have been made to modify the time consuming and expensive techniques. Anna Freud told me of efforts Freud made to do this, but each time he was impressed with the fact that the modifications interfered with the results obtained. Since 1931 I have attempted to apply what I had learned from child analysis to working with children in psychotherapy, and so have many of my colleagues. I agree wholeheartedly with the authors that in seeing the patient once a week the therapy must be vastly different than if they are seen in the classical methods of psychoanalysis. Patients when seen once a week in psychoanalytic therapy are not

allowed to regress to the same degree, though some do despite all precautions, and a few remain dependent much longer than we wish. This may be due to our errors, but is often due to ego weakness that defies attempts at separation. We attempt to avoid the development of a transference neurosis. Interpretations of unconscious material are not made except in rare instances when the meaning has become clear. Dreams are used for the help they give in understanding the implicit roles of the patient, but there is no interpretation of deep basic conflicts that may be apparent to the therapist. If early memories are stirred up and can be understood, they are related to the current and at times past conflict.

The differences as I see them between the so-called psychoanalytic therapy and the transactional approach are that the latter is more active, and interpretation of preconscious material begins earlier. More anxiety is stirred up, and attempts are made to prevent its becoming excessive. There is a closer bond, or a more personal one between the therapist and patient, and more feedback of communications. Apparently there is a greater tendency also to refer more frankly to the therapist's implicit roles, and therefore more discussion of counter-transferences. There is thus a greater sharing of emotional reactions. The transactional approach keeps the therapist more keenly aware of the combination of explicit messages and different opposite implicit messages. He is thus able to recognize "double binds" (Bateson) in which the patient has found himself by virtue of these kinds of messages received in his relationships with others—primarily his parents.

References in this book to the literature on communication theory should be carefully read. If as the authors believe after their long clinical investigation, the transactional approach is superior to other psychotherapies, it is important that this method be carefully studied. As in the case of any new technique in psychotherapy, it must be thoroughly understood, objectively tested and evaluated before passing judgment.

Social work has long been dedicated to lessening unhappiness and suffering. It was the first of the disciplines, as many of us can personally testify, to reach out in large numbers to psychoanalysis for a knowledge of psychodynamics. Social workers were very close to their clients through their case work and had long been aware that they could not help those whose behavior they could not understand. Knowledge of unconscious factors in human behavior opened up new horizons,

and offered hope of eventually understanding what made these disturbed people suffer. Social workers proceeded to develop techniques of their own and made important contributions to the therapy and prevention of neurotic conflict and illness. It is good therefore that psychiatric social workers were given the opportunity in this research to demonstrate their skills as psychotherapists.

I am pleased to recommend this book as an important addition to the bibliography for social workers and the other disciplines engaged in the study and treatment of people in emotional conflict.

St. Paul, Minn.

LEHRBUCH DER PSYCHIATRIE. By W. A. Gilarowski. Trans. by H. Lambert. (Berlin): VEB Verlag Volk und Gesundheit, 1961, pp. 540. DM 55.00.)

There has been an ever-increasing interest in psychiatry in the U.S.S.R., and the present volume is, perhaps, representative of many of its kind. The translation into German seems to be better than average. Although the translator, a psychiatrist, "edited" while translating (reducing the voluminous original to 540 pp.), the reader will receive an adequate impression of contemporary Russian psychiatry.

The Table of Contents gives the reader an impression of the differences between Russian and American psychiatric literature. The first part, comprising about one-fourth of the book, deals with "General Problems of Psychiatry"; the second part, "Special Problems of Psychiatry," contains the largest portion of the book. The non-Russian editor is quite candid about the Russian methods in psychiatry: Pavlov gave the initial stimulus to the Russian psychological species of "psychiatric theory." Preventive and pathogenetic therapy are the most important concerns of Russian psychiatry. Particularly characteristic "is the attention which the Russian psychiatrist devotes to the patient, his gentle and humane treatment" (*die sanfte und humane Art der Krankenbehandlung*). Needless to say, Russian psychiatry abounds in successes, and they are documented, step by step. On psychotherapy, however, there is but one page, most of which is devoted to work therapy (*Arbeitstherapie*), since "psychiatric phenomena will be suppressed and the healthy sides of the personality will be stimulated whenever the mentally ill are kept busy with work (*Arbeitseinsatz*)."

For the researcher, this volume represents also a valuable source of references to the Rus-

sian literature, mostly since World War II. The volume is richly illustrated, particularly with color plates of paintings by schizophrenic patients. As was to be expected, little attempt is made to classify the forms of mental illness; neuroses are a "bourgeois phenomenon," which the mentally ill in Russia apparently do not experience. However, while the "Pavlovian" brand of Russian psychiatry has been known in this country for some time, perhaps it is not quite as well known that most of the free countries of Europe (with the notable exception of England) are equally as devoid of dynamic psychiatry as is Russia. Visiting a number of European institutions and clinics, this reviewer found that most psychiatrists in Germany, Austria, and Switzerland are, perhaps, as well acquainted with and practice Pavlovian psychiatry as the Russians. It is in the Pavlovian method that this book aims to teach physicians, even though the interest in psychiatry as practised in the U. S. A. and Canada is lively and in high demand among Western psychiatrists.

HANS A. ILLING, PH.D.,
Los Angeles, Calif.

RECENT ADVANCES IN NEUROLOGY AND NEUROPSYCHIATRY. Edited by *Lord Brain*. 7th Ed. (London: J. and A. Churchill; Boston: Little, Brown, pp. 282.)

This is the seventh edition of a volume which has been appearing regularly since 1929, and which has been almost completely rewritten since the last edition in 1955. Previous volumes appeared under the joint editorship of Lord Brain and the late Dr. E. B. Strauss, who died last year.

The emphasis here is on neurology and on those aspects of psychiatry which overlap with it. Psychiatrists will find particular interest in the chapters which deal with "Consciousness and Unconsciousness" and with "The Cerebral Basis of Mind." The importance of the reticular system is fully discussed and Lord Brain emphasises that if the reticular formation is to be regarded as an "alerting system," this does not mean that it prepares the cortex to receive sensory impulses. However, the *piece de resistance* of the collection is undoubtedly the section on electroencephalography by Professor Denis Hill and Dr. Driver. As a comprehensive review of knowledge in the subject this must be quite unrivalled, and its bibliography is formidable. Sections on intracranial tumours and neuroradiology are also excellent, but that dealing with parkinsonism and its surgical treatment is disappoint-

ingly brief. In general, this is a book of tremendous value to all who are concerned with the nervous system, both in its neurological and psychiatric aspects.

HUGH FREEMAN, D.P.M.,
Salford Royal Hospital,
Lancs., England.

THE ART OF THE STONE AGE. By *Hans-Georg Bandi, Henri Breuil, et al.* (New York: Crown Publishers, 1961, pp. 249. \$5.95.)

This is an admirable volume in every way, beautifully produced, with numerous illustrations excellently reproduced in color, and a text written by the leading authorities on prehistoric art. The price is incredibly low for such a work, and is possible only because the work was produced in Europe.

For those interested in the evolution of the human mind and the emergence of man the art of prehistoric man is an indispensably valuable stock of source material.

The present volume by no means covers the whole world of prehistoric art, but only the rock art of the Old Stone Age, and only a limited portion of that, for the available material is now quite large. The aim of the book is to give the reader a glimpse of that art, but this modest aim is far exceeded by the performance of both the text and the well-chosen illustrations. The whole world is represented, in this highly praisable volume.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

MACROMOLECULAR SPECIFICITY AND BIOLOGICAL MEMORY. Edited by *Francis O. Schmitt*. (M.I.T. Press, 1962, pp. 119. \$3.00.)

This collection of lectures offers a fascinating insight into the future of neurophysiology. It whets the appetite for speculation about the function of the brain as a control system, and brings to light for many of us our weakness in the logical appreciation of control systems in general so necessary for a basic understanding of nervous system function.

To serve its purpose of being read easily and at least partially understood by a broad group of readers, which it does so very well, it must also of necessity lack the depth of detail, both experimentally and speculatively, that is sought by the interested participant in this field.

It must be hoped that a more complete volume in this area will be forthcoming to satisfy the desire that this volume has created.

WILBUR R. MCCRUM, PH.D.,
Detroit, Mich.

OFFICIAL NOTICES

ABSTRACT OF THE PRESIDENT'S MESSAGE TO CONGRESS ON MENTAL ILLNESS AND RETARDATION

FEBRUARY 5, 1963

Government at every level, private foundations and citizens must back a totally new approach to the problems of mental illness and retardation—an approach that will seek out the causes and eradicate them, that will strengthen the knowledge and the *manpower* to sustain the attack, that will improve programs and facilities serving the mentally ill and retarded. *Prediction* : If we launch this new approach, it will be possible in a decade or two to reduce the number of patients now under custodial care by 50% or more.

MENTAL ILLNESS

We will avoid throwing more money into the states to finance more custodial care. The prime emphasis in the new approach will be on community mental health centers which will have in common these essentials : diagnostic and evaluation services, emergency, outpatient, inpatient, consultative, and rehabilitation services, day and night care, foster home care, and mental health information and education services. Starting in fiscal '65 the Federal Government will finance 45%-75% of the construction cost. It would also finance up to 75% of the *initial* staffing cost and allow another \$4.2 million for the planning of them. Until these centers get fully underway, however, it will be necessary to continue to improve public mental hospital care and \$10 million is recommended for demonstration and pilot project grants to these hospitals. The manpower problem is, of course, basic to everything. It is proposed to expand professional manpower from the existing pool of 45,000 to 85,000 by 1980. Once established, we may anticipate that the comprehensive mental health centers will be financed in the same way as other medical and hospital costs. Long-range Federal

subsidies for operating costs are neither necessary nor desirable. The growth of health insurance coverage will play a vital part.

MENTAL RETARDATION

Mental retardation stems from many causes. Socio-economic-cultural factors play a major causative role. The only feasible program must not only aim at the specific causes and the control of mental retardation but seek solutions to the broader problems of our society with which mental retardation is so intimately related. Prevention should be given the highest priority.

Recommendations : (1) A new 5-year program of project grants to stimulate comprehensive maternity and child health care services and doubling of existing authorizations for Federal grants for maternal and child health and crippled children's services. (2) Improvement of educational opportunities, particularly in slum and distressed areas. (3) Grants to enable states to review needs and programs and for the construction of facilities for comprehensive treatment, training and care. (4) Legislation to increase output of teachers for handicapped children. (5) Expansion of vocational education and rehabilitation services. (6) Project grants to state institutions for mentally retarded. (7) Establishment of three (and eventually 10) new interdisciplinary centers for human development and training of scientific personnel. (8) New authority for the Children's Bureau to engage in research in maternal and child health and crippled children's services.

Note : The President will discuss the health manpower problem at greater length in a later message to the Congress.

Robert L. Robinson

UNCONSCIOUS MOTIVATION AND THE POLYGRAPH TEST

H. B. DEARMAN, M.D.,¹ AND B. M. SMITH, Ph.D.²

A young bank vice-president was referred to the senior author by his employer, the president of the bank, because a lie detector examiner had alleged that the man had stolen money from the bank. A complete audit of the books had revealed no losses, and the president, expressing great confidence in his employee's integrity, wanted to "get to the truth of the matter." In the course of giving the client a complete medical, psychiatric, neurological, and psychological examination, a number of psychological, ethical, and possibly legal issues were raised.

The use of polygraphs ("lie detectors") in research and in law enforcement situations is well known (7, 10) and need not be reviewed here, but our search of the literature has revealed a dearth of authoritative reports of their use in business operations. *Business Week* (2) describes the burgeoning of such services both by reputable detective agencies and by individuals. This article also raises questions as to the possible misuse of the technique by unethical "examiners" who are subject to no legal regulations (except in Massachusetts) and who may make claims far beyond the established limits of the procedure. The case reported here exemplifies the hazards of using a method that is not totally reliable even in the hands of the best trained personnel. The implication for the person who is a "false positive" are incalculable, but in the present case they could have cost him his job and could have made future employment difficult. In the case of suspected criminals, unwarranted sentences could be assessed. It was in view of the more extensive danger that this report is offered to a wider audience.

The most frequent uses of "lie detectors" in business are to screen job applicants and to examine employees periodically "to keep them honest." It was in a routine testing of employees that this client gave "positive evidence of lying" and was alleged to have stolen money.

The essential details of the case are here summarized:

The patient, a white, married, 27-year-old man was the only child of parents of average economic status. When he was 7, his parents were divorced ("because the father drank too much"), and he and his mother lived with her parents until he was 13 when the mother remarried. The boy and his stepfather did not get along very well, but he lived at home until he graduated, in the upper third of his class, from high school. He went to college primarily "to get away from home," flunked his first year, but settled down and earned his degree. In his second year of college he met the girl he was to marry 2½ years later. They have one child. He went to work for his present employer shortly after graduating from college and was rapidly promoted to vice-president and manager of a branch bank.

On the occasion of the "routine" polygraph test by the examiner from the bank's detective agency, the patient showed a "violent" reaction to the question, "Have you ever stolen any money from the bank or its customers?" And positive responses to other questions concerning the bank. He also showed a positive reaction to the supposedly neutral question, "Do you drink coffee?" The patient was very upset by his failure to "clear the polygraph" and admitted to some minor misuse of bank funds, such as including parking fees on his expense account. The polygraph test was administered again, and again he "failed to clear." The patient confessed to the polygraph examiner that maybe his worry about personal problems, which he discussed with the interrogator, accounted for the positive reaction, so a third polygraph test was made. Again the interpretation was that the patient was lying and had stolen money. A final polygraph test was done in an effort to pinpoint the amount of money involved. The machine indicated

¹ Formerly, Chief Resident Psychiatrist, Dept. of Neurology and Psychiatry, University of Virginia School of Medicine. Present address: 208 E. Watauga St., Johnson City, Tenn.

² Assoc. Prof., Dept. of Neurology and Psychiatry, University of Virginia School of Medicine.

that he showed peak reactions at \$800 and at \$1100. The patient was thoroughly confused because he could not remember taking any such sums. However, since he had been convinced that he couldn't "fool the machine," he signed a confession that he had taken \$1000 and told how he must have done it. The books were audited, and it was discovered not only that he had not used the method that he had stated but that no shortage of that amount had occurred in his branch since he had been employed there.

As a result of this dilemma, the patient was referred for examination. In the course of the 7 hours of psychiatric examination (including a 2-hour sodium amytal interview) and subsequent psychotherapeutic interviews, the following relevant material emerged:

1. The patient had strongly ambivalent feelings towards his mother. She had divorced his father and 7 years later married a man with whom he did not "get along." In the interim the patient felt neglected by his mother and developed positive feelings for his grandparents. He also felt that some of his mother's behavior towards him was somewhat seductive.
2. The patient's wife was two years his senior, and she had previously been married and divorced. His wife was very similar to his mother in many respects.
3. His wife and his mother were both "customers of the bank."
4. He had been involved in financial affairs with his wife and his mother to the extent of approximately \$800 and \$1100 and about which he felt somewhat guilty.
5. In a number of instances he unconsciously identified wife with mother. His unconscious hostility for his mother was apparently the motivating force for a number of incidents (including wrecking her car and for which one of the sums mentioned above was involved).

It will be remembered that the question on the polygraph examination that evoked the most violent reaction was, "Have you ever stolen any money from the bank or its customers?" It seemed reasonable to assume that the patient was responding to the "customers" part of the question inasmuch as he identified his wife and mother as customers and inasmuch as he felt guilty about financial transactions that he had had with each of them.

In order to test this assumption, an independent polygraph examiner (a woman) was employed. She was given no background information prior to her examination of the patient. She was asked to give the exact questions used by the original interrogator and an additional set of five questions in which "bank," "customers of the bank," and "wife

and mother" were separated.

This interrogator's interpretation of her findings prior to learning the background of the case was that the patient was lying and that he was guilty of theft. A careful examination of the polygraph records shows, however, that only in those questions in which the word "customers" appeared did the patient consistently show emotional reactivity on the polygraph record. On the basis of this evidence, it was concluded that the assumption made above of the patient's identification of wife-mother-customers was responsible for his emotional reaction.

It is interesting to note, however, that at the time of the polygraph examination, even though this material was conscious, it still evoked autonomic responses. It is of further interest that the positive response accompanying a truthful "yes" to the question, "Do you drink coffee?" was apparently due to his mother's prohibition of coffee during the patient's childhood.

The psychiatric diagnosis made for this patient was "acute anxiety reaction" and "adult situational reaction."

The case presented above illustrates the major problems involved in the practical application of the polygraph technique to the detection of deception. In the first place, the concept of "truth" is not easily defined; nor is the concept of "lying" any easier to clarify. Perhaps "truth" must be thought of in relative terms.

In crime detection the usual and obvious assumption of the investigator is that the suspect either did or did not commit the alleged act and that deviations in the autonomic responses reflect conscious deviation in his verbal statements from the "truth," as the "truth" is conceived by the examiner. Laboratory and field studies have shown that this assumption is not always valid. There are many variables other than "intent to deceive" that can produce the observed results. Some of the major variables will be discussed briefly, and the adequately trained, ethical polygraph operator must be aware of and take into consideration these factors in the conduct of his examination and interpretation of his records.

There is evidence of constitutional (biological) variability in autonomic responsivity(8) "which may be at least partially an inherited characteristic." Other studies

have demonstrated correlations between autonomic sensitivity and personality types and between autonomic sensitivity and various physical and psychosomatic illnesses (9, 14). An anxiety reaction is, in one major aspect, a hyperactivity of the autonomic nervous system.

Psychological factors other than conscious deception causing deviant autonomic responses include such situations or stimuli that produce frustration, surprise, pain, shame, embarrassment, *etc.* Some of these stimuli (*e.g.*, startle and pain) are almost universal (though there are some exceptions), whereas others (frustration, shame and embarrassment) tend to be more idiosyncratic. The polygraph examiner may not, and the commercial operations usually do not, know enough about their clients to evaluate these idiosyncratic factors. This aspect is even more complex when the client is, himself, unconscious of the emotional quality of the stimuli.

Experiments in which polygraph recordings were taken during the administration of a word association test show that single words that have very personal (and often unconscious) meanings for the subject will produce deflections of the styli(5). Such an emotionally toned word embedded in a question could be responsible for a response that could be attributed to the question. Compound questions such as were used in the initial interrogation of this patient increase the possibility of misinterpretation of the record.

It has also been demonstrated(6) that learned emotional responses are retained in the autonomic system long after evidence from the voluntary system has dissipated.

The polygraph technique is a very useful research tool, but the courts are wise in their policy of not yet admitting evidence from such procedures. It is possible to get "false positives" and "false negatives." The possible harmful effects on an individual who happened to be a "false positive" cannot be calculated.

The moral and ethical problems related to the use of lie detection in business, and even in criminology, are much too complex to be dealt with in detail in this paper. It must be mentioned, however, that the standard procedure recommended by the pro-

ponents of this technique stresses that the subject be impressed with the idea that the machine "can't be beat." The patient in the present instance had been so convinced of this infallibility that he "confessed" even though he was not guilty and consciously did not consider himself guilty. Thus, the examiner in effect uses deception in his effort to detect deception.

Another ethical question touches the concept of "invasion of privacy." In our case the interrogator elicited private and personal information that was irrelevant to the sole purpose of the test, and his use of that information was ethically questionable. Supreme Court Justice Pierce Butler(3) made the following relevant comment :

It has always been recognized in this country, and it is well to remember, that few, if any, rights of the people guarded by fundamental law are of greater importance to their happiness and safety than the right to be exempt from all unauthorized arbitrary or unreasonable inquiries and disclosures in respect of their personal and private affairs.

As stated above, Massachusetts is the only state that has enacted legislation prohibiting the use of the polygraph examination as a condition of employment. The National Labor Relations Board (1961) prohibited the use of polygraph examinations to determine attitudes of prospective employees towards labor unions by a Washington, D. C. employer.

SUMMARY AND CONCLUSIONS

A case has been presented which illustrates some of the psychological, ethical, and possibly legal problems associated with the use of the polygraph examination (lie detector) in commercial establishments.

The polygraph technique only provides measures of various autonomic responses. The stimuli that elicit these responses, the intervening variables (constitutional predisposition, past learning, conscious and unconscious motivation, *etc.*) and the interpretations made of the resulting graphs are highly complex and are inferences made from more or less incomplete data. In any event, these instruments do not identify lying *per se*. The interpretation of the polygraph record is based on inferences of

varying levels of remoteness. Inference is subjective; hence, polygraph examiners can, and do, make different interpretations of the same record.

It is our conclusion that the application of the polygraph technique as a lie detector is fraught with too many variables and sources of error for it to be used as it is currently being used in business and industry. Its use in criminal investigations and in other situations involving the commonweal (such as screening employees for sensitive government positions) should be carefully and continually scrutinized, lest we find that George Orwell's 1984 is upon us.

PSYCHIATRIC FINDINGS OF THE STIRLING COUNTY STUDY¹

D. C. LEIGHTON, M.D., J. S. HARDING, Ph.D., D. B. MACKLIN, M.A.,
C. C. HUGHES, Ph.D., AND A. H. LEIGHTON, M.D.²

For the past 10 years the staff of the Stirling County Study has been investigating psychiatric epidemiology. We embarked on this study with the idea that an increased understanding of what kind of people develop what kind of disorders would probably lead both to better knowledge of the etiology of such conditions, and eventually to prevention. Since our focus was on the possible effects of the social environment, the research team included not only psychiatrists, but also anthropologists, sociologists, psychologists and statisticians.

Ever since 1955 when we presented some preliminary findings⁽¹⁾ we have continued the analysis of the data, struggling to assess the true meaning of the prevalence estimates, and trying out various ways of relating the mental health results to sociocultural findings that might lead to significant correlations. One major hypothesis has been that the state of social integration of the environment will affect the mental health of the people living in it. In order to assess this it was necessary to distinguish between different levels of integration from effective to ineffective or malfunctional. We looked for communities which would contrast quite sharply with each other in this respect in order to see if psychiatric disorder would be significantly greater where disintegration prevailed. Our criteria of disintegration included broken homes, few and weak asso-

ciations, inadequate leadership, few recreational activities, hostility and inadequate communication, as well as poverty, secularization and cultural confusion.

Methods. The study was made in a rural and small town county in one of the Atlantic provinces of Canada. The population of 20,000 is about half English and half Acadian French and is scattered through the county in small communities of a few hundred or less, with one town of 3000. A major means of data collection was a questionnaire survey of a probability sample of the adults of the county. A systematic sample of households was made, interviewing alternately the male or the female household head. This was supplemented by interviews with local physicians regarding all the individuals surveyed. In addition hospital records pertaining to county residents were collected both locally and from the nearest large metropolitan hospitals. The social scientists made extensive use of key informant interviews and participant observation as well as questionnaire schedules.

The psychiatric data obtained regarding each individual in the sample consisted in a review of the systems of the body for physical symptoms, and a series of questions about psychiatric symptoms. Much of this was derived from the Army Neuro-psychiatric Screening Adjunct, the Cornell Medical Index and other sources. The doctors interviewed were asked about the medical history and symptoms of each respondent, his psychological characteristics and social behavior.

For evaluating these data we used independent ratings by two or more psychiatrists who then prepared a joint evaluation of the person as to whether he did or did not show significant psychiatric symptoms, as to how much his functioning was impaired by such symptoms, as to what the symptoms were, and as to the confidence felt that he might be a psychiatric "case." With a few modifications it was possible to use the terminology of the *Diagnostic and Statistical Manual* (APA, 1952), but we did not try

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

The work has been conducted as part of the Cornell Program in Social Psychiatry and has been supported through funds provided by the Milbank Memorial Fund, the Carnegie Corporation of New York, and the Dominion Provincial Mental Health Grants of Canada. The foundations are not, of course, the authors, owners, publishers or proprietors of this report and are not to be understood as approving, by virtue of their grants, any of the statements made or views expressed therein.

² Dept. of Psychiatry of New York Hospital (Payne Whitney Psychiatric Clinic) and Cornell University Medical College, and Dept. of Sociology and Anthropology of the College of Arts and Sciences.

to make diagnoses. Instead we employed the terms descriptively and recorded for each person as many different symptom patterns as he showed. With this method it was possible to achieve a high degree of agreement between as many as four psychiatrists on each of the required judgments.

A first task of the social scientists was to select communities showing low and high levels of social integration. This was done initially by interviewing knowledgeable local informants. These communities were then studied intensively by social scientists who usually lived in them. The social scientists also analyzed the survey data according to various sociocultural criteria which included occupational position, education, migration, extent of French or English cultural commitment, and religious involvement.

Psychiatric Findings. The first psychiatric findings we shall discuss are those for the whole county, where we surveyed 1010 household heads. The confidence as to whether or not the person is or has been suffering from psychiatric disorder is expressed in a 4-point scale where A means high confidence that he shows disorder, B probable but not as certain, C doubtful but suspicious, and D high confidence that he has *no* disorder. While we used the Manual scale for estimating impairment, the discussion here will be limited to the distinction between significant impairment (20% or more) and insignificant (Table 1).

TABLE 1
ABCD Ratings and Significant Impairment, 1010 Stirling County Household Heads

RATINGS	MEN	WOMEN	TOTAL
A%	21	40	31
B%	26	25	26
A+B%	47	65	57
C%	33	20	26
D%	20	15	17
	<u>100</u>	<u>100</u>	<u>100</u>
Percent with significant impairment	31	33	32

In the Total column of Table 1, one sees that 31% of the sample were evaluated as showing clear psychiatric disorder, while an additional 26% were in the B or "proba-

ble" group. Only 17% show no psychiatric disorder which is almost the same figure as was found in the Midtown Study in Manhattan(2). Approximately one third of the Stirling group are impaired to a significant degree. The columns for men and women give the women almost 20% more with clear psychiatric disorder than the men, though the significant impairment is very nearly identical.

Table 2 presents the kinds of psychiatric

TABLE 2
Percentage of Respondents Showing Various Symptom Patterns *

SYMPTOM CATEGORIES	MEN	WOMEN
Psychophysiologic	66%	71%
Psychoneurotic	44	64
Sociopathic	11	5
Mental deficiency	7	7
Personality disorder	7	6
Brain syndrome	4	2
Psychosis	1	2

* Since more than one symptom pattern can be assigned to an individual, the total of the columns exceeds 100%.

symptoms found in this community sample of people living at home. As one would expect, the great bulk are psychophysiologic or psychoneurotic. Principal sex differences are the extra 20% of women with psychoneurotic symptoms and the double amount of men showing sociopathic behavior.

The considerable excess of persons with psychophysiologic symptoms over those with A or B level psychiatric disorder is a function of our policy in counting this type of symptom. With survey methods we found it impossible to follow the Manual specifications for counting only those psychophysiologic reactions "in which emotional factors play a causative role." This means that we get a high proportion of psychophysiologic symptoms, but it does not mean that we overestimate psychiatric disorder. The corrective comes in the ratings of Table 1, for psychophysiologic symptoms alone are never rated higher than C or B.

Although these figures were not collected from patients under psychiatric treatment but from persons living at home, most of whom did not consider themselves in need of psychiatric treatment and had never had any, yet 55% reported symptoms

which we assessed as indicative of clear (A) or probable (B) psychiatric disorder, and 32% appeared to be significantly impaired. On the other hand, it is apparent from the symptom list that most of the disorders are not what is usually thought of as "mental illness" in any major sense but rather "neurotic" syndromes.

We tried to see if our questionnaire was giving us too many "cases" in several ways, one of which was a collaborative experiment with a general practitioner who initially felt quite sure that we were overestimating the amount of disorder(3). Without knowing any more of our findings than that we had examined a sample of his clientele, he undertook to prepare summary sketches of the adults of his village, noting both physical and psychiatric disorder. He reported the same percentage of people with psychiatric symptoms that we had found by our methods.

In order to make a practical assessment of our findings, we eventually devised a means of categorizing respondents according to apparent need for psychiatric attention. This takes into account both rating, impairment and the nature of the symptoms, including conditions that need attention for diagnostic and prognostic purposes, whether or not treatment is possible. Table 3 shows the proportions of our sample

in the various types of need. Types IV and V are the same as the C and D ratings respectively, while the first three types are ways of distinguishing the level of urgency among the A and B ratings.

From everything we have learned about the relationship between our findings and "reality," we believe that this Table is something of an underestimate of the need for psychiatric attention, but at least it provides a service-oriented assessment of the figures given in Tables 1 and 2. The Type I cases get medical if not psychiatric attention because the environment cannot tolerate them, but the proportion of Type II and Type III cases that can and do utilize psychiatric help varies with all sorts of not easily defined circumstances.

In sum, it appears that at least 20% of the general population has definite need for psychiatric help, while a larger percentage would presumably be assisted by either preventive or therapeutic measures. This corresponds in size with the Midtown group who have "serious" symptoms and varying degrees of impairment(23.4%)(2).

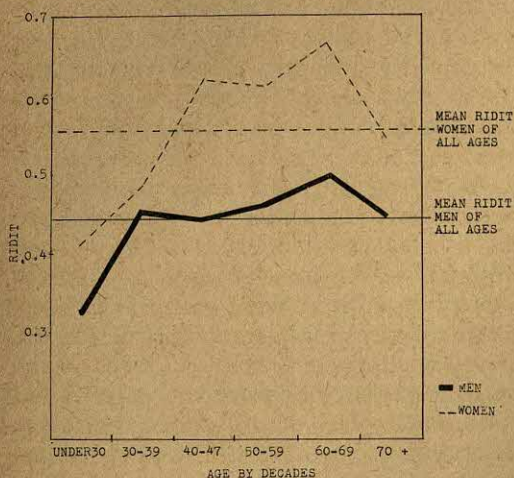

The next aspect is the difference found between various age groups, measured in decades. Instead of using percentages of A, B, C and D here we change to a score based on these percents which is called a ridit(4). This score is adjusted so that the overall county average is at the midpoint, and for any given sub-group account is taken of the proportion of members rated A, B, C or D. Used in this way it provides a rating of the risk that a member of the sub-group will show psychiatric disorder as compared to the county as a whole. The higher the ridit, the worse the mental health status or risk.

Graph 1 shows the variation in ridit with different decades, the solid line being men, the broken line women. The straight lines represent the ridit level for all men or all women, respectively. The graph shows that, from a low ridit at the youngest decade, there is a rather steep rise which is maintained or increased up to the 60 decade, after which there is a drop. We had no upper age limit. This drop is evidence that the method used for collecting and evaluating psychiatric data is not merely reflecting the accumulation of symptoms of all sorts

TABLE 3

TYPOLOGY OF NEED FOR PSYCHIATRIC ATTENTION, WHOLE COUNTY	
	%
Type I. Most abnormal (A rating, plus either psychosis/ brain syndrome or severe impairment)	3
Type II. Psychiatric disorder with significant impairment (A rating, plus significant impairment, but not Type I)	17
Type III. Probable psychiatric disorder (B rating, or A rating but not included in Types I or II)	37
Type IV. Doubtful (C rating)	26
Type V. Probably well (D rating)	17
Total	100

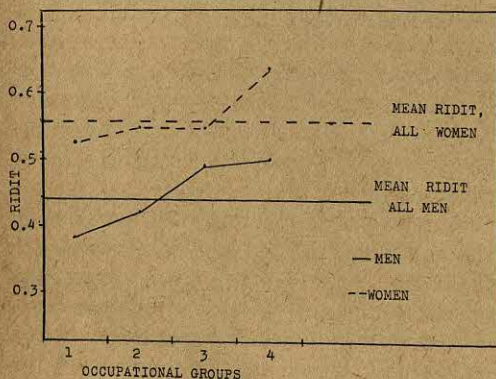

FIGURE 1

as the years roll by, for if this were the case the line would continue to rise. Our data do not reveal whether the drop is due to actual diminution of psychiatric disorder as age increases, or that only individuals without serious psychiatric disorder tend to survive past 70. Further studies are needed to settle this point.

Turning next to differences found in mental health status in relation to sociocultural features, we examined its variation with our nearest equivalent to social class, which we call occupational position. Graph 2

FIGURE 2

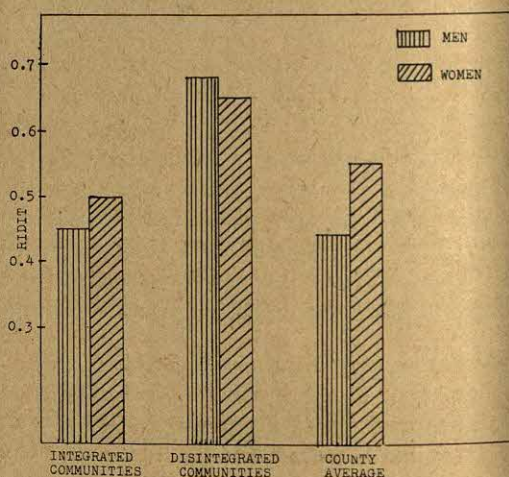

shows that with the highest occupational position, Group 1, there is the least risk to mental health and that risk increases as occupational position worsens. This is much like the findings of other studies, except that in this untreated population we found no

particular type of symptom to be commoner in lower class levels. Most categories are more prevalent (5). One can see a difference between men and women as to which shift in class level seems to make the most difference to mental health status.

Without going into detail, it can be said that the effect of education on mental health status parallels closely that of occupational position, while we did not find any significant differences associated with migration, ethnic identity, or religious involvement across the county. Moreover, when we examined the effect of occupational position in our largest town (3000), the clear linear relationship between class and mental health such as we had found for the county did not obtain.

Considering next the effect of social integration, Graph 3 shows the contrasts be-

FIGURE 3

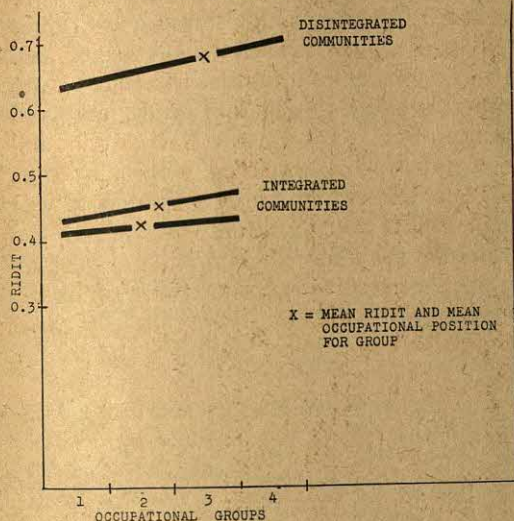

tween persons in integrated and disintegrated communities as compared to the county average. The striking increase in psychiatric risk in the disintegrated communities as compared to either the whole county or the integrated communities is accompanied by a shift in the sex ratio, men in disintegrated communities having a slightly greater risk of developing psychiatric disorder than women.

The question that naturally follows from these two graphs is, "Is it an accumulation of low social class representatives in the disintegrated communities that raises the risk there?" We can say quite firmly, No, it is not as simple as that. Lower class people

in integrated communities are at much less risk than upper class people in disintegrated communities. Graph 4 demonstrates this for

FIGURE 4

the men, for one can see that there is much less difference in risk between highest and lowest occupational groups within a community than there is between integrated and disintegrated communities for any given occupational position. It is the same for the women—no significant difference in rit within a community, but a striking difference between integrated and disintegrated communities.

What do we think is the answer? We believe that it is not any single factor, but that the net effect of all the sociocultural factors mentioned at the beginning creates a social environment which can be characterized as either integrated or disintegrated and which makes the difference in the level of risk of psychiatric disorder for the people who live there. In a rural county these different types of environment are separated geographically so that it is possible to see the contrasts. People tend to live in only one kind of environment, so one has for research purposes something that approximates "pure cultures" for comparison.

We have limited the discussion to the polar types, where either the upper or the lower limits of most of the various sociocultural factors tend to converge. Much commoner are the intermediate communities where there is a mixture of factors, lead-

ing to a mixed effect of the environment on its inhabitants and to intermediate levels of psychiatric risk. In Stirling County the best integrated communities were only a little better off than the average, whereas the disintegrated were much worse off than average.

We found such a mixture, also, in the town of Bristol, where our experience had much in common with that of Clausen and Kohn(6) in Hagerstown when they tried to relate hospitalized schizophrenics to some sort of social stratification without success. When we applied to the town of 3000 the social indicators (occupational position and education) which had shown a linear relationship to mental health status in the county, the result was merely random variation. Similarly, when Clausen and Kohn analyzed their schizophrenics for social class indicators, this did not produce the clear relationships that have been reported in very much larger cities like New Haven(5) and New York(2).

To be sure, there are many differences besides the size of the town among these various studies. Thus the New Haven investigators studied the whole range of psychiatric disorder that was under treatment, while the New York group had aims similar to those of the Stirling County study. Our experience, however, both in the very small homogeneous communities and in the one town of 3000 leads us to feel that size of population has an important bearing on the impact of integrative or disintegrative sociocultural forces upon individuals.

In the town we went one step further and, by rough sociometric methods, determined the groups of social associates of the respondents. The results suggest that there is less risk of psychiatric disorder for a person who is a firm member of a local, well-integrated group than for one of a group of non-conformists. While our numbers are too small for this finding to have statistical significance, it is congruent with the differences between integrated and disintegrated communities, and provides a hint for further lines of enquiry.

CONCLUSIONS

1. As in Manhattan the prevalence of psychiatric symptoms in the general popu-

lation of this rural area is higher than one might expect, with only 17% of adults free of all symptoms of psychiatric significance. About a third of the population shows significant impairment from psychiatric disorder, while twenty-plus percent stand in need of some sort of psychiatric attention.

2. The amount of disorder differs with the biologic variables of age and sex. Except in the disintegrated communities, women tend to show more psychiatric disorder than men though the proportion with significant impairment is approximately the same. Older people tend to show more than younger people until they reach 70 years or so.

3. Considering the 1010 county survey respondents as a whole, our indicator of social class showed what has been found in other studies, namely that better mental health is associated with higher social class. This relationship could not be demonstrated, however, in the largest town in the county.

4. Intensive studies of communities that are polar with respect to level of social integration showed a far stronger association of better mental health with higher level of integration than with higher social class within these communities.

5. It is not poverty or limited education or lower class status, *per se*, that makes the difference to mental health, but rather a whole group of factors that tend to be associated with these and that create a social en-

vironment that lacks features that are vitally important to mental health. To improve mental health, economic resources must be mobilized up to a point, education must be provided up to a point, but this will not be enough unless these factors bring with them the other environmental forces which add up to giving the individual the feeling that he is a worthwhile member of a worthwhile group.

Something like this is probably the most important contribution of such endeavors as Hull House or the Peckham Experiment, which by various means served to re-integrate the social environment for many of their patrons.

A LONG RANGE PLAN FOR MENTAL HEALTH SERVICES IN CALIFORNIA¹

AND RALPH LITTLESTONE²

*The State Senate on May 19, 1961, in recommending increased salaries for treatment personnel in the Department of Mental Hygiene requested that the Department submit by January 1, 1962 a statement on its current program and a long-term plan for future developments.

The idea of long-term planning is not new. The Department has had a program committee for a number of years which continuously considered ways and means of improving the care, treatment, rehabilitation, staffing and treatment goals of the Department in line with increasing needs of the state. Previous directors of the Department have discussed this matter. The present director, upon assuming office in 1959, immediately suggested the preparation of a "white paper" on the subject, "Mission, Responsibilities, Goals and Program of the Department of Mental Hygiene." The narrative introductions to budget requests in the past three years have referred to the need for more community services, pre- and post-hospital services, and a speeding up of current institutions to handle increased admissions.

The following developments made it appropriate to present a detailed study at this time.

1. The state's population is increasing by approximately one-half million a year, 200,000 of whom are new-born children in the state and about 300,000, both adults and children, moving into the state from other parts of the country. The result of this population increase is felt throughout the state in terms of many misplaced individuals who have to be absorbed, the constant demand for enormous increases in various facilities, particularly roads, water, hospitals, school rooms, recreation facilities, etc.

It is hard to appreciate the job of providing for the formation of a new city of several hundred thousand each year. The community is changing, as land devoted to citrus in many places is being used for housing; rural areas become suburban; problems related to urbanization are increasing.

2. Another event of marked significance was the release of the report of the Joint Commission on Mental Illness and Health. The Department has agreed with most of the recommendations of the Joint Commission, particularly with regard to the importance of public education and information, community services, training and recruitment of personnel and research. It has differed with the Joint Commission in terms of the size of the small hospital, deeming that even 1,000 is too large; it does not believe that the state hospital should be related only to chronic patients, or that the direct services to patients conducted by the state should be left in the hands of the state government but rather that an increasing amount of responsibility, treatment services and administrative authority should be placed in both public and local private hands. It does not believe that the federal government should pay an appreciable amount of the running expenses of state hospitals, but that federal funds should be increased for current types of expenditures, particularly research, training, demonstrations in hospitals under Title 5, and community services' funds under the State Mental Health Authority and construction. The impact of the report of the Joint Commission on California has been large and extremely useful and in general it endorses the findings and plans of leading authorities in the field of mental health and psychiatry and the leadership of the Department of Mental Hygiene.

3. Dramatic advances from a low relative position among the states in 1940 include more importantly: a) An increase

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² From the Dept. of Mental Hygiene, Calif.

in admissions from 8,000 in 1948 to 27,000 in 1961. Releases have kept up with admissions and in recent years have exceeded admissions. b) A reduction in number of beds for general mental patients from 303/100,000 population in 1950 to 208/100,000 for 1962-63. This is better than 30%. An absolute reduction in numbers of patients in hospitals has also been achieved in face of the rising population. c) The state operates 35,800 beds for general mental patients, 12,000 for retarded. The only other large state with comparable population, New York State, operates 88,000 for general mental patients and 26,000 for retarded. Yet each admits about the same number and releases about the same number. Personnel have increased chiefly on admission and acute treatment wards—altogether from 9,000 in 1950 to 21,000 in 1961; from 4.3 to 2.4 ratio of patients to employees. *Per diem* expenditures have risen from \$1.10 in 1940, to \$3.49 in 1951 and \$7.90 in 1961-62.

The state has spent about \$200 million in capital construction since the war. Programs in training and research, follow-up and after care have developed, but *serious deficits exist in 2/3 of our 580 wards which have still only decent custodial care and no treatment services. Salaries are below competitive level, administration is stretched too thinly.*

4. Increased pressures at this time force the department to request large sums for support or construction. These must be justified.

5. An isolated position by state service apart from other efforts in the state can no longer be continued and a good look at state responsibility for the whole state is needed, *i.e.*, leadership—not direct services.

6. Conflict between tax supported services and non-governmental services as a way of life demands reconciliation, and mental hygiene services in California offer a possibility of suitable compromise.

METHOD

A high level committee was created following legislative action and about \$40,000 was obtained from state and federal sources. All departmental staff units, standing committees, advisory committees and many professional and citizen groups were utilized

and 11 task forces of leading citizens were organized and produced a large volume of material. The committee decided on the following steps:

1. A statement should be submitted of general principles relative to the nature and the development of mental disorders and their treatment, which would act as guidelines to all parties in working out the material for the plan.

2. The plan should take into account the variety of needs and resources bearing on mental health, indicating the part to be played by various Federal, state, local and private agencies and individuals, and specifically spell out the Department of Mental Hygiene's role in carrying out the plan.

3. In addition to traditional responsibility for hospitalization of the mentally ill and retarded, *primary prevention of mental disorders* including the nature and extent of the responsibility of the Department for primary prevention was recognized. It was decided to approach these by using the zonal plan for classification of persons.³ This plan called for efforts in Zone 1 (prenatal and birth) which are in the nature of primary prevention; in Zone 2 (normal social milieu) towards the growth and development of healthy citizens as a positive mental health effort; efforts in Zone 3 (non-psychiatric trouble), the relief of external stresses as a deterrent to the development of mental disorders (primary prevention); and Zone 4, direct services (treatment and rehabilitation) for mentally ill and retarded.

General Propositions. Encouraged by the task forces three general propositions were accepted and dominate the plan. These are:

1. The responsibility of the treatment of mental patients shall be essentially the same as in other diseases. It shall rest first with the patient himself and his family and his local doctor, then with other non-governmental agencies and, as these are unable to fill the needs, it shall spread to municipal or county government, state and federal.

2. Responsibility for financing shall be by the individual assisted by private agencies and a variety of federal and state welfare benefits. Local government should

³ Daniel Blain: *Am. J. Psychiat.*, 113: 176, 1956.

be assisted by state funds through adequate subvention, and by federal funds in various ways.

3. Belief that the private sector of society can markedly increase its treatment services is based on the increasing and better distributed number of private licensed mental hospitals and nursing homes, increased units in voluntary hospitals, the anticipated increased participation of the medical profession, and an increased number of psychiatrists. Greater utilization of day treatment services will bring more local resources, part-time professional persons of all kinds, use of non-professional persons and more volunteers.

THE PLAN

Philosophy of the Plan. Current trends are pursued to a logical conclusion. These trends are factors bearing on the local treatment and administrative responsibility with multiple financing :

1. Treatment in the future will require a minimum of hospitalization as treatment techniques improve and the results of early local treatment are further demonstrated.

2. The state is already achieving a reduction of 1/3 of state hospital beds for general mental patients in the last 11 years from 1950 to 1961 and an absolute drop in beds of 1,000 each for the last 2 years. The drop in this curve has accelerated in the last 3 years and with the aid of increased personnel there seems no doubt that it can continue to drop. Thus both a relative and absolute reduction of beds is being accomplished.

3. The third major current trend is extension of the traditional hospital program to extramural services, greater dependence on physician practice, outpatient clinics, day hospitals, family care, and follow-up service. Hospitals are expanding their operations in the neighborhood and this year in a rural clinic additional staff has been added to visit homes for emergency evaluation and disposition.

4. McNeel's Guide ⁴ to treatment services is accepted as a guide : "Adequate treatment should be available (a) as early as possible : (b) as continuously as possible ;

(c) with as little dislocation as possible ; and (d) with as much social restoration as possible."

5. It is believed more economical and administratively more effective to plan treatment services on a local level. This is in accordance with the medical principle above.

General Principles. A set of principles was developed by the Committee as a brief statement of the framework in which mental disorders are developed and influenced toward recovery. These include the relationship of stress, basic goals, practical limitations, environmental implications, range and scope of the subject, importance of local availability both geographical and financial, problem identification, value of generic services, important basic services, timing and location of treatment, basic program elements, the need for goal-centered objectives, subject to measurement, economy and efficiency, and the importance of public responsibility.

Functions of Department of Mental Hygiene. Proper functions of the Department were developed as follows : As the major arm of the state government in this field, and as a member of the Health and Welfare Agency, under the Administrator of this agency and the Governor, and under authority and with resources furnished by the Legislature, this Department should continue to :

1. Provide leadership, consultation, and suitable assistance to the administration and other departments for their personnel and wards and the carrying out of their functions, as they may pertain to the field of mental health.

2. Work particularly closely with the Department of Public Health and Department of Social Welfare as co-members of the Health and Welfare Agency in matters pertaining to mental health needs of the state and mental health as parts of their major concern and programs.

3. Represent the state in efforts toward overall evaluation of the needs of the state as a whole and assist other responsible parties in efforts towards meeting these needs.

4. Represent the state to the Federal Government as the "Mental Health Authori-

⁴ Mental Hospitals, 9 : 27, 1958.

ty" and share in the policy determination on use of federal moneys in other departments as they apply to mental health institutions or mentally ill people.

5. Furnish consultation, organizational and developmental skills as requested to local government and private agencies in their operations and in the development of new services.

6. Work with citizens groups, professional and service organizations, industry, labor, religion and education groups and others to further mutual understanding of the mentally ill and retarded and their needs, and the provision of prevention and treatment services, and avoidance of discrimination.

7. Assist local governmental units in giving effect to the State-Local (Short-Doyle) Mental Health Services and other appropriate subvention programs, and carry out the responsibilities of the department relating to program standards and fiscal control.

8. Encourage and assist appropriate agencies and professional persons to carry out activities useful in preventing the occurrence of mental disorders and retardation in the unborn and new born; and relief of those under excessive stress and in danger of mental breakdown; and in the mental health growth and development of the total population.

9. Operate direct treatment services (inpatient and outpatient), including the maintenance of patients in outside institutions, for mentally ill and retarded who cannot be cared for by private physicians and institutions and voluntary agencies, or by city, county or federal treatment services, within the limit of state resources, and in accordance with the necessity to share the load, and that treatment should be available early, continuously, near home and with social restoration.

10. Assist in the advancement of scientific knowledge and its application by a research program using state funds and attracting outside funds.

11. Assist in the development of manpower by programs of professional and inservice training both for the state services and for the state as a whole.

12. Cooperate and work with the Uni-

versity of California and the state colleges in all ways mutually helpful, especially in the operation of the neuropsychiatric institutes for training of undergraduate physicians and residents in psychiatry and in research.

13. Provide and maintain suitable housing and equipment for its own operations, and stimulate and assist efforts in construction by private agencies, architects, and local government by advice and consultation and whatever financial help may be authorized.

Essential Elements of the Plan. The general objective of the Department of Mental Hygiene may be stated simply : to improve the psychiatric care for all citizens of the State of California. This will be accomplished primarily by joining other responsible parties in a partnership program so that adequate treatment is available as early as possible, as continuously as possible, with as little dislocation as possible, and with as much social restoration as possible. The Department will do this by :

1. Maintaining its ability to keep up with demands of increasing pressures.

2. Efforts to shift the treatment program : first, as much as possible to the private sector of medical care; second, to local government in terms of administrative and operating responsibility.

3. It will share the responsibility that the cost of such treatment is available from multiple resources and that services for all persons will be developed under whatever appropriate responsible parties may exist in different parts of the state.

4. It is necessary to assume that other agencies will increase their share in providing direct services, with appropriate help. Under this plan the state will look forward to a reduction of direct services by the state government, to a minimal amount, to the end that all persons with mental illnesses shall be treated as every other medical condition may be treated. Direct treatment load, therefore, will continue to be reduced, slowly as now, but with increasing speed, and its current operation will shift its emphasis to demonstrations in the hospitals, outpatient clinics and day treatment centers. Action by state government chiefly through the Department of Mental Hygiene will be

characterized by close association between a number of departments of state government, primarily those related to the Health and Welfare Agency, and also the Departments of Education, Corrections and Youth Authority as they operate programs in the school systems for retarded, and for emotionally disturbed children, and for psychiatric conditions in state correctional facilities.

The State Government led by the Department of Mental Hygiene will assume broader responsibilities in terms of leadership, education and promotion to the end that all responsible parties throughout the state will exert a maximum influence toward broader and more adequate mental health coverage, including a strong emphasis on influencing conditions which may be proved to have a part in preventing the occurrence of any of the mental disorders including mental retardation. Accomplishment of the above program will be in four major phases, all of which have started and will emerge progressively as dominant as the program unfolds.

Phase 1. The improvement of current direct services in hospitals, clinics and day centers and follow-up services so that the increased admissions resulting from increased population shall be adequately handled. This means that these services must have improved level of service, up to at least 25% to be achieved in 5 years, or at the most in 7 or 8. This may be accomplished in two ways; 1. By reducing the total number of patients (2%) and thereby automatically achieving higher ratio of personnel; 2. By increased financial appropriations each year up to 3%.

Phase 2. The development of alternative services to state care. These will be helped and pushed by the state in every possible way including financial. These are: increase in private licensed hospitals and nursing homes (1/3 of all such beds in the nation are in California), psychiatric units in general hospitals, the greater use of non-governmental clinics and greater participation of the general medical profession in treatment of mental cases. Also the increase of psychiatric treatment and attention in all chronic disease hospitals, county institutions and non-medical institutions (such as

homes for the blind, deaf, aged and for children without homes), and a vast build-up in a system of foster home care, both medical and non-medical, as well as specific increases in the care of moderately severe retarded in the school system known in California as the Point Two System. As these develop long-term patients will be transferred.

Phase 3. This phase consists of the marked reduction of state operations in direct services and as a shift of treatment services and locations to local facilities is accomplished, long-term patients are not retained. This will be markedly accelerated after the initial build-up process of Phase 1.

The Mentally Retarded. The relative reduction in state hospital beds for the retarded will continue in the same fashion but will be carried out more slowly. It is likely that the state will be able to take care of its responsibilities without adding to its current 12,000 beds for the retarded though this is a low rate of hospitalization. However, as it is planned, these hospitals shall be restricted to specific hospital care and will not continue to be used for custodial and residential care for large numbers of retardates who have long ago received maximum benefit from the state institutions. Under other auspices, with state assistance, treatment centers should increase by at least ten 250 bed units, each surrounded by day services for 750. It is believed that a careful classification of cases will screen out those who are better treated elsewhere, such as new born, badly crippled, brain-damaged cases for whom nursing care is the major objective, and certain neurological cases. Ambulatory retarded over 21 years of age with good physical condition may often be well cared for elsewhere.

Financing. This is a critical issue because of the variation in relative power to pay for services by individuals, local, county, state, and federal resources. It is believed that individuals will markedly increase their ability to select private treatment and pay for it because of 1) the increase of insurance for mental patients which is making such rapid progress; 2) increases in community chests; 3) industrial clinics funds; 4) pension funds; 5) other operations carried out with voluntary contributions; and

6) increased eligibility for welfare funds of both county and state, and from federal sources as the Social Security Laws and Amendments up through 1959 are changed. These now exclude mental patients.

We see the State as it conducts less direct services for mental patients and retarded, continuing to assume the same relative financial load, with a minimum of 8½% of the General Fund, monies being transferred from Federal to state to county in general by special grants-in-aid and by the subvention principle. In California this is already laid down in the Short-Doyle Law which, we believe, will be changed within 12 months to allow for a broader coverage and an increase of state participation.

Phase 4. As the State reduces its opera-

tions in terms of direct care and treatment it will devote itself more and more to its program of training for the State as a whole, research, public information and education, consultation and community organization, standard setting, exerting strong leadership shared with other responsible parties. It will particularly push towards a strong and widespread effort by all appropriate groups toward healthy growth and development in the society, control of prenatal maldevelopment and birth trauma, and relief of excessive pressures and tensions which, unmet, may lead to the development of one of the mental disorders in a large number of people. This could become a method of mass primary prevention.

PSYCHIATRY IN INDIA : FAMILY APPROACH IN THE TREATMENT OF MENTAL DISORDERS ¹

W. A. KOHLMAYER, M.D., AND X. FERNANDES, D.P.M.²

India, with a population of over 400 million inhabitants, has only 15,000 psychiatric hospital beds. Taking the overcrowding into consideration the number of psychiatric patients in psychiatric hospitals is approximately 30,000. De(1) states that the Indian Ministry of Health has recently estimated that 1.5 million persons in India would require institutional treatment if facilities were available. However, this is only an estimate. No actual survey has been done and no accurate figures are available. De believes that a figure of 3.5 million mental patients would be more accurate. Comparative figures for U.S.A. are 185 million inhabitants, and 750,000 hospital beds for in-patients. There are many more psychiatric facilities in general hospitals and open hospitals for voluntary admissions and there is a great potential for help in psychiatric private practice. These types of facilities are only beginning in India, and no exact figures are available. It is obvious, however, that the total facilities are hopelessly inadequate for dealing with the mental health problems of the country. Further evidence is contained in the figures of organized members of the profession: over 12,000 in the A.P.A., as compared with less than 100 in the Indian Psychiatric Society.

In contemplating this vast discrepancy in facilities and personnel we must ask: Is the incidence of mental illness lower in India? And if not, what happens to the patients and where are they located? Studies of the epidemiology of mental disorders in various countries throughout the world indicate that the incidence is approximately the same regardless of race or cultural background. Mayer-Gross, *et al.* (2), writing on the chronic mental patients in India and England state: "The vastly different social and cultural background from which the two groups are drawn suggests that these factors are not of major importance in the causation or prevention of chronicity."

We have to assume that there are proportionately equal numbers of chronic mental patients in all countries but they are to be found in different locations. In the United States they make up the vast population of the back wards of mental hospitals. In India they are usually at large being cared for by the family. Lambo(3) has studied the chronic mental patient in Africa and comes to the conclusion: "It may be that institutionalization tends to produce severe chronicity in patients in all races and cultures." He reports that he found relatively few cases of severe regression among African mental patients. He explains this fact with the support which the mental patient receives from his cultural and family background. In India, the traditional joint family system has provided material and emotional support to mental patients throughout the ages and is continuing to do so, although there have been signs of decrease of the strength of the family system. Any method to solve the mental health problems of this country has to take into account the various aspects of this family system and to utilize them in the treatment of the patients.

The Joint Family System. In Western countries—and particularly in the U.S.A. with her more mobile population—the prevalent form of the family is the so-called nuclear family consisting only of parents and children up to the age when they can care for themselves and earn their own living. This has led to individualism and isolation. As a result, there has been increasing shift of the responsibility for the mental patients to social agencies and the State. Only recently there has been a trend toward more interest in the family and the social environment. A number of publications have appeared describing this development, e.g., Ackerman's *Psychodynamics of Family Life* (4) which gives an excellent review of the increased interest in the family influence in mental illness.

In contrast to the nuclear family of the

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Patuxent Institution, Jessup, Md.

west, the joint family system is still prevalent in India although it shows some signs of decay under the impact of modern industrialization and the increasing influence of western thinking. Devanandam and Thomas(5) state "We call that household a Joint Family, which has a greater generation depth (*i.e.*, three or more) than the nuclear family and the members of which are related to one another by property, income and mutual rights and obligations. The members may be related collaterally or lineally." Sometimes as many as five generations live in a joint family because of early marriage and procreation. Thus the lineal spread includes family members of all ages from infancy to senility. The collateral spread includes cousins up to the third degree and the term "cousin brother" indicates that this relationship has equal status with a direct relationship between brothers and sisters. The head of the family is always the oldest male however senile he may be. If he dies, his oldest brother takes over his rights and responsibilities. However, his direct descendants split off from the family at that point to form a new family group under his oldest son. This cuts down the excessive collateral spread in the family which otherwise would extend indefinitely. The families are held together by joint property, housing on the same compound, a joint system of keeping money and accounts into which all members put their earnings and from which necessary expenses are made for each member according to the decision of the head of the family council. The influence of the family on the life of different members is extremely dominant and questions like schooling, training for various trades and occupations, studies, choice of marriage partner, and the question of dowry are all decided by the family. Little initiative is left to the young family members, who are not expected to make decisions until relatively late in life. The women join the husband's family in marriage where they start with an inferior role in the new household and are often severely dominated by the older women. The closeness of living together and the excessive influence on the life of every family member has produced extreme interest in personal and even intimate spheres. Interpersonal

relations, which are a matter of extreme privacy in other cultures, are often a question of common interest and concern in these large families. For example, everyone will participate in the nuptial ceremonies of a young married couple, and in other intimate matters. If family members take ill it has been the traditional course of events that sometimes a few and sometimes many members of the family will accompany them to the magician, faith healer or doctor. If the patient has to be hospitalized, it is often difficult to ward off the influx of family members. While the patient is in the hospital they participate very actively in his care. The mentally sick are usually kept at home and cared for by the family for considerable periods of time during which the various healing procedures are performed according to superstition and primitive belief. The fact of mental illness is kept secret because of the stigma which it throws on the rest of the family. It will also put the patient at a disadvantage later on if the fact is known in the community that he has been mentally ill. It may cause difficulty in getting a job or in making suitable marriage arrangements. Keeping the mental patient at home often necessitates considerable expense in effort and time by some relatives. This is possible only because there are usually one or several family members either unemployed or able to take time from their routine work in order to help the relative who needs constant supervision and care.

Description of the Mental Health Centre. The Mental Health Centre is built on the campus of the Christian Medical College, Vellore, and consists of: administration building, two wards—one for 10 public and one for 8 private patients, treatment building, occupational therapy building and mess hall. The staff consists of 2 psychiatrists, 2 house surgeons, 1 psychologist, 1 social worker, 1 occupational therapist and 1 trained psychiatric nurse, with 4 general duty nurses and 5 attendants, and an office staff of 3. The psychologist, psychiatric nurse and social worker participate in the examination of the patients along with the doctors, taking anamnesis and mental status of patients in their own language. There are three prevalent languages: Tamil,

Telugu and Malayalam, as well as a number of languages from more distant provinces. This method of gathering information is necessary before each patient is presented to the senior psychiatrist for diagnosis and planning of treatment. All forms of modern psychiatric treatment are provided at the Health Centre. Electroshock, sub coma and coma insulin and drug therapy as well as psychotherapy and group therapy are provided according to the need of the case. The patients are located in open rooms and there is no restraint or restriction. They are provided with a room with adjacent bathroom and kitchen which forms a small living unit similar to that which they are used to in their own home. It has been established as a firm policy at the Centre that one or two members of the family have to stay with the patient throughout his treatment. Rarely has there been any difficulty in finding family members to provide this service. On the contrary it is often a problem to eliminate a large crowd of relatives who want to stay with the patient throughout his hospitalization. It is very helpful to the patient—particularly to those who come from small villages and have not previously stepped out of the boundaries of their own setting—to be surrounded by familiar persons, thus avoiding the frightening aspects of a sudden separation. The close participation of the relatives in the treatment of the patient provides an opportunity to give them a better understanding of the peculiarities of the individual case. Through spread of this knowledge into wider circles of the public, a general education in the matters of mental health is effected.

In a country like India, with its many sub-cultures and traditionally determined language groups and castes, the food habits of the people vary greatly. Therefore it would be impossible to provide food for all of them from a central hospital kitchen. It would be an additional cause of upset to the patients if they were forced to eat strange preparations of food. Therefore, the relatives are encouraged to set up their own household with the kitchen facilities provided by the Centre and to prepare their own meals. This, at the same time, lessens the cost of hospitalization for them.

The relatives take an active part in the

treatment of the patient. For example they bring the patient to the treatment room for EST and afterwards supervise him throughout the recovery period. They sit with the patient throughout the insulin treatment while the nurse is supervising the various stages. They provide the food after recovery. Thus they learn about the treatments and are able to overcome their superstitious beliefs about illness and treatment. The relatives also are encouraged to take part in group therapy which is conducted every day. There they learn about the problems of other cases and about the psychological aspects of the illness of their own patients. They are given valuable suggestions for the handling of the cases, learn to observe the early symptoms of the breakdown as well as the appropriate steps to counteract them.

In this setting the most disturbed psychiatric patients can be treated without difficulty. The responsibility for the patient is left with the family members who have been dealing with his disturbed behavior prior to his admission and are often quite skillful in handling him. With active psychiatric treatment most of the disturbances are brought under control within a few days. The relief of the pressure which the patient's disturbed behavior has exerted on the family members gives them an additional incentive for cooperation, and willingness to follow the advice regarding further treatment. When the patient is ready for discharge, again an abrupt change in his relationship to his environment is avoided and the same persons are around him through the period of recovery and rehabilitation in his home.

All patients and relatives are encouraged to remain in contact with the Centre after their discharge. Those who live close by are invited to return for follow-up interviews and continued treatment with medication or psychotherapy. Some of those from a distance will avail themselves of similar help by correspondence or are placed under the supervision of their family physician. However, with patients coming from as far away as several hundred miles from North India, Assam, Arabia and other places, a close follow-up is not always possible.

This system of utilizing the family in the care of the patient has the additional advantage of relieving the psychiatrically trained staff, particularly nurses and attendants, from routine duties. The nursing staff supervises the physical treatment and provides medications, observes the cases and is on hand to give advice to the relatives at all times. Thus the staff is relatively small considering the large number of patients treated.

Evaluation of the Program. The psychiatric department of the Medical College in Vellore was opened in August 1955 and the inpatient services in the present situation were opened on March 1st, 1957. Since this time there has been a steady increase in the number of patients. In 1956, 380 patients were examined and in 1960 this number had increased to 650. These figures demonstrate the great demand for psychiatric services, the increasing popularity of treatment in an open setting and the decrease in superstition and the fear of stigma.

During the 18 months from July 1959 to December 1960, 849 patients were examined at the Centre. Of these, 284 were treated as inpatients and 264 as outpatients, and 301 came only for consultation.

Of the patients treated, 417 came from a rural and 432 from an urban background; 275 were illiterate, 259 had elementary schooling, 191 high school education, and 124 college education. Compared with the average population the number of educated persons is much higher among our patients because they are more willing to avail themselves of western treatment.

Considering the age distribution, the striking feature is the preponderance of the younger age group from 20-30 (326) with 30-40 (202) following closely behind. Compared with the western countries there is almost an absence of the older groups. This is explained by the cultural attitude of veneration toward the older person. The families refuse to send their older relatives away for treatment, taking the gradual decline of their mental power, and consequent mental disturbance, as a natural course of life.

The distribution of diagnostic categories is of interest. The most frequent diagnosis

is schizophrenia with 305 patients (35.8%). Next is psychoneurosis with 266 patients (31.2%). This group represents a biased sample compared with the average population in India because the Mental Health Centre has the reputation of being a place primarily oriented towards psychotherapy. It draws persons with western education from the cities who come for psychotherapy.

Affective psychosis was represented with 129 (15.7%) patients and organic with 70 (8.1%). Mental deficiency with 39 (4.5%) patients and personality disorder with 32 (3.7%) are represented less than in the average patient population. Eight (1.0%) remained undiagnosed.

The sex distribution in the various diagnostic categories is interesting. Of the total number 60% are men and 40% are women. Among the schizophrenics 56% are male and 44% are female. The ratio is reversed among the affective psychoses to 47% male, 53% female. In all other groups we find a preponderance of males which is particularly striking in the psychoneuroses with 69% male and 31% female and in the personality disorders with 75% male and 25% female. Among the organic cases we found a somewhat smaller discrepancy—57% male to 43% female. In mental deficiency 64% male and 36% female. In all these figures a preponderance of male patients is evident. They come or are brought more readily for treatment, while families are disinclined to expend money or effort on women members.

The figures regarding duration of illness show approximately even numbers up to 1 year while the group of 1-5 years is bigger and the group over 5 years still bigger. Thus we see that the larger number of patients consists of chronic cases. This bears out the facts previously discussed that the patients are treated with other methods for prolonged periods or simply kept at home without treatment prior to coming for psychiatric care. Of the patients, 258 or 47% were treated previously in other places, and 290 (53%) received first treatment at this Centre. The figures indicate that there were slightly more first admissions than previously treated patients.

Data on the duration of treatment in the various diagnostic groups shows the largest

number was treated for periods under one month. If we add the figure for the second month we have included almost all patients. Only 44 of 548 patients treated—that is less than 10%—were treated for over two months and more. The results of treatment of the total group indicate that 100 or 18% recovered, 363 or 66% improved, 85 or 16% were unchanged and 301 or 35.5% were seen for diagnosis only.

The difficulties of follow-up were mentioned above. Of our 849 patients, 456 or 58% were followed. There was an increase in follow-up, particularly among the patients who benefited from treatment, while the figures for relapse remain approximately the same; 393 could not be reached by our follow-up. Of the 456 patients who were followed, 395 maintained their improvement through a follow-up period which extended 3 months beyond the date of discharge, while 61 relapsed.

COMMENTS

This statistical evaluation compares favorably with the results obtained in Western psychiatric clinics. It shows that a relatively

small psychiatrically trained staff can handle a large number of patients, even with a considerable percentage of excited and disturbed acutely psychotic patients. With the help of the family the patients can be brought under control rapidly, and an intensive follow-up is possible.

It is suggested by these results that this Mental Health Centre could be used as a prototype for the development of small psychiatric clinics attached to General Hospitals throughout India. Thus the necessity to build large mental hospitals, comparable to those in the West, could be avoided.

PSYCHIATRIC RESIDENCY TRAINING FOR PUBLIC INSTITUTIONAL SERVICE¹

JULES H. MASSERMAN, M.D.²

In July 1959, the Illinois State Psychiatric Institute for Training and Research was officially opened. This paper outlines some of its somewhat unique functions in psychiatric education in the hope that they may be of general interest and applicability.

Background. Plans for the Institute had been developed for over two decades by a Council consisting of the successive heads of the Depts. of Psychiatry of each of the five medical schools in Chicago, and respective Directors of the Chicago Psychoanalytic Institute, the Illinois Psychopathic Institute, and the Psychiatric and Psychosomatic Institute of Michael Reese Hospital. The most recent personnel of this Council, appointed for 6-year terms by the Governor of Illinois, had been: C. Knight Aldrich U. of Chicago), Percival Bailey (IP), Benjamin Boshes (Northwestern U.), Francis Gerty (Chairman, U. of Illinois), H. H. Garner (Chicago Medical School), R. R. Grinker, Sr. (PPI), John Madden (Loyola U.) and G. Piers (CPI). Dr. Otto Bettag, then Director of the Illinois Department of Public Welfare, appointed Dr. L. Rudy as Superintendent of the Illinois State Psychiatric Institute (ISPI), with Dr. Percival Bailey as Director of Research. I accepted the post of Director of Education with the provisos (1) that my appointment would be approved by the Council, since the cooperation of its members was obviously essential and (2) that my part-time services would end when a properly qualified full-time director could be found to take over.³ As may be inferred from what follows, during the ensuing 27 months the position proved challenging and demanding, but the gratifying results obtained may attract others to similar investments of time and effort.

Organization and Liaison Relationships of the Institute. The 7 clinical floors of ISPI, totalling 412 beds, were distributed for individual supervision among the five medical schools and the PPI, reserving only one floor for the Dept. of Public Welfare (DPW). The cooperation of the various schools and institutes was insured by the following advantages:

1. Each was invited to nominate, as a member of its faculty, the full-time Chief and Assistant Chief of its ISPI service, whose salaries were paid by the State.

2. Each school could also designate from 1 to 4 part-time consultants, with stipends likewise paid by the State, to serve a total time of 12 hours a week in supervising ISPI residents, conducting seminars, etc.

3. Each school could, with the consent of the Council and the Superintendent, organize its own clinical and research services in any way it preferred, including the establishment of day or night hospital, group and family therapies, etc.

4. Each school could not only rotate residents from its own training program through ISPI for 6 months or more, but could also appoint two additional residents for a full initial year at a stipend of \$4200 paid by ISPI, after which these residents continued in their respective university programs.

5. The participation of the Chicago Psychoanalytic Institute was invited through the presence of its Director on the Council, the appointment of many of its graduates (including the Director of Education) to positions in the Institute, and by having its trainees serve as teaching consultants, especially in the outpatient department and in various state hospitals affiliated with the ISPI program.

Residency Training. A nucleus was provided by a 3-year program previously conducted by the Illinois Psychopathic Institute under the direction of Dr. Percival Bailey, which had enrolled only some 15 residents, mostly foreign graduates who would be re-

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Medical School, Northwestern University, Chicago, Ill.

³ Dr. R. C. Drye assumed full-time duties in Oct. 1961.

quired to return to their own countries on expiration of their exchange-visitor visas. The new program, in order to justify the expenditure by the State of Illinois of about \$10,000 per year per resident, was to be designed not only to prepare trainees of high calibre for specialization in psychiatry, but to enroll them if possible for greatly needed services in Illinois public hospitals. To make this explicit and also to forestall possible criticism by economy-minded legislative committees, justifiably concerned with local problems, the Residency Training Brochure was headed by the following paragraph:

"This program will furnish didactic instruction, laboratory training and supervised experience designed to qualify the candidate for the professionally competent and socially responsible practice of psychiatry, and interest him in the dignity and satisfaction of the clinical, research, teaching and administrative careers available to him in the Illinois Department of Public Welfare and related institutions."

Another step, which mitigated covert misgivings in various quarters that the well-subsidized ISPI program might seriously compete with others at the five medical schools and the two Veterans Administration facilities in the Chicago area, was to require of each resident that he furnish at least a year of service in a State institution other than ISPI during his residency. This was true in each of the four types of appointment offered: 1. *Straight Residency*: First year of intensive basic instruction and two 6-month services at ISPI; *second year at a State hospital* with one day a week for lectures and outpatient services at ISPI; third year divided into 6 months of advanced outpatient therapy, day and night hospital experience, court consultations, etc., and the other 6 months in child psychiatry at the Institute of Juvenile Research—also a state institution. Stipends, \$4200, \$5200, and \$6000. 2. *Career Residency*: As above, with 2 additional years of supervised staff service at an assigned State hospital interspersed among the 3 years of formal training. Stipends from about \$7500 to \$9500. 3. *Child Psychiatry*: First year at ISPI, second divided between a State hospital and OPD

with ancillary forensic and other training at ISPI; third and fourth years at IJR as a Fellow in Child Psychiatry. Stipends, \$4200, \$5200, \$7500 and \$8000. 4. *General Practitioners Grant*: As above, with stipends for qualified candidates from the National Institute for Mental Health.

Plan of Instruction. First Year: It was manifest that if the residents were to remain interested in and qualified for this progression of responsibilities their first year of didactic training in psychiatry must be made fairly intensive without neglecting the concurrent development of their clinical skills. The latter was particularly emphasized by requiring their uninterrupted presence on the wards from 9:00 a.m. to 4:00 p.m. for individualized care of from 5 to 12 specially selected patients. Here their work was directed by the various chiefs and assistant chiefs of service and the faculty consultants (whose reports were turned in regularly to the Director of Education) and supplemented by ward meetings, therapeutic team seminars with psychologists, nurses, social workers, etc. However, this emphasis on clinical skill left ample time from 8:00 a.m. to 9:00 a.m. and from 4:40 p.m. to 5:30 p.m. for lectures and demonstrations by ISPI personnel (Directors of the Divisions of Social work, Nursing, Psychology, Activities Therapy, Music, etc.), faculty members of the various participating institutes and departments of psychiatry and lecturers from various Chicago universities in sociology, anthropology, linguistics and other fields of growing relevance to psychiatry. For those interested in academic schedule-building, Tables 1 to 5 outline the content, progression and timing of courses and their balance with clinical work during the first year. In principle, after a week of general orientation and an initial trimester of introductory instruction in basic techniques of examination, diagnosis and therapy, the essentials of psychiatry, neurology and their related disciplines were presented in lectures and seminars limited to one or two hours a day; the rest of the time was spent in well-supervised individual and group work with patients. This included specifically scheduled opportunities for admission and follow-up experiences in the outpatient department, where a patient could, if neces-

sary, be treated by a resident for as long as 3 years.

Second Year : Most residents are assigned to the nearby Chicago State Hospital as staff psychiatrists in charge of the active treatment wards of 50 or more adolescent and/or adult patients of both sexes and with a wide variety of neurologic and somatic illnesses and behavior disorders. Occasionally, residents are also assigned to Elgin State Hospital for special geriatric experience, or to Galesburg for an opportunity to participate in the intensive physiopharmacologic research at the Thudichum Laboratory. However, in all cases provisions were made for their continuous training as follows :

1. In addition to attendance at staff lec-

tures and seminars, each resident is provided with a minimum of 4 hours per week of individual supervision by visiting consultants appointed and paid by ISPI.

2. Residents are assigned to teach student nurses, aides and other hospital personnel.

3. All residents maintain their contacts with the central program by spending Tuesday of each week at ISPI, where their time is divided between advanced instruction in the behavioral sciences from 8:00 to 10:00 a.m.; lectures, seminars and demonstrations in child psychiatry from 10:00 a.m. to noon, and, in the afternoon, OPD treatment of new patients or those previously treated by the resident in the hospital, and finally, attendance at lectures presented generally at bi-monthly intervals by visiting authorities.

	Lecturers					

Third Year : Thus prepared, half of the third year residents are given a 6-month assignment for specially supervised work with children and their families at the Institute for Juvenile Research, and then alternate with their fellows who had spent their time in outpatient work, municipal and family court, consultations, and reviews of basic and clinical neurology. Third year residents join their fellows at ISPI every Tuesday for continued contact with the faculty and final courses in ethology, ethnology, information, communications and systems theory, research design and evaluation, and various psychologic, psychoanalytic, philosophic and sociologic schools of thought contributory to psychiatry.

Individualization. The general program is made sufficiently flexible so that residents

with special qualifications and objectives could be given time for psychoanalytic training, attendance at university courses, or full-time assignment for 6 months or longer to laboratory or clinical research.

Results. These must remain presumptive until ISPI graduates have proved their competence in clinical service, teaching and research in Illinois and elsewhere, but the following interim data are significant: 1. Despite a nationwide shortage of candidates for psychiatric training, and without advertisement other than sending our brochure on request, ISPI had over 200 applicants in 1960-61 academic year, of which only those with high scholastic standings and personal qualifications were selected. 2. The number of physicians in residency training, most of whom are now graduates

of American or Canadian schools, has increased from 14 to our maximum of 60. 3. Relationships between the residents and the ISPI staff have remained excellent and the evaluation reports of the consultants have been almost uniformly favorable.

Each of the current trainees has expressed a sincere desire to continue in full or part-time institutional service, teaching or research after the completion of his training, and most prefer to remain in Illinois.

State Hospital Staff Training Program. Nevertheless, from a political-economic standpoint, the residency program was open to a pointed reservation: a putative Legislative Subcommittee on Mental Health could be well aware that Illinois mental hospitals were in *immediate* need of trained psychiatrists and might reasonably enquire

why we should not engage ready-made specialists or train available hospital physicians instead of investing so much tax money training residents on their mere promise that they might later serve our State. During the second year the facilities of ISPI were therefore also mobilized to provide one full day per week of teaching and consultations and direct clinical service to 9 of the 13 State hospitals in Illinois. This was done as follows:

1. In order to provide continuity of relationship and mutual interest each of the participating medical schools and institutes at ISPI agreed to adopt one or more of the State hospitals as its special concern, and was thereafter jointly responsible with the Director of Education for the local training program in that institution.

2. The Chief and Assistant Chief of the ISPI service of the sponsoring school formed a team with two or more of its faculty consultants (including psychologists, social workers, nursing supervisors, *etc.*), each of whom then arranged to spend one full day a month at the designated State hospital. In this way, with only moderate demands on individual team members, each of the State hospitals could arrange one pre-set day a week for lectures, seminars, ward rounds and other activities that improved staff skills, raised standards throughout the institution, and thus directly benefited many of the 45,000 patients in Illinois mental hospitals. The Chicago Psychoanalytic Institute, which did not have a separate service at ISPI, also designated such a team under the direction of Dr. P. Seitz, and ably served the East Moline State Hospital, 320 miles away.

3. The entire program was coordinated by reports from both the visiting teams and hospitals, and by monthly meetings of the ISPI staff and all participating consultants with the Director of Education.

State Hospital Staff Instruction at ISPI. Finally, to complete the cycle of pedagogic exchange between ISPI and the outlying State hospitals, each of the latter sent one or more of its staff members every year for a month or more at the Institute for didactic reviews and clinical experiences designed to emphasize the dynamic, comprehensive and efficacious therapy of institutional patients (*cf.* Table 3). These post-graduate trainees, in turn, kept the ISPI staff and residents apprised of the practicalities of institutional work and thus also helped in maintaining

realistic and pragmatic orientations. All of the participants, despite the demands on their time and energy, have expressed their appreciation of the benefits derived from such interchanges.

Discussion. As may be surmized, the programs here outlined did not spring parthenogenetically from the oracular foresight and infallible administrative skill on the part of the Director of Education; on the contrary, he could often have better anticipated predictably differing interests in a Council composed of heads of departments accustomed to complete autonomy, and the conflicting demands on the program made by the clinic and teaching staffs, the medical school consultants, the state hospitals, and the residents themselves—let alone ever-present budgetary considerations. However, since nearly all those concerned with the ISPI program were motivated by a sincere desire for its success, the gratifying results here described were eventually achieved.

SUMMARY

Since 1959, interrelated programs were evolved at the 7 medical schools and training centers in Chicago, and the Illinois State Psychiatric Institute with its affiliated teaching facilities which have: (1) motivated and prepared residents for service in State hospitals and clinics; and (2) utilized the Institute in the continuous teaching of state hospital physicians and allied personnel. The development, vicissitudes and relative success of these programs are summarized to indicate their general applicability.

PSYCHODYNAMIC DIAGNOSIS IN PSYCHIATRY

RUDOLF DREIKURS, M.D.¹

The diagnosis of psychopathological conditions is usually of a descriptive nature, based mainly on symptomatology. Dynamic factors are generally considered in the diagnosis only if they refer to organic etiology, such as senile, toxic, climacteric, or traumatic conditions and pathological changes in the central nervous system, the metabolism, the endocrine system, *etc.* Although such a diagnosis is important for therapy and prognosis, it is incomplete because it disregards important psychological dynamics. Psychological factors are recognized in the differential diagnosis of psychoneuroses, such as anxiety states, conversion hysterias, *etc.*, but even here the diagnosis is mainly based on symptomatology.

Even more inadequate are the prevalent methods for the diagnosis of the psychological dynamics in each patient. Sometimes adjectives are used to describe the patient, according to his overt behavior, as timid, aggressive, repressed, suspicious, restrained, apprehensive, *etc.* Sometimes mechanisms are taken for granted because they were observed on other patients before, and the present symptoms are interpreted as being based on insecurity, hostility, discouragement, guilt feelings, oedipus complexes or castration fears.

There are several methods available for diagnosing dynamic factors more objectively and not merely on the basis of superficial observations or haphazard guessing. The technique which I have developed, and which I hereby submit, is based on Alfred Adler's concepts.

Psychodynamic Differential Diagnosis. Neurosis, psychosis, and psychopathy are differentiated not only by their symptoms but by fundamental differences in their respective mechanics.

All psychopathological conditions are expressions of conflicts between the individual and his social obligations, since all human problems are essentially social in nature.

Psychopathology is characterized by mental, emotional, and characterological conditions which prevent the individual from functioning at an adequate social level and keep him from participating in harmony with others. The fundamental interpersonal conflicts are reflected in the intrapersonal conflict between the conscience, which recognizes social obligations, and the personal desires, which may stand in the way of cooperation. The conflict between the individual's private logic (private sense) and his conscience (common sense) may be resolved in three ways:

1. The patient may maintain his common sense consciously, but may look for alibis and excuses should he act contrary to his common sense. Thus, he uses his symptoms as alibis and yet maintains his good conscience. This is the characteristic mechanism of neurosis.

2. The conflict may be resolved by bringing the conscience in line with the demands of the private logic. This is accomplished through delusions and hallucinations which serve the patient as a means of escape from the logic of social living, his private logic acting as a substitute. This is a characteristic mechanism of psychosis and is usually associated with certain predisposing conditions. These are organic inferiority of the brain, exhaustion, excessive stress, disturbance of the CNS, of the metabolism, toxic or infectious conditions, *etc.* These can be considered as release mechanisms in crisis situations and are more and more recognized as favoring conditions, but not as causes, of psychosis.

3. The conflict between common sense and private sense may be avoided through neglect of the conscience as a result of inadequate training (excessive indulgence, suppression or neglect). This is a characteristic mechanism of the psychopathic personality.

The recognition of these dynamics permits a clearer differential diagnosis in certain borderline cases, such as between reactive depression and depressive psychosis,

¹ Professor of Psychiatry, Chicago Medical School.

obsessive neurosis and schizophrenia, neurotic usage of alcohol and psychotic or psychopathic conditions. The most important feature of this dynamic differentiation seems to lie in the differential diagnosis between organ neurosis and organic disease. In all cases of neurosis and psychosomatic disorders a proper psychological diagnosis is imperative for treatment, management and counselling. The diagnosis of neurosis can no longer be based on the mere lack of evidence of organic pathology. The deciding factor must be the proper recognition of the purpose for which the symptom is used. If it serves as an alibi, then the case must be classed as a neurosis regardless of the presence and extent of organic pathology.

The technique I use permits a rather quick diagnosis of the psychodynamic factors of each case. We must recognize the dynamics of the present life situation in the light of the deeper dynamics of the whole personality. Our investigation is, consequently, directed towards a systematic examination of both aspects.

The Acute Situation. The examination starts with an inventory of the subjective symptoms and complaints of the patient. They represent his *subjective condition*. The next step is an investigation of the *objective life situation*. This consists of a careful examination of his participation at work, in social contacts, and in his relationship to the opposite sex, uncovering existing conflicts and dissatisfactions. The connection between the subjective condition and the objective situation is established by the question "What would you do if you were well?" The answer will reveal the dynamics of the existing psychopathology. It will indicate against what person or what situation the symptoms are directed. Caution must be used, however, to determine carefully whether the non-participation is justified objectively (by the conditions) or is justified only subjectively, and really out of proportion to the existing personal and social conditions.

The evaluation of the present situation is then substantiated by an examination of the patient's life situation at the time of the onset of the disturbance. Such examination reveals a "crisis situation" in which the

personality clashed with the then existing conditions and the patient retreated, withdrawing or limiting his participation.

The crisis situation cannot be understood in its dynamics without recognition of the patient's whole personality, *i.e.*, his life style. No real difficulty in itself causes retreat if the person is properly prepared for it. As long as an individual is confronted with living conditions which permit participation on the basis of established patterns and approaches, no conflicts will arise and no psychopathology will develop.

The Life Style. It is possible to determine the "life style" of a person objectively by analyzing his *family group*, the early group situation during the formative first years of his life and by interpreting the *early recollections*.

The family group may be recorded diagrammatically; the diagram shows the dynamic interrelationships of all members. The most important factor is the position of the patient in the sequence of children, whether he is the first born, second, middle, youngest or only child. Although the parents are the most important force, directing the mutual relationships between patient and all other members of the family, of greatest significance is the relationship to brothers and sisters. The interview will determine which one of the siblings was most different in character, interests and temperament. In most cases it is the next older or younger one. These differences indicate competition; in this competition the patient developed his ideas and concepts, and his manner of conduct contrasting to those of his rival. Further inquiries will establish possible favorites of father and mother, the personality of the parents, the nature of their relationship, the method they used in training each child, the alliances of siblings which is always expressed objectively in the similarity of traits and interests. These are the dynamic factors which influence the patient to develop a characteristic attitude towards society and the world.

These personal concepts and attitudes are revealed in the early recollections. The fact that one remembers from all the childhood experiences only certain impressions, makes these recollections highly significant. As all early recollections substantiate and

supplement each other, they reveal thereby the general outlook of a person, and indicate his subjective interpretation of life.

The proper evaluation of early recollections requires training and experience in soliciting the material and in considering each detail in its full dynamic implication. The psychiatrist trained in this method is capable of making an objective diagnosis of the patient's life style on the basis of family group and early recollections.

The psychological examination as outlined can be accomplished in one or two interviews. It provides an objective basis for the evaluation of the problems and the personality of the patient. During psychotherapy other pertinent material may appear, clarifying the first diagnostic impression. But this technique provides information about the most essential psychological aspects and may protect the psychiatrist from making unsound assumptions or neglecting relevant material.

I report one short case to demonstrate the technique :

Subjective condition. The outstanding symptoms are pains in the abdomen, constipation, diagnosed as spastic colitis. Patient was examined in several hospitals and by many physicians. State of depression has occurred several times. He is in a state of anxiety, worries a great deal, has experienced several incidents of a "nervous breakdown" where he could not sleep, could not eat, felt weak and had to stay in bed. All objective findings were negative, but once an appendectomy was performed without any improvement in his condition. He has felt sick for the last 20 years.

Objective situation. At work he cannot work effectively, is constantly on the defensive against being called upon or criticised, cannot accept more responsible positions offered to him, has to lay off several times when he gets pains or feels sick.

Socially. Has a few friends but hardly sees people ; is distant to people, suspicious when he meets new people, wants to be sure first.

Sexual and marital relationship. His wife has been sick almost since they were married. Very tense situation. He feels the victim. She is perfectionist, demanding and criticizing him. Complains constantly.

Question. What would be different ? He would have proven at his company that he is the best professional worker. His nervous condition has shattered all his hopes. Before

he got so nervous, 7 years ago, he blamed his wife for his failure. The attention and care which he needed prevented bigger and better jobs. Afterwards his pain kept him from accepting more responsibility. He would be more tolerant to his wife if he were well.

Crisis situation. Twenty years ago he had a mean boss who cursed him and laid him off despite hard effort. It was the first time in his life that he failed. He went home hiding his face. At that time the first symptoms started. An acute recurrence of severe pains in the abdomen, 7 years ago, when he was scolded at work. Five years ago a severe nervous breakdown, was unable to work for several months when his mother died without his having visited her. He blamed his wife who by her sickness prevented him from going.

Family group. He is the third of 9 children. Most different from him is the oldest brother, 3 years older. The brother was a bad student, flunked in school, slow thinker, dislikes work, does not take on responsibility, but takes life easy and is happy. Patient was a favorite of the mother who expected him to be the only one to extricate himself from poverty. He helped around the house and in the field where he was the leader of the older children. One sister, two years older, was more like him but soon accepted his leadership, too. The father was away in the war when patient was 10 years old, and he took on his place and responsibility. After the father returned, he accepted the patient as an equal. Patient picked on the oldest brother and made fun of the next younger one. All in the family accepted his superiority.

Earliest recollection. At 11, he was not allowed to go to high school, but went for himself to register. All other children were well dressed and with their parents. He was ashamed. When it came to making the application, he started to cry, but the principal spent some time in trying to console him.

At 9, the teacher put him in charge of the class while she left the room. He helped correct papers. Once she hit him on the hand : he felt innocent, cried for hours. The teacher felt sorry for him, apologized and tried to console him. Actually, he had been at fault by not following instructions.

At 5, patient had bitten the older brother, who was much stronger than he. He ran away, cried, and complained to his parents, who scolded the brother.

Evaluation. Patient wants to be the first but knows he cannot be. Tries to conceal his antagonism by feeling innocent and by suffering. Instead of admitting his rebellion he

blames others and circumstances for his "defeat."

Outcome. During psychotherapy he first changed his concept that he must be first or otherwise he would be lost. Then he realized his rebellion and antagonism and changed his attitude. He discovered the function of his pain as a means to escape humiliating situations. His stomach "spoke up" for him and permitted him to withdraw and to refuse participation. His relationships at work and at home changed. He became easy going, learned

"to take it" without resentment and without retreat. His pain subsided completely; he became happy, accepted a higher position which he had refused previously because he was afraid of failing there. The condition of his wife improved, too, since he no longer used it for excusing his own inadequacy, instead of pushing her down, and gaining his superiority on the grounds of her complete deficiency. Patient has been seen periodically for a check-up during the last three years, without relapse.

PSYCHIATRIC, COMMUNITY AND RACIAL INTEGRATION IN A GENERAL HOSPITAL¹

HAROLD H. MORRIS, JR., M.D., KENNETH E. APPEL, M.D.,
AND JOHN L. PROCOPE²

In 1956, the Mercy-Douglass Hospital was given the task of instituting a major psychiatric department, developing a much closer liaison with the University of Pennsylvania School of Medicine, and becoming an integral part of the state and city program for mental health. In addition, since the hospital had been one of the outstanding Negro hospitals in the community, it faced the problem of integrating its staff racially by including more non-Negro professional workers at all levels.

The purpose of this paper is to describe some of the methods used, the problems encountered, and the results up to this time. In addition, we propose to present a preliminary report of studies now conducted, trying to determine how inter-racial attitudes have affected the professional staff and the treatment the patients receive. These several areas of interest will be discussed under the following general headings: 1. Community-hospital integration; 2. Integration within the hospital, racial and psychiatric; 3. Inter-racial aspects within the psychiatric department.

Community-Hospital Integration. Both the Douglass and Mercy Hospitals were established (in 1895 and 1907 respectively) because facilities for Negro patients and physicians were not adequate or open in Philadelphia(1). In 1948 these two institutions merged to form the Mercy-Douglass Hospital. In 1954, The General State Authority, an agency of the state government, built the present physical structure, which was then leased to the Mercy-Douglass Board on a long-term basis for a nominal sum. Up until this time, the professional staff and the Board had been predominantly Negro. Through the Board of Managers, active volunteer groups, community groups and outpatient services there had been a

long tradition of close cooperation between the hospital and the community. The hospital was primarily oriented toward servicing the local community.

As part of the agreement with the state in 1956, the hospital was asked to provide 100 beds as part of the city-state program for the care of the mentally ill, and to make a determined effort to recruit more non-Negro personnel for the staff at all levels. The second of these proposals was accepted with enthusiasm; there was considerable opposition on the part of the staff to the first proposal. The staff was reluctant to devote 100 of its 263 beds to psychiatry, and there was apprehension as to the effect of introducing that number of seriously ill psychiatric patients into a general hospital. Finally, with many misgivings, they agreed under the pressure of circumstances. A medical advisory committee, consisting of some of the senior members of the clinical and administrative staffs of the University of Pennsylvania School of Medicine, was created to assist the board and staff of the Mercy-Douglass Hospital.

In the "old" hospital there had been no provision for psychiatric patients. The hospital was unable to recruit on short notice the professional personnel necessary for staffing such a large service. A three-way agreement, involving the hospital, the state, and the University Department of Psychiatry, was negotiated. Under this agreement, the state provided financial support; the hospital provided 100 beds, nurses and attendant personnel, housekeeping and all ancillary professional and laboratory services; the Department of Psychiatry of the University provided all professional personnel except nurses.

From its inception, the psychiatric service was conceived of by the University Psychiatric Department as a major clinical resource for teaching and research. Medical students, student and graduate nurses, psychiatric residents, and students from related

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

² Philadelphia, Pa.

fields receive clinical instruction here. Medical students are assigned to the Medical Department of this hospital as part of their undergraduate course in physical diagnosis. Clinical research, carried out by members of the University Department and supported by various grants and awards, has been exceedingly active since before the first patient was admitted in 1956.

Also from the beginning, the hospital psychiatric service had as one of its basic aims the reduction of the isolation of the seriously ill psychiatric patient from the community. To implement this goal, one floor of the psychiatric unit is open. Patients may leave the hospital during the day or night to work in the community or attend classes. Whenever possible, community facilities for treatment and rehabilitation are used instead of setting up separate facilities for the patients. As examples of the latter, the nearby Community Recreation Center, a function of the city Department of Recreation, is used quite freely by the patients. This center contains athletic fields, a gymnasium, swimming-pool, library, and programs many activities which have become an integral part of the rehabilitation program of the psychiatric service. Meeting rooms in a nearby church are used for social activities by patients. Some of them work in local business establishments and serve as volunteers in local community projects. Psychiatric outpatient and home-visiting care are provided by the service to a limited extent for residents of the immediate area.

As part of the city-state mental health program, the Mercy-Douglass psychiatric service was designated one of four psychiatric receiving hospitals in Philadelphia. These hospitals admit the majority of their patients directly from the state psychiatric reception center, which is located in the city General Hospital. The state pays the cost of inpatient care above what the patient is able to pay. The city underwrites a major portion of the cost of outpatient care for these same patients following their discharge from the hospital. The same professional staff operates the inpatient service and the follow-up clinic, providing continuity of care for the patients. Under this arrangement, the psychiatric service of the

community hospital is an integral part of the state hospital system, of the city division of mental health, and the University's teaching and research activities.

Integration within the Hospital. Even before the agreement with the state in 1956, the Mercy-Douglass Hospital was admitting non-Negro patients from the community. The proportion of Negro to non-Negro patients continues to reflect the racial composition of the community served by the hospital. The medical and nursing staff of the "old" hospital was almost entirely Negro, as was the Board of Managers and the volunteer community groups. Since the change in policy effected in 1956, the nursing staff and the Board of Managers have become more racially mixed. As for the medical staff, the two new Departments of Research and Psychiatry consist almost entirely of non-Negro physicians, because there have been no applications by Negro physicians for appointments to either of these two departments. Non-professional workers at the hospital have also become more racially mixed since the change in policy. Racial integration within the hospital has proceeded smoothly; it has not been complicated by any obvious problems.

The integration of the psychiatric service with the general hospital has not proceeded as smoothly. For example, the house staffs of psychiatry and the rest of the hospital have remained quite separate. Several factors account for this split: The general house staff is provided room and board as part of their stipend, the psychiatric house staff is not; therefore the two groups do not live and eat together. The psychiatric house staff is composed largely of American citizens; the reverse is true of the general house staff. Thus, the cultural background and community identification of the two groups are quite different. The psychiatric house staff is selected by the University, the general house staff by the hospital; hence the two groups are not subject to the same administrative or professional authority. The psychiatric house staff is primarily oriented toward the University, the general house staff toward the hospital. Another factor working toward a division between the psychiatric service and the general hospital is that the psychiatric outpatient clinic and

all ward psychiatric consultations are handled by psychiatrists in the Department of Medicine and not by the Department of Psychiatry.

Efforts to combine the teaching programs of the hospital and the psychiatric service have not been pushed by either side, and as a result there is not a close liaison in this area. However, on the clinical side all females admitted to the psychiatric service are seen routinely by members of the Gynecology Department, and the Medical Department makes regular rounds on the psychiatric wards. There is active and close collaboration between the Department of Clinical Research and the psychiatric service.

The initial attitudes of the general medical staff toward having large numbers of seriously ill psychiatric patients in the general hospital have been modified considerably in the direction of more acceptance and understanding. This has come about not through a deliberate policy but through "living together." Psychiatric patients are accepted as workers and volunteers in other parts of the hospital. There is much less tendency to assume without investigation that psychiatric patients are responsible for "incidents" occurring about the hospital. Noisy patients have not been a problem despite the lack of sound-proofing; staff and patients from other divisions of the hospital frequently participate in the evening social activities held on the psychiatric floors, which are no longer considered "alien territory." In this manner they have become familiar with the operation and atmosphere of the psychiatric unit. As a result, in several instances when they needed psychiatric care subsequently, they have requested admission to our unit. Discharged psychiatric patients have later returned to the general OPD or the inpatient services when the need arose, because of their positive feelings for the hospital.

Inter-Racial Relations within the Psychiatric Department. No Negro physician or resident has been a member of the psychiatric staff for the reason that none has applied. Psychologists have not been racially mixed for the same reason. Of three social workers, one is Negro. Recreation workers have included members of both

groups; most have not been Negro. Both Negro and non-Negro nurses have served as chief psychiatric nurse; floor nurses have been divided about 2 to 1 in favor of Negroes. The great majority of attendants have been Negro. Patient admissions to the service have been 40% Negro, a higher percentage than similar socio-economic groups in the area served. According to the criteria used by Hollingshead and Redlich(2) just under 95% of all admissions may be placed in class IV.

Infrequently, patients express hostility and center their delusional content around racial difference. Three non-Negro patients have been removed against medical advice from the unit when their families learned that the patients were racially mixed. Interestingly, one of these three, following recovery at another hospital, returned to our psychiatric unit for employment and has been working here for more than three years. Many of the patients come from racially mixed neighborhoods. It is no new experience for them to be in fairly close contact with individuals of another race, although most have not lived in as close proximity as residence on a psychiatric ward requires.

Patients and staff usually deny that racial issues are a matter of concern or friction. However, there is considerable indirect evidence that race does affect attitudes. For example, in replacing the psychiatric nursing supervisor on one occasion the administration hinted that they were looking for a white nurse, feeling that she could exert authority more effectively over her mixed staff than could a Negro nurse. At one time, there was considerable covert friction between the attendant staff (Negro) and the medical staff (white). Finally it came out that the attendants felt the doctors were favoring the white patients. They cited as an example their belief that more Negro than white patients were being transferred to other hospitals for continued treatment. Such transfers have been regarded as punitive by patients and many of the staff. The facts were shown to be otherwise (see below) and relationships improved, probably because the attendants were given an opportunity to express their feelings about racial discrimination openly

to the medical staff, and their feelings of bias were accepted as quite natural.

In an effort to arrive at more subtle evidences of racial bias, a study project has been set up to determine if psychiatric treatment patients receive is affected by race to the extent that it is by social class (2).

In view of the great interest that has been shown in the effect of social class on psychiatric treatment, there is an amazing paucity of literature on the effect of racial differences. As a guide to setting up this study, some preliminary, tentative indices of differences in treatment have been reviewed on the basis of 1000 admissions to the psychiatric service. (See Table 1.)

half as many of this group were treated with EST than in any of the other 3 groups. At first glance, this might indicate that in this respect at least there is a striking difference in the type of treatment received on a racial basis. However, the use of EST in our unit is restricted almost exclusively to the more severe, psychotic types of depression. Reference to Table 2 reveals that the diagnosis of depression of psychotic proportions was made less frequently for the Negro males in our sample than in any other group of patients.

The number of white males with a depressive diagnosis was only slightly higher than Negro females, so the difference in diagnosis would not seem to be great

Treatment Received by Sex and Race

	1 TOTAL CASES (1)	2 TREATED WITH EST (2)	3 INTENSIVE PSYCHO- THERAPY	4 READ- MISSIONS	5 TRANSFERS	6 LEFT AMA	7 FOLLOWED IN OPD	8 MEDIAN LENGTH OF STAY IN DAYS (3)
White female	39.9%	13.3%	47	12.8%	9%	8.5%	25.8%	68
Negro female	21.4% (214)	12.2%	8	14.0%	6.5%	7%	24.8%	63
White male	23.3% (233)	11.6%	6	14.1%	15.9%	4.3%	16.3%	75
Negro male	15.4% (154)	4.6%	2	13.0%	14.3%	4.3%	23.4%	65

1. Except for column 1, % refers to percent of total N for sex and race. 2. Children under 18 and over 60 excluded. 3. Patients under 18 and over 60 excluded.

Table 1 presents varieties of treatment considered by sex and race. The striking finding in column 2 is the low percentage of Negro males receiving EST. Less than

enough to account for the difference in number of Negro and white males treated with EST. Our conclusion is that there is a difference in the treatment received

TABLE 2
Diagnosis by Sex and Race

DIAGNOSIS	WHITE FEMALE (399)	NEGRO FEMALE (214)	WHITE MALE (233)	NEGRO MALE (154)
Chronic brain syndrome	3.8%	2.8%	7.7%	10.3%
Acute brain syndrome	.8%	2.8%	3.6%	6.5%
Psychotic depressions (1)	15.5%	3.7%	12.0%	3.2% (5)
Schizophrenic reactions (2)	27.5%	26.6%	25.3%	34.4%
Acute schizophrenia	9.3%	24.3%	8.7%	12.8%
Chronic schizophrenia (3)	14.3%	14.4%	20.6%	19.5%
Neurotic reactions	22.6%	20.6%	20.6%	12.3%
Other (4)	6.2%	5.8%	1.5%	.2%

1. Includes involuntal, MDD, and psychotic depressive reaction; 2. Includes catatonic, schizo-affective, and paranoid; 3. Includes hebephrenic and simple; 4. Manic, undiagnosed; 5. Does not include any diagnosed manic-depressive depressed.

by Negro males and white males in regards to this form of treatment which cannot be explained by difference in social class or diagnosis.

With regard to patients selected by the residents for intensive psychotherapy, there is a major bias in favor of white females. The resident staff is allowed great freedom in selecting patients for intensive psychotherapy; the presumption is that they will select those patients in whom they are the most interested. Of more than 30 residents who have received their first year of training at the Mercy-Douglass, none have been Negro and all except 4 have been male. The 4 female residents tended to choose adolescent patients and middle-age females for intensive work.

Readmissions to this unit include those patients who have been treated here and were then readmitted for subsequent treatment. There is a considerable degree of selectivity governing such readmissions, and this selection is considerably governed by staff interest in the patient. The percentage of readmissions for the various categories does not show any major difference in readmission policy on a racial or a sexual basis.

Transfers to other hospitals for continued care is another criterion of interest in the patient. There is no fixed policy as to how long a patient may remain for treatment; as long as active treatment is in progress, and as long as someone on the professional staff is devoting time to individual treatment, a patient may remain almost indefinitely. Several patients have remained a year or longer (28 altogether). Figures for the number of patients transferred indicates that there is a bias in favor of females, but race does not seem to be important in influencing selection for transfer.

The next criterion, that of patients signed out of the hospital against medical advice, is a much less clear indication of staff attitudes toward patients. The staff is taught to regard a discharge against advice as a treatment failure. They are urged to spend considerable time with patients and families trying to persuade them against resorting to this action. However, there is a tendency to spend more time advising against such a discharge in the case of those patients in

whom the staff is more interested. Probably a more important factor in determining a discharge against advice is the attitude of patient and family toward the hospital. Our figures indicate that sex is more important than race with regards to discharges against advice. Only once has a patient been kept in the hospital when the family insisted on her discharge.

The resident staff is encouraged to select a number of their inpatients to follow in the outpatient clinic when discharged from the hospital. We feel that this is another indicator of potential bias toward the patient. Here, bias seems to be against white males, with an almost equal number of the other 3 categories being followed.

The last column in Table 1 shows that there is no significant difference in median length of stay as regards to race and sex. However, a length of stay considerably exceeding the median does indicate a special interest in the patient. Of the 28 patients who remained a year or longer, 10 were white females, 12 were white males, 4 were Negro males, and only 2 were Negro females. This would indicate a strong racial bias on the part of the staff. Patients under the age of 17 and over the age of 60 pose particular problems in disposition in this community; they have been excluded from the calculations for median length of stay, but have not been excluded from the group remaining longer than 1 year.

Tables 2 and 3 present some of the general characteristics of the patient population studied. In the diagnostic table, the high incidence of organic brain syndromes and paranoid schizophrenia in Negro males is of interest. In our group, Negro patients showed a low incidence of psychotic depressions and a high incidence of acute schizophrenic reaction. Males of all races showed a high incidence of chronic schizophrenic reactions, and Negro males were seldom given a diagnosis of neurosis.

In Table 3, the preponderance of single men over single women and the low divorce figures for Negroes are of interest. The figures for patients reported as separated or widowed seem to be culturally determined. Age at time of admission shows a high rate of young Negro males which is balanced by low figures for older patients

TABLE 3
Age and Marital Status by Sex and Race

MARITAL STATUS	WHITE FEMALE (399)	NEGRO FEMALE (214)	WHITE MALE (233)	NEGRO MALE (154)
Single	32.8%	21.9%	49.5%	52.5%
Married	42.5%	50.6%	36.3%	30.9%
Separated	7.5%	20.6%	4.7%	6.5%
Widowed	9.7%	3.8%	4.2%	1.4%
Divorced	7.5%	3.1%	5.3%	.0%
AGE				
0-17	3.3%	5.6%	8.3%	15.6%
18-40	58.1%	69.2%	53.2%	63.6%
41-60	30.3%	22.0%	31.3%	18.2%
61 & over	8.3%	2.3%	8.2%	2.6%

in the same racial group. Since the majority of patients are selected for admission by the State Reception Center, the age groupings reflect their selection rather than the hospital's.

SUMMARY

A description of 5 years' experience involving a cooperative effort is presented. The chief cooperating agencies involved are the State and City governments, a community general hospital, and the Department of Psychiatry of a large university. This cooperation has worked rather smoothly with some administrative problems. Integrating a large psychiatric service in a community general hospital has not worked smoothly. Community-hospital cooperation has proceeded, but can be developed much more extensively.

Race relationships within the Department of Psychiatry have been the subject of special scrutiny, and the results of a pilot survey in this area are given. This preliminary survey has included some of the social and diagnostic characteristics of the patient population, and ways in which patients are treated psychiatrically. These figures are presented in terms of race and sex as applied to patients selected for intensive psychotherapy, electroshock, transfers to other hospitals, outpatient clinic referrals, discharges against medical advice, readmissions to the service, and length on the service.

CONCLUSIONS

1. A workable arrangement involving many different agencies can be established.

2. The difficulties of integrating a proportionately large psychiatric service for severely ill and chronically ill patients with a general community hospital are marked but not insurmountable.
3. Previously reported diagnostic differences in groups of Negro and white patients are supported by this survey.
4. Race appears to be a major factor in the selection of patients for intensive psychotherapy in this setting.
5. Sex appears to be a more important factor than race in determining other types of psychiatric treatment, such as electroshock, transfers, discharges against advice, and referral to outpatient clinics in this setting.
6. Racial differences are frequently used as rationalizations for expressing buried feelings, both on the part of staff and patients.
7. Racial difference in symptomatology need to be explored further.
8. Cultural differences are more important influences on psychiatric treatment than are racial differences.

PSYCHIATRIC CORRELATES OF EVOKED CEREBRAL CORTICAL POTENTIALS^{1,2}

CHARLES SHAGASS, M.D., AND MARVIN SCHWARTZ, Ph.D.³

The potentials evoked at the cerebral cortex by sensory stimulation are not detectable in the usual electroencephalogram recorded from electrodes placed on the scalp. However, the evoked potentials may be extracted from the larger "spontaneous" rhythms of the EEG by applying Dawson's (1) averaging principle. Using averaging, we have been exploring the characteristics of somatosensory evoked potentials in psychiatric syndromes. The recovery cycle is one aspect of cerebral responsiveness which can be measured by this approach. It is determined by administering pairs of stimuli, separated by varying intervals. The size of the second response, compared to the first, indicates the extent to which responsiveness has recovered after a given interval.

We have previously reported the results obtained in an initial study of recovery function in 13 nonpatient subjects and a mixed population of 92 psychiatric patients (2, 3). The normal recovery curve to 200 msec. tended to be biphasic, with initial return of full responsiveness by 20 msec., followed by a phase of diminished recovery, and a second phase of full recovery, or supernormality, peaking at 120 msec. The main differences found between groups were in the early recovery phase. The amount of recovery by 20 msec. was significantly less than normal in three groups of patients: personality disorders, schizophrenias, and psychotic depressions. Recovery did not differ from normal in a group which could be designated as "dysthymic neurosis"; it consisted of patients diagnosed as

anxiety, depressive, or psychophysiologic reactions. After successful treatment, the recovery curves of psychotic depressive patients returned to normal, indicating that deviant recovery is reversible (4).

The study was carried out to verify the previously found relationships between recovery function and psychiatric diagnosis, using another experimental population.

METHODS

Detailed descriptions of recording procedures have been presented elsewhere (2, 3). The photographic averager described by Shipton (5) was used to extract evoked potentials. The central component of this averaging system is a modified Tektronix 502 twin beam cathode ray oscilloscope. Its basic feature is that amplitude changes are depicted by fluctuations in beam brightness instead of the usual vertical, or Y-axis, deflections. Each sweep is thus a straight line, varying in brightness. For successive sweeps, the beams are systematically displaced by a raster. They are recorded on a continuously exposed Polaroid transparency. Consistent effects of the stimuli are seen as regular vertical light or dark bands on the film. Optical analysis of the film is accomplished by moving it over a slit through which a beam of light passes onto a photomultiplier, the output of which is written out by an XY plotter. This yields tracings like those shown in Fig. 1, which are the average of 100 responses.

Somatosensory potentials were evoked by electrical stimulation over the ulnar nerve at the wrist, using a Grass S4 stimulator and isolation unit. Recording and stimulating electrodes were chlorided silver discs. Scalp leads were bipolar, placed 7 cm. parasagittally on the hemisphere contralateral to the stimulated wrist, with the presumably active lead 2 cm. behind the mid-coronal plane and the other lead 5 cm. anterior. Stimulus durations ranged from 0.1 to 0.24 msec., and intensity was adjusted to produce a visible twitch of the little finger. The stimu-

FIGURE 1

Sample tracings and recovery curve to 100 msec. for one subject. Each tracing, average of 100 responses. Upward deflection indicates relative positivity at electrode over somatosensory area. Amplitudes measured from T, maximum negativity (trough) to P, maximum positivity (peak). All calibrations, 3 microvolts. Peak ratio of amplitudes (R_2/R_1) during initial recovery phase was at 12.5 msec. in the smoothed curve although ratio appears largest at 15 msec. in tracings; this was because correction for effect of first stimulus was greater at 15 msec. than at 12.5 msec.

lus repetition interval was 1.3 sec. For a single averaged tracing 100 stimuli or stimulus pairs were administered. The initial, or primary, component of the somatosensory evoked potential begins with a negative deflection (downward in Fig. 1), which is maximum about 20 msec. after stimulus onset. This is followed by a positive (upward) deflection, which reaches its peak at an average latency of 25 msec. There are then a number of later components, which are rather variable from person to person in form and latency, and may also change considerably in the same subject depending upon such factors as the intensity of stimulation and the state of alertness. Because the later components are so variable, we have devoted our attention to the primary evoked potential, which can nearly always be identified with certainty. Amplitude was measured from maximum negativity to maximum positivity of the primary component, indicated by T and P in Fig. 1.

To measure a recovery cycle to 190 msec.,

29 averaged tracings were taken. Three of these were of responses to single, unpaired, stimuli. Twenty-six were with paired stimuli. Stimulus separations were increased in steps of 2.5 msec. from 2.5 to 20 msec., in steps of 5 msec. to 30 msec. separation, and in steps of 10 msec., thereafter. Fig. 1 shows a series of tracings from a subject whose recovery cycle pattern was like that of the average nonpatient. Actually this was a patient who had recently recovered from an acute schizophrenic episode. The second response appears larger than the first at separations of 12.5 and 15 msec. The curve at right plots the relative amplitudes of second, compared to first, responses (R_2/R_1) as a function of stimulus separation to 100 msec. There may seem to be some degree of discrepancy between the ratios plotted in the curve and those expected from inspection of the tracings. These are due to two procedures regularly used in processing the data. One is a subtraction procedure employed to estimate the actual size of the

second response, independent of the effects of the first stimulus. The changes, which responses to an unpaired stimulus indicate would have occurred at the same time as the second response, were subtracted from the apparent response to the second stimulus. The second is a smoothing procedure (6), which has been applied to all our data.

*The subject population was composed of 27 nonpatients and 75 patients. Table 1

significantly lower than normal in personality disorders, schizophrenias and psychotic depressions, and would not differ from normal in the group we have called dysthymic. Table 2 shows the median recovery ratios for each of the main groups, together with the proportion of cases with a recovery ratio above .90, a value which is close to the median for all subjects. Comparing the non-patient group with the group of 75 patients

All Patients	75	24	14-62	27

describes the groups in terms of diagnosis, sex and age. Nonpatients were paid volunteers, mainly college students. Patients were consecutive, testable, hospital admissions. Diagnoses were those made at discharge by senior staff. The patient sample contained fewer cases of schizophrenia and psychotic depression than one would have liked. The relatively small number in these categories admitted during the data-taking period was further reduced by prior administration of medications, which could not be stopped for at least 48 hours prior to testing. The nonpatient group was somewhat younger than the patient group, and contained a higher proportion of male subjects.

RESULTS

Results are presented in terms of the maximum amount of recovery achieved by 20 msec., as indicated in the smoothed recovery curve (Fig. 1). This is the convenient single numerical index used in our previous studies. From the first study, it would be predicted that initial recovery would be

TABLE 2
Diagnosis and Peak Recovery by 20 msec.
(Present Study)

DIAGNOSTIC GROUP	NO. CASES	MEDIAN RATIO	RATIO NO.	>.9 PERCENT
Nonpatients	27	1.04	22	81.5
Personality disorders	23	.73	3	13.0
Schizophrenias	9	.75	2	22.2
Psychotic depressions	10	.86	4	40.0
Total	42	.77	9	21.4
Dysthymics	18	1.04	12	66.7
Miscellaneous	15	1.06	12	80.0
Total	33	1.04	24	72.7

as a whole, the ratios were significantly higher in the nonpatients (chi square, 9.7; 1 df; $P < .01$). As indicated by the table, median ratios of the dysthymic and miscellaneous groups of patients were almost the same as the nonpatient median, whereas

median ratios were lower in the personality disorder, schizophrenic and psychotic depressive groups. The chi square obtained by treating the patients as two groups, divided as indicated by the totals in Table 2, and the controls as a third, in a 2 by 3 table, was 30.8 ($P < .001$).

The results for the psychotic depressive patients did not differ as much from those of controls and dysthymics as they did in the earlier study. Examination of their case histories suggested that this may have been due to inclusion of some atypical cases under this diagnostic heading. The results for patients with personality disorders were more clearly deviant from normal than in the previous study and the results for schizophrenic patients were about the same. In general then, present results verified the previous recovery cycle findings.

We have previously reported that the coefficient of reliability of the index of initial recovery was .78(2). This reliability coefficient refers to the peak ratio by 20 msec. Additional data, obtained in 25 subjects of the present sample, permitted us to estimate the reliability of the shape of the early portion of the recovery curve. In these subjects, two curves were determined during the same test session to separations ranging from 25 to 50 msec. For one curve, three stimuli were administered instead of two, but it was possible to compare the R_2/R_1 ratios for each. For each subject, rank order correlations were determined between ratios at identical separations. Correlation coefficients ranged from .25 to 1.00, all but 4 being .60 or higher; 11 of 25 were .90 or higher. The median coefficient was .75. This indicates that the shape of the whole early portion of the recovery curve was about as reliable as the peak value by 20 msec.

Table 3 shows the results obtained by combining the data of both studies on recovery cycles. Two patients, classed as undiagnosed in the earlier study, were subsequently diagnosed schizophrenia and are so placed in the table. The ratio of .90 was exactly the median for all 207 subjects. Whereas 87.5% of the controls had a peak initial recovery ratio of .90 or greater, only 22.3% of patients with diagnoses of personality disorders, schizophrenia, or psychotic depression achieved this level of initial re-

covery. The difference between nonpatients and each of these three patient groups was highly significant ($P < .001$). Recovery ratios in dysthymics, who constituted the only other large patient group, did not differ significantly from those of nonpatients. Fig. 2 shows the percentage distributions of

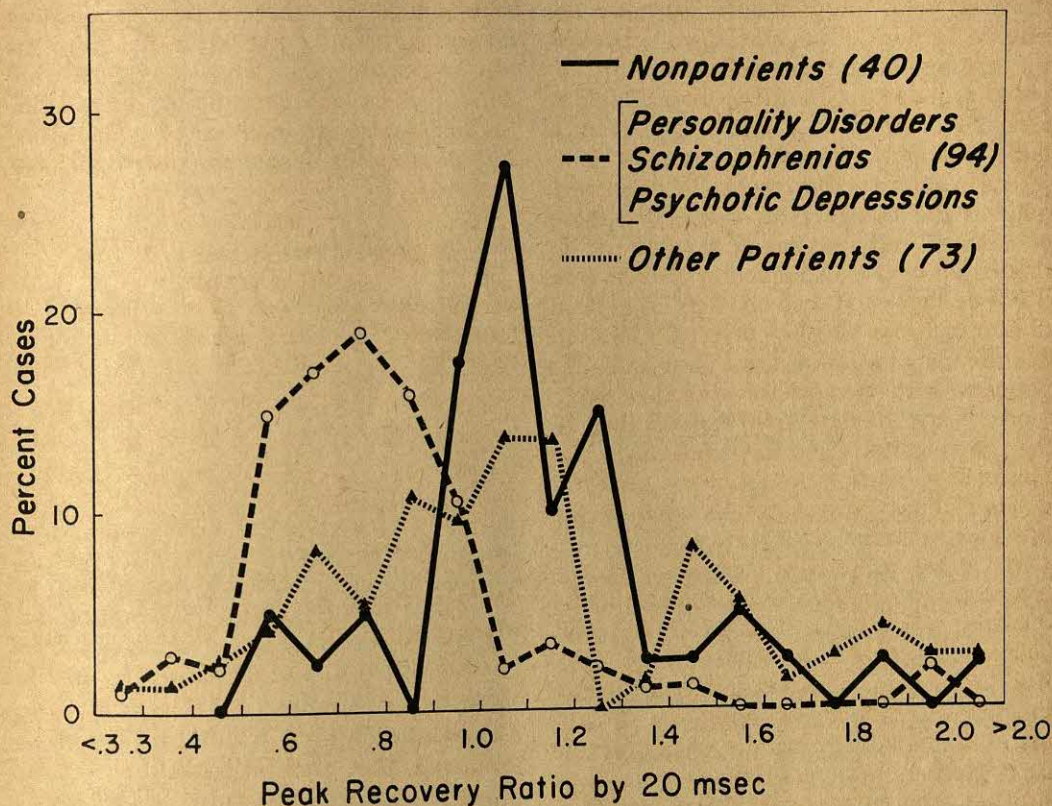

TABLE 3
Diagnosis and Peak Recovery by 20 msec.
(2 Studies Combined)

initial recovery ratios for nonpatients, the deviant patient groups combined, and the remaining patients.

Combining the data of the two studies still did not provide sufficient numbers of cases for statistical analysis in diagnostic categories, other than those mentioned. Some trends suggested by the results in these other groups are, however, worthy of comment. There were 5 cases of paranoid state, of whom only one had a ratio below the median. The results in this group present the only exception to the general conclusion that recovery is lower than normal in the "functional" psychoses. The 6 cases with diagnoses of conversion reaction tended to have lower recovery ratios than the dysthymics; although more cases are needed, the difference has prompted us to treat the conversion reactions separately from other psychoneuroses for the time being. The data for the 6 cases with brain syndromes are of particular interest. Ratios

FIGURE 2

Percentage distributions of peak initial recovery ratios for subjects of present and previous studies (2, 3), divided into three groups.

in this group tended to be high. The brain syndromes were rather diverse, ranging from toxic psychosis to craniopharyngioma. The fact that recovery was not diminished in this group has the important implication that the behavioral changes associated with organic brain damage need not necessarily be accompanied by altered recovery, *e.g.*, the case with the craniopharyngioma displayed marked memory deficit and personality change, but his recovery ratio was normal.

In both present and previous studies, the initial recovery ratio was not correlated with age. Although the ratio did not differ significantly between the sexes in the first study, there was a sex difference in present data. The ratios of females were significantly lower than those of males. Combining the data of the two studies, the sex difference was still highly significant (Table 4). Accordingly data were compared for sub-

ject groups of the same sex. Table 4 shows that group differences in recovery within each sex were highly significant statistically, indicating that they did not depend on sex distribution differences. It will also be noted that the median ratios of male and female nonpatients were almost identical. The absence of sex difference in nonpatients favors the probability that recovery does not really differ between the sexes, and that differences found in the present sample may be attributed to unequal sex distribution by diagnosis.

DISCUSSION

The results of this study were in general agreement with those of our previous investigation of somatosensory recovery function in psychiatric patients. Here, as before, recovery in the initial phase was found to be diminished from normal in patients with personality disorders and major "functional"

psychoses, and similar to normal in dysthymic neuroses. Although the remaining patients did not, as a group, differ significantly from normal in recovery, many more cases will be required to evaluate each diagnostic group separately.

In a recent investigation we found that another evoked potential measure of cerebral responsiveness, the intensity-response gradient, was correlated with psychiatric diagnosis (7). The evoked potential first appears at sensory threshold and increases as a function of stimulus intensity (8). The curve relating response amplitude to intensity is the intensity-response gradient. In our data, the gradients were linear if intensity was scaled in logarithmic units. The slopes of these linear gradients were found to be significantly steeper in psychiatric patients than in nonpatients. Dysthymics, as in the recovery studies, were the exception; their gradients were like those of nonpatients. In the same study relationships between intensity-response gradients and recovery functions were analyzed in 44 subjects with both determinations. The results indicated that these were relatively independent correlates of psychiatric diagnosis.

Our studies of evoked potentials have so far yielded two psychiatrically relevant measures of cerebral responsiveness. It seems reasonable to expect that additional indicators will be found with further investigation. The evoked potential method thus seems to offer a fruitful approach to

the study of brain mechanisms in psychiatric disorders. More precise delineation of relationships can reasonably be expected as techniques are refined and larger samples of subjects, classified along variables which may be more discriminative than psychiatric diagnosis, are studied.

One outcome to be hoped for from these studies is that they will serve to focus animal experimentation on the problems of mechanism. Our own work in the cat has so far implicated the reticular formation as an important influence on the recovery function. We found that recovery changes with spontaneous or drug-induced alterations of alertness (9), that it is retarded by barbiturates (10), and that it is speeded by direct electrical stimulation applied to the mesencephalic reticular formation. It is too early to relate these effects to recovery changes found in psychiatric illness.

Our current ideas about the functional significance of the recovery index are at a primitive level. We have been struck by the fact that recovery is diminished or retarded in conditions which are characterized by unusual conduct, the personality disorders and "functional" psychoses. Diminished recovery implies that stimuli following the first in a sequence do not elicit the same cerebral response until some time has elapsed. This could form a basis for perceptual distortion, or incapacity to perceive all available cues, which could in turn lead to deviant conduct.

QUANTITATIVE RELATIONSHIPS IN THE SYSTEMATIC DESENSITIZATION OF PHOBIAS¹

JOSEPH WOLPE, M.D.²

One of the most widely applicable generalizations from modern medical research is that pathological processes are functionally related to normal physiology. It may be assumed that this is true in psychiatry too, but, in the field of the neuroses, there has been little attempt to study such relations, largely because conventional psychiatric training has discouraged interest in experimentally established psychological laws. Only recently has there developed an approach to the problems of neurosis based on experimental psychology. This has given the therapist for the first time a substantial degree of direct control over neurotic reactions. The present contribution demonstrates the concordance of the effects of a particular therapeutic procedure with a general psychological law—the psychophysical law(7, 8).

Introductory Background. That anxiety is a feature of almost all human neuroses is acknowledged by all psychiatrists no matter what theories they hold. The conventional belief (for which there has never been scientifically acceptable evidence) is that neurotic anxiety is secondary to other processes, e.g., repression. By contrast, there is now substantial experimental and clinical evidence that neurotic anxiety is nothing but a conditioned (learned) response. In broad terms, neuroses are seen as persistent, unadaptive, learned habits of reaction acquired in anxiety-generating situations with

anxiety usually pre-eminent among the reactions learned(12).

It has been shown that, by the application of principles of learning, neurotic habits can be overcome both experimentally (9, 12) and clinically (2, 4, 10-12) with effects that are evidently permanent.³ In both contexts, particularly effective use has been made of the *reciprocal inhibition principle* first recognized by Sherrington(6). In psychotherapy this is applied by arranging conditions so that the neurotic response can be inhibited by the simultaneous elicitation of a dominating incompatible response.

The therapeutic possibilities of the reciprocal inhibition principle first appeared in the course of studies on experimental neuroses in cats(9, 12). Unlearning of neurotic responses was procured by feeding the animal a number of times while it was responding with mild anxiety to a stimulus slightly resembling some aspect of the conditioning situation. The strength of the anxiety response to the particular stimulus progressively declined, eventually to zero. Increasingly "strong" anxiety-evoking stimuli were successively dealt with in this way; and eventually the conditioned anxiety responses were eliminated from the whole range of stimuli. Apparently, each time the animal fed, the anxiety response was to some extent inhibited; and each occasion of inhibition was followed by some degree of weakening of the anxiety response *habit*.

Among various psychotherapeutic methods that have been based upon this experimental paradigm there is one that is known as *systematic desensitization*(12, 13). In this deep muscle relaxation is the source of inhibition of anxiety. The procedure consists of three sets of operations: 1. The patient is given training in Jacobson's progressive relaxation but in an abbreviated way, occupying only part of each of about 6 sessions. 2.

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

For assistance in the mathematical treatment of the data I am indebted to Frank Banghart, Ph.D., Dept. of Preventive Medicine, University of Virginia School of Medicine; Norbert L. Erick, Graduate School of Business, University of Virginia; and John C. Wooddy, actuary, North American Insurance Co.

² Research Professor of Psychiatry, Dept. of Neurology and Psychiatry, University of Virginia School of Medicine. On leave of absence 1962-63, c/o Institute of Psychiatry, Maudsley Hospital, London, England.

³ Numerous clinical reports have been assembled by Eysenck(3). For recent discussions of theoretical issues see(1, 5).

During the same interviews steps are taken toward the construction of what is called an "anxiety hierarchy." This is a list of stimulus situations to which the patient reacts with unadaptive anxiety. The items are then grouped according to themes: *e.g.*, a particular patient may have a social disapproval theme, a crowd theme, and a height theme. The items of each theme are ranked, the most disturbing of them being placed at the top of the list and the least at the bottom. 3. When the hierarchies have been prepared and the patient has received sufficient training in relaxation, he is made to relax as deeply as possible. He is then asked to imagine a scene embodying the least disturbing member of an anxiety hierarchy. The scene is presented again and again until it ceases to evoke any felt disturbance whatsoever. The therapist then proceeds to deal in the same way with the next scene higher in the hierarchy. Through such progressive steps, even the highest member of the hierarchy is eventually deprived entirely of its ability to evoke anxiety. There is almost invariably a one-to-one relationship between what the patient can imagine without anxiety and what he can experience in reality without anxiety.

The desensitization method, though most obviously suited to the treatment of the classical phobias, is also very effectively applied to overcome neurotic anxieties evoked by a very wide range of stimulus themes, such as situations of rejection, the sight of discord between others, and the stimulus sources of hypochondriacal reactions. It is applicable, in fact, to almost any source of neurotic anxiety not involving inadequacies in the handling of interpersonal relationships (12).

Results of desensitization therapy were recently published with respect to 68 hierarchies from 39 patients (13). They included both classical phobias and allied neurotic response habits related to more complex situations. The treatment was judged effective in 35 of the patients. Forty-five of the phobic and allied anxiety habits were apparently eliminated and 17 more were markedly ameliorated, *i.e.*, estimated to be at least 80% improved.

The Present Investigation. Because of the repetitiveness of its operations, the desen-

TABLE 1

Mean session expenditure per successfully treated phobia	12.3
Median number of sessions per patient	10.0

sitization technique lends itself to quantification. The number of scene presentations needed to overcome a particular thematic system of neurotic anxiety responses has varied in different cases from a dozen or so to more than 2,000.

Some time ago, during a perusal of the records of cases treated by desensitization, it was noted that the number of scene presentations required to make a given amount of progress was often not uniform, in some cases increasing and in others decreasing as treatment went on. In other words, in the advance of desensitization to encompass increasingly disturbing situations, sometimes more and more effort was required per unit advance, and sometimes less and less.

Subjects and Material. To investigate the determinants of these quantitative variations, it was necessary to select for study hierarchies that varied along a quantifiable stimulus dimension. In all hierarchies there is *ipso facto* quantitative variation in terms of magnitude of anxiety response, but the magnitude of the stimulus sources can not always be compared. For example, if a patient is neurotically disturbed by situations of implied criticism or rejection, while the situations can be ranked according to amount of disturbance they produce, they can not be objectively measured and compared with each other as stimulus quanta. On the other hand, in acrophobias, for example, anxiety increases with height, and height is independently quantifiable.

As might have been expected, the hierarchies that can be quantified relate to

phobias of the classical type. The phobias that have been the subject of the present study have been grouped as follows: 1. Phobias in which anxiety increases with *decreasing* distance from a fearful object or situation (proximation phobias). 2. Phobias in which anxiety increases with *decreasing* space and/or freedom of movement (claustrophobias). 3. Phobias in which anxiety increases with *increasing* distance from a *safe* point or person (remoteness phobias). 4. Phobias in which anxiety increases with number of phobic objects.

Among the cases surveyed for possible inclusion in this study there were many who had phobias that fell into the above groups but that had to be excluded for practical reasons. In some cases, the patient's level of anxiety was influenced by other factors than the linear phobic dimension, and operations desensitizing to such factors were interspersed in an irregular manner among operations relevant to the studied dimension. For example, in a patient who had a fear of being alone, the intensity of fear was determined not only by distance but also by time of day. Since desensitization on the two variables was carried on concurrently, it was not possible to determine how much of the work at any particular stage was due to the distance factor per se. In other cases the hierarchies were not conceived in quantitative terms, although they could have been. For example, a claustrophobic hierarchy included such items as being in an elevator, lying under a bed, and lying in bed under tight blankets—for much of which changing cubic dimensions in a constant situation *could* perhaps have been substituted, but in fact were not.

Our subject matter is 20 series of desensitization operations in phobias of 13 patients, all of which were completely overcome. Most of these phobias were self-contained, but in 2 patients—a phobia for funerals in one, and phobias for dead dogs and tombstones in the other—the phobias were parts of extensive anxiety response groups on the general theme of death.

Procedure. In each case we had a written record of the number of repetitions of each scene presented to the deeply relaxed patient at every session, and of how much, if

any, decrement of anxiety followed the presentations. Thus, in a phobia for heights it would have been recorded that 8 imaginings of looking down from a height of 10 feet reduced anxiety at that scene to zero, 6 imaginings at 20 feet, 5 at 30 feet, and so forth.

The procedure was to plot graphically for each stage of conquest of the phobia the *cumulative* number of scene presentations that had been given, up to and including that stage. The reason for using the cumulative number and not that for the separate stage of the hierarchy is that the pre-treatment level of anxiety at any stage would be indicated by the *total* number of presentations employed to bring down to zero the totality of anxiety aroused by stimuli up to that stage. To illustrate this, let us consider the acrophobic example just mentioned. The relative intensity of anxiety at 10 feet before treatment is conveyed by the scene presentations to reduce it to zero—*i.e.*, 8. The relative pre-treatment intensity of anxiety at 30 feet would be indicated by the *total* scene presentations used to achieve zero anxiety at 30 feet, *i.e.*, $8 + 6 + 5 = 19$ —and obviously not by the last group of presentations only, *i.e.*, 5.

Results. In every case, the cumulative curve displayed a consistent trend, being either a positively or a negatively accelerating function. The character of the trend was determined by the type of phobia being treated. In phobias in which anxiety increased with increasing proximity to a particular object, and also in claustrophobias, the cumulative curve accelerated positively. In phobias in which anxiety increased with distance from a *safe* point, and in those in which it increased with increasing *numbers* of phobic objects, the curve accelerated negatively. No exceptions were found. The broad findings are illustrated by the first four figures, each of which contains the curves of a particular group. (In order to make them comparable, the curves have been subjected to percentile transformations.) The horizontal axis shows attained percentage of criterion of recovery, and the vertical axis scene presentations as a percentage of the total number finally employed to overcome the whole hierarchy.

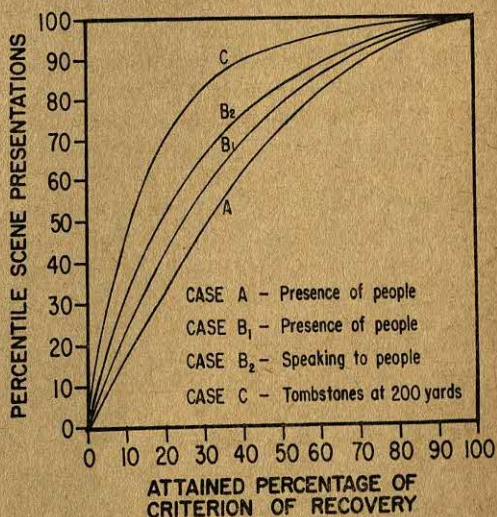

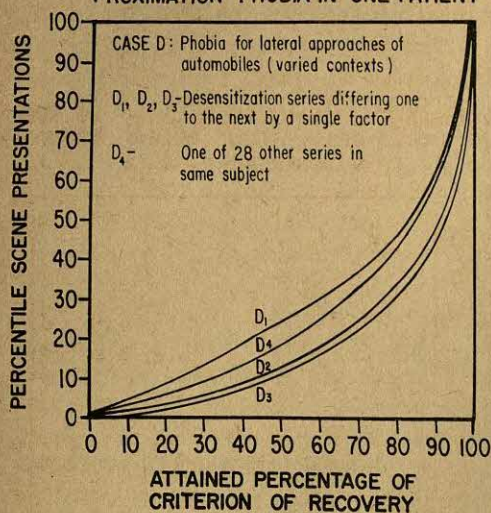

Figure 5 shows the general consistency of form of the desensitization curves of 4 hierarchies in one patient with a severe phobia for laterally approaching cars (reported in detail elsewhere(14)). Hierarchies D₁-D₃ differed from each other by a single stimulus variable. The curve of hierarchy D₄, which lies snugly among the others, comes from quite a different manifestation of the phobia.

A question that may legitimately be

raised is: Is the form of a desensitization curve simply a reflection of the type of phobia, or is there something about the personality of the patient that determines both the type of phobia he acquires and the course desensitization takes? An immediate answer is afforded by Figure 6, which shows 3 cumulative curves obtained from a single patient. That displaying negative acceleration (B) delineates the therapeutic effort involved in desensitization of the

FIGURE 5

PERCENTILE CUMULATIVE CURVES: DESENSITIZING OPERATIONS IN SEVERAL ASPECTS OF PROXIMATION PHOBIA IN ONE PATIENT

anxiety response to an increasing number of tombstones at 200 yards. The positively accelerating curves belong respectively to proximation phobias to a dead dog (A) and to a stationary automobile (C), and are strikingly similar. Desensitization functions, then, are phobia-specific, not person-specific. (Note, incidentally, how closely the fitted curves approximate the plotted points.)

Functional Relations. Mathematical analysis of the above curves reveals that, with the exception of that for agoraphobia curve

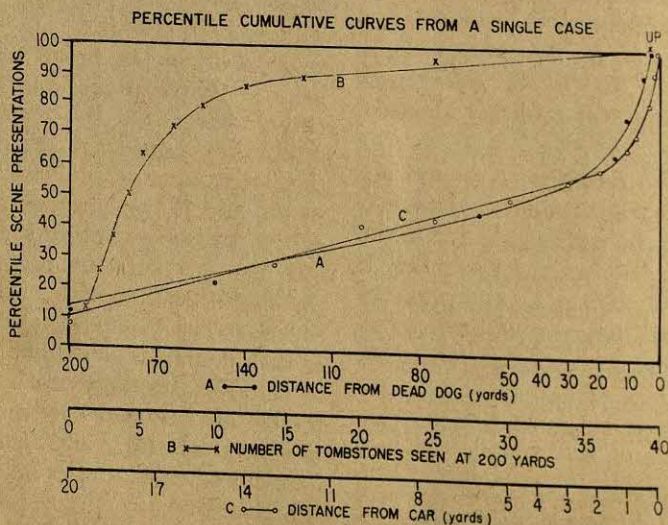

A in Figure 3 and curve C in Figure 4 (both of which will be commented upon subsequently), they express the same kind of functional relation as had been noted by Stevens (7, 8) in relating the physical magnitude of a stimulus to its perceived intensity—the “psychophysical law.” The method of direct correlation has yielded the general empirical rule that the psychological magnitude is a power function of the stimulus magnitude. This means that to make one stimulus seem twice as strong as another, the physical energy must be increased at a fixed ratio, no matter what the initial intensity level. The relationship is expressed by the formula: $P = kS^n$ where P stands for perceived intensity (psychological magnitude), S for stimulus magnitude, k is a constant, and n the exponent of the relationship. The exponent is determined empirically by the formula

$$n = \frac{\log 0.5}{\log r}$$

where r is the ratio between the physical magnitude of a given stimulus and the physical magnitude of the stimulus that appears twice as strong as the given stimulus.

Insofar as the desensitization curves portray this kind of functional relation it may be deduced that the amount of work required for each measured unit of progress in overcoming these phobias is a function of the correlated magnitudes of the subject's

FIGURE 6

pre-treatment response, the relevant measure of response here being *autonomic response magnitude* instead of perceived magnitude.⁴ As a decisive test of our presumption an investigation is needed that would compare 1) the curve of directly measured autonomic magnitudes of response to stimuli at different points in hierarchies before treatment and 2) the curve of subjective disturbance to these stimuli before treatment, with the desensitization curve subsequently obtained.

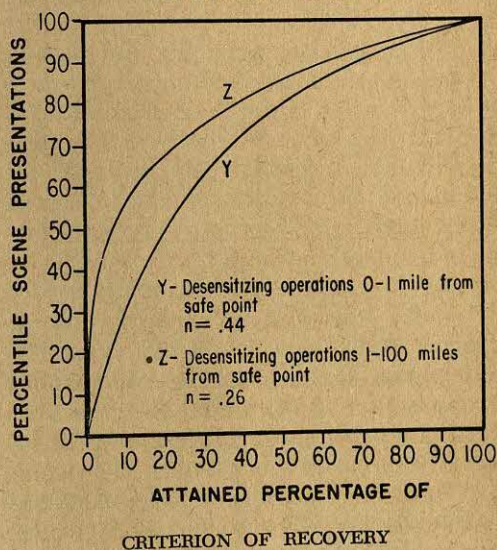

The foregoing applies quite obviously to the proximation phobias, the claustrophobias, and to the phobias in which anxiety increases with number of feared objects. In all these the attention of the patient is focused on fearful stimulus configurations. In the case of the remoteness phobias (agoraphobia and acrophobia) the focus is on a safe point to which in a sense the patient looks backward as he moves into "danger," and the curve is clearly the reciprocal of that of the proximation phobias—as would be expected if it is a function of stimulation intensity of the safe point. The *increment* of fear per unit increase of distance becomes less as gross distance grows greater.

For several of the curves the value of the exponent n was determined by Stevens' formula (v.s.), the value of r being derived from the point on the x axis at which $y = 50\%$ (0.5). Among the proximation phobias (Figure 1) the exponent of the middle curve, "C," is about 3.0. Among the phobias varying with numbers of phobic objects (Figure 4) the value for Curve B₂ is 0.43. The middle curve, "C," in the remoteness phobia group (Figure 3) is almost identical with this.

Curve "A" of the remoteness group does not conform to a power function. However, the desensitization distances reflected in the curve ranged from 20 yards to 100 miles. It is obvious that a person's perception of differences of yards may vary in quite a dissimilar way from that of differences of

miles. It was therefore decided to plot separate curves for 0-1 mile and for 1-100 miles. Two power function curves were obtained (Figure 7), the first (0-1) being

FIGURE 7
PERCENTILE CUMULATIVE CURVES OF SUB-DIVIDED DESENSITIZING OPERATIONS IN AGORAPHOBIA CASE "A"

fairly similar to the theoretical curve $n = 0.44$, and the second (1-100) conforming almost exactly to the theoretical curve $n = 0.26$. Curve C in Figure 4 fits an exponential function [$P = 76.11 (1 - 0.85^n)$] a good deal better than a power function, but remains close enough to the power curve $n = 0.3$ not to constitute a damaging exception to the rule.

Implications. In broad terms, this study has two implications, one theoretical and one practical. On the *theoretical* plane it establishes more firmly than ever (14) that the desensitization procedure has its therapeutic effects by conditioning. Therapeutic effects that seem to accord with psychophysical laws are consonant with conditioning theory, rather than with so-called "dynamic" theories. The *practical* result of this study is that it affords a method for predicting, in certain cases, how much more treatment is likely to be needed when desensitization has gone on for long enough to provide data from which to derive a mathematical function.

⁴ A corollary of the present study is the prediction that in cases in which stimulation has both perceptual and autonomic response consequents, the perceptual and autonomic magnitudes will, as a rule, be linearly related to each other.

SUMMARY

Since it had been noted that in the desensitization treatment of phobias the number of presentations of a scene required to bring the anxiety level down to zero is not uniform but tends to increase or decrease on the way up a hierarchy, an attempt was made to establish quantitative relations by a study of those phobias that vary along a physical dimension. It was found that in claustrophobias and phobias in which anxiety rises with increasing proximity to a feared object the number of scene presentations to zero anxiety is low at a distance and increases with proximity, the cumulative curve corresponding to a positively accelerating function. In agoraphobias as in phobias increasing with number of objects the number of presentations needed is initially high and progressively falls as distance grows, the cumulative curve corresponding to a negatively accelerating function. In both cases the number of presentations to advance a segment of given size varies inversely with the distance of that segment from the central "safe zone" (as in agoraphobia) or "danger zone" (as in claustrophobia) in accordance with a simple power function such as has been constantly found to be the functional rela-

tion between stimulus magnitude and psychological magnitude.

PROGNOSIS FOR PSYCHIATRIC ILLNESS IN THE AGED ¹

M. STRAKER, M.D.²

The marked increase in the number and proportion of elderly citizens is having an impact on medical practice and on hospital procedures. There is a sharpening focus on problems related to aging, embracing medical, social, psychologic, economic and cultural issues. In some of these areas, clarification is proceeding, but solutions have not yet evolved, and much work remains to be done.

The biologic basis of aging is not yet understood, so that therapy cannot be founded on etiologic considerations, but remains empiric in nature. However, the application of trial and error therapy justifies a new optimism regarding the medical care of the aged. When unwarranted therapeutic pessimism is overcome, it can be shown that medical, psychiatric, surgical and rehabilitation resources can be brought to bear effectively in rescuing many of the aged from progressive ill health, neglect, and psychological regression and dilapidation.

The writer's experience with the aged group consists of patients seen in private psychiatric practice, in the institutional setting, and the general hospital; it includes also a lengthy association with a hospital for the chronically ill.² Particular considerations pertaining to diagnosis and therapy in the latter institutionalized group have already been reported(1-5). The present study, in contrast, is from material drawn entirely from the community level. This report deals with 100 patients who were examined, assessed, and treated in private

practice. The data obtained are analysed in relationship to etiological and precipitating factors, the kind of illness reaction, the type of therapy used, its effectiveness, overall treatment results, etc.

Age and Sex Distribution. Table 1 outlines the age and sex distribution in the 100 cases.

TABLE 1

AGE (YRS.)	FEMALES	MALES	TOTAL
60-64	22	14	36
65-69	15	14	29
70-74	12	12	24
75+	6	5	11
Average Ages	66.9 yrs.	67.4 yrs.	
TOTAL	55	45	100

The predominance of females over males reflects the greater longevity of the female and is consistent with overall population studies. There is no clear agreement about the chronological age appropriately labelled as "old age." Thirty-six patients fell into the 60-64 year group, while 64 were 65 years of age and older. The oldest patient was 85 years of age.

Social Milieu: Marital, Economic Working Status, Social Activities. Table 2 sets down the sociological data of the group. The importance of sociological factors in understanding the problems of aging has been underlined by many writers(6-9). Most frequently mentioned are disturbances of roles and the concept of the self

resulting from aging, and the special effects which emerge from retirement or the deaths of friends and family members. Existing cultural reactions towards the aged, and other varied factors which tend

to isolate the elderly, result in a loss of self-esteem and prepare the ground for emotional upsets.

In this group, the analysis of marital status revealed two interesting facts. The first is that 63% were still married and living with their spouses. The second is the sharp predominance of widows over the number of widowers. This again seems to reflect the increased longevity of females compared to males. Six patients were either single or separated.

The inquiry into economic factors revealed that 94% of the group had no important problems in this area, while only 6 were living at a marginal level. This, of course, is a reflection of the specific patient selection which determines the referral to the private practitioner's office. No doubt a sampling of a geriatric outpatient population at any general hospital would support a different impression regarding the importance of economics. However, it is interesting to note that in no case in this series was economic difficulty blamed for the emotional illness of the patient. This certainly challenges the generally held impression that economic factors are of primary concern to the aged, particularly in relationship to the breakdown in health. It also seems to support the work of Wiggins and Schoeck (10), who surveyed aged members in the community rather than institutionalized aged. From their study, they stated that the "normal" aged are not characteristically dependent, inadequate, in financial need or senile.

The interest in work and social participation was enquired into, as this was taken to be one measure of the individual's capacity to deal with and find some gratification in

reality contacts. Thirty-four patients were unable to work at any level, either through forced retirement or illness of an incapacitating kind. The remaining 66 were able to work at some level, or hoped to do so at the time of their assessment and treatment. This then includes a number who were unemployed because of illness but who had not given up the hope or goal of working again. A striking finding was that 81 patients had a very restricted kind of social life, not as a function of their illness disturbance, but rather as a lifelong pattern. This finding seems too heavily weighted to be regarded merely as a coincidence. I suspect that this is really an important precipitant for emotional breakdown in the aged. When the time comes for the elderly to reallocate interests and activities, the socially isolated person has a more difficult and lonely task. The typical occurrence of the typical psychological regression in the aged person is also fostered and accelerated by diminished capacity to find external gratifications.

Existing Health Evaluation. The physical status of the patients revealed that 50 had well marked (rather than marginal) physical disease. Twenty percent showed cardiovascular disease, 18% various degenerative disorders and altogether they presented a representative cross-section of the medical disorders of the elderly. In some instances at least the organic disease and the attendant disability was the primary etiological consideration in the development of the psychiatric illness. In other cases, the organic deterioration was the major obstacle to recovery. However, except for such specific instances, the presence of complicating physical disease did not diminish the pos-

sibility of improvement of the psychiatric disorder in other patients.

Etiological and Precipitating Factors. The incidence and analysis of the precipitating and apparent etiological factors are set forth (Table 4). This divides naturally into external environmental stresses and calamities, and especial individual vulnerabilities. The

conquered and/or prevented. This provides us with a basis for hope about the future. Retirement is also a potent factor in psychological disintegration. However, preventive measures in this area may well be in operation out of necessity before too long. Our previous naive phantasies about the benefits of early retirement from work are

TABLE 4

Overall Total			39				24			29	16	46

latter are difficult to measure, but one sign was taken to be a previous psychiatric illness. This had occurred in 46 patients. Separation problems, threatened or real, and introduced by a death, illness or change of residence were described as a major precipitant in 39 patients. The dramatic or more insidious loss of vitality, energy and freedom of movement and action attending physical personal illness shattered the emotional equilibrium of 24 patients. Forced automatic retirement from the job or usual life work was given as the precipitant in 29 patients. Family conflict as a potent cause of breakdown occurred in 16 cases. A few patients presented multiple problems rather than a single etiological event.

Although it was difficult to assess the role of individual vulnerability, what did emerge clearly as critical environmental stresses were problems related to separation and death, to personal illness, retirement, and family conflicts. These issues have been described in other studies as the important sources of breakdown in the elderly. While the catastrophic impact of personal illness can not be eliminated in the given individual who is affected, the number of patients who will become disabled by the cardiovascular diseases, for example, may well shrink in the foreseeable future. This applies as well to other diseases which will be

rapidly disappearing. In many industries, this matter is now under active review, to reassess and postpone the retirement age in well and efficiently functioning workers. Ultimately, however, what society will have to provide and underwrite is a protected work program for the elderly citizen who is retired from the competitive industrial job, but who desires, needs, and can function at another job where competitive pressures are absent.

The chief motivations for the elderly worker are the need to work in order to maintain self-esteem, to maintain contacts with others, to find satisfaction in contributing, and in being regarded as a useful and functioning human being and a first-rate citizen of the community. Baruch(11) has noted that peaceful idleness can lead to anxiety, tension and atrophy.

The importance of family conflict in precipitating emotional illness in 16 patients is worth noting. It is an obviously nonsensical generalization which holds that elderly parents must live with their children, who have the duty and responsibility to care for them personally. Each case is an individual matter. Older persons are best housed with their own families providing that they can retain a place of independence and dignity in the family group. When their position is either that of an interfering domineering

elder, or a dependent childish irritant, then they themselves are not happy and they often produce friction and conflict in the family group as a whole.

As hard and fast attitudes and existing misconceptions are gradually broken down, there is fresh basis for hope and optimism. The therapeutic interpretation of the reversal of roles between parents and their children can guide some cases to the resolution of recurrent crises in the family setting and provide for the elderly a firmer anchorage to reality.

which follow from retirement and the interruption of habitual, reassuring, reality based work gratifications. In fact, one might say that old age is primarily concerned with the need to adjust to a variety of losses, environmental and personal, and the main restorative work is in the direction of retrenchment, reorganization of assets and the search for new ways to find acceptable meanings for life within the framework of reality. Depressive reactions were not the only pathological responses to such stresses. In some patients, the rapid crystallization of a

TABLE 5

Primary Psychiatric Diagnosis. The table of primary psychiatric diagnoses (Table 5) utilizes the standard APA classification. Of 100 patients, 18 were senile, 4 were long standing schizophrenics who were also well advanced in age, 15 presented various neurotic reactions and 63% fell into the diagnostic category of the depressive reactions. The high proportion of depressions is not too surprising in the aged group as old age is predominantly concerned with the adjustment to losses and the increasing awareness of the nearness of death. The high diagnostic incidence of depressive reactions can be correlated with etiological factors already reported upon. The latter concerned the kind of stresses which are represented by the death of spouse, relatives and friends, the loss of strength and vitality associated with aging generally, and especially enhanced in the presence of debilitating, sensory depriving or immobilizing illness. To this was added the losses of self-esteem and confidence

chronic brain syndrome followed an environmental insult. In other patients, an earlier depressive reaction had been unrecognized and untreated and had rapidly progressed into an irreversible organic deterioration reaction. Prompt treatment of depressive reactions, even in the presence of organic cerebral deficit, can reverse the syndrome in an appreciable number of patients (1). Table 6 details the number of patients in this series who showed cerebral organic contaminants. Of 39 patients who varied from transient confusional reactions to the most severe mental deterioration states, 16 patients or 37.5% of the total showed recovery or marked improvement in response to treatment.

Duration of Symptoms Prior to Referral.

An essential factor in the recoverability of the patient is often the length of time he has been sick. This is particularly important in the aged group because the resources for healing are diminished. Table 7 shows this in a striking way, as the response to therapy for those sick 6 months or less is in the range of 80%, whereas those sick over one year (39% of the group) showed a satisfactory response to therapy in only 25%.

Treatment Procedures. The aged patient deserves the fullest consideration in the application of treatment and remedial measures. This starts with a careful considered appraisal of the essential elements of the patient-environment disturbance. A medical, neurologic, psychiatric and social diagnosis is the basis of further action. The estimation of interpersonal interactions, especially within the family setting, is most important. The presentation by a patient of a hostile denial very often conceals the patient's plea for help and understanding which cannot be more directly brought to attention. The special features of the mourning reaction in the aged must be recalled else many missed and

masked depressions will go unattended. These features are 1) the relative absence of depression, 2) the presentation of a hostile affect, displaced from the deceased (to whom it is essentially felt), 3) the prominence of somatic symptomatology in a hypochondriacal setting.

The diagnostic evaluation has also to include the basic psychopathology and the extent and kind of regressive phenomena, and an estimation of the strengths and resources of both the patient and his natural environment. On the basis of this kind of diagnostic appraisal, the relative values of psychotherapy (supportive or interpretive), environmental manipulations, drug therapies, hospitalization, electroshock and other psychiatric therapies will emerge. Except for some modifications, all forms of psychiatric treatment are applicable to the aged group. Care must be exercised in the use of drugs as they are not as well tolerated as in the younger adult. EST can be used, if judicious caution is exercised, and the indications for a therapeutic response are strong. Here, age is literally not a contraindication. Psychotherapy is mainly supportive, and is aimed at helping the sick person face and deal with reality issues. Regressive effects in psychotherapy are sometimes unavoidable, and are sometimes desirable. This aspect should be estimated as a calculated risk. The achievement of insight is not a primary or necessary therapeutic goal in the elderly psychiatric patient(12). The majority of the patients responded to brief simple psychotherapeutic management aimed at levels which included not only the presenting reality problems, but also basic personality needs as recognized by the therapist. Surprising results could be achieved in two to six visits.

In this group, the drugs used were anti-depressant agents, phenothiazines, androgens, insulin therapy, hypnotics. Cerebral stimulants were found to have little value and barbiturate use was minimal. Other drugs were used as specifically indicated, as digitalis, anti-parkinsonian agents, *etc.* EST (19 patients) was always done in a hospital setting with maximum precautionary measures. Muscle relaxants and pentothal were regularly used. Hospitalization itself proved to be a valuable therapeutic meas-

ure—providing a protected supportive environment, free from conflict and the anxiety of upset relatives. The average hospitalization lasted between 2 to 4 weeks and was always carried out in a psychiatric ward setting in a general hospital. In every instance multiple approaches were utilized in a psychotherapeutic setting, but in the review of the material, an attempt was made to evaluate critically the main therapeutic technique, and the results are set forth in Table 8.

TABLE 8

	DRUGS MAINLY	E.S.T. MAINLY	HOSPITAL- IZATION	PSYCHO- THERAPY	COMMIT- MENT
Female	14	12	13	6	8
Male	18	7	4	1	9
Total	32	19	17	7	17

It is interesting to note that so few males were hospitalized or were able to become involved in a psychotherapeutic relationship in comparison to the larger number of women so treated. The impression I have is that the female aged sick complained more and received more family support than the men, and that a helping transference relationship could more readily be established. Countertransference reactions must receive consideration. The approach of the therapist to the aged patient carries reflections of his own feelings to his parents and may include his personal aversion to aging, decay and nearness of death. Dealing with the chronic sick is also a challenge to the physician's omnipotence phantasies. Such countertransference phenomena interfere with treatment and with its successful outcome. As a matter of fact, the change of feeling in the therapist from pessimism to hope in treating the aged is the most important factor in the progress of treatment for the aged.

Overall Outcome. In the reported group, the overall recovery or improved rate came to 55%, somewhat higher in the female group (58%) than for the men (51%) (Table 9).

This response to treatment in the psychiatric disorders of the aged surely supports optimism in the approach to such problems.

TABLE 9

	TOTAL NO. OF CASES	RECOVERED	IMPROVED	BETTER
Female	55	27	5	58%
Male	45	19	4	51%
Total	100	46	9	55%

From the review of these patients, it is clear that physical disease and cerebral organic contaminants do not, per se, preclude a favorable response to treatment. The most important factors related to outcome appear to be the length of time before appropriate treatment is begun and the interest of the therapist in the therapeutic task. The treatment failures (45 cases) were reviewed and the data summarized (Table 10).

TABLE 10

Analysis of Treatment Failures

Of 45 failures—13 patients did not follow treatment.
 17 patients were committed to institutional care.
 15 cases were senile deterioration states.
 20 cases had marked cerebral organicity.
 24 cases were over age 70.
 28 cases were of 1 year + onset to indefinite.
 8 cases had severe disabilities, cancer, severe parkinsonism, blindness, etc.

Some of these patients seem to present irreversible conditions, but others are definitely salvageable by better, more skillful use of existing techniques.

SUMMARY

The review and analysis of 100 patients aged 60 and older, examined and treated in private psychiatric practice, has served to clarify a number of important questions regarding geriatric patients. An impoverished social life and retirement from the job often set the stage for the development of illness. Forty-six percent presented a special emotional vulnerability. The reaction to separation threats or realities, retirement, personal illness and family conflicts emerged as critical environmental stresses. Fifty percent presented physical diseases, primarily cardiovascular or degenerative in nature. Cere-

bral organic contaminants were present in 39%. Although these factors tended to reduce the recovery rate, they did not prevent recovery in many patients. The predominant psychiatric diagnosis was the depressive group of reactions. In the consideration of this particular group, the possibilities for improvement are excellent, especially when the pretreatment illness period is not protracted. Many complicating factors which now retard treatment or which in the first instance lead to breakdown are potentially preventable. This will occur through progress and advances in medical knowledge, through greater understanding of the problems of the aged person, and ultimately through the introduction of restorative interventions at the community level.

Treatment measures, although empiric in nature, resulted in an overall 55% recovery or improved rate. The older patient can be treated with all the psychiatric techniques now available. When treatment is pursued energetically and with optimism, reversal of serious psychiatric illness in the aged person results, and chronic illness and deterioration is prevented, or postponed. The willingness of the therapist to become involved in the problem, to remain interested, and to search for answers to unknown processes, is critical to the success or failure of treatment in meeting psychiatric illnesses of the aged.

Community resources must be developed in imaginative ways. Active treatment centers for chronic illness are an essential need, to provide hospital care and day center care.

The development of psychiatric units in general hospitals must be supported. The six weeks in, six weeks out program for geriatric patients described by Delargy(13) is an intriguing therapeutic concept. Development of home care programs, the greater use of visiting homemakers and the development of post-retirement employment facilities can beneficially influence the medical, social and psychiatric aspects of the aging process.

THE EFFECT OF TRANQUILLIZERS ON SOME ASPECTS OF THE TREATMENT OF LONG STAY PATIENTS

A. A. ROBIN, M.D.¹

This paper examines the effect of tranquillizers on the discharge and re-admission of long stay patients by means of a retrospective study of a whole hospital from 1952, when tranquillizers were first used, to 1958. Three types of ward were also examined retrospectively to show any changes of ward behaviour which might be related to the advent of tranquillizers.

At the time of the study tranquillizers were listed as: 1. Rauwolfia and reserpine derivatives—Serpasil, Harmonyl; 2. Phenothiazines—chlorpromazine (Largactil), promazine (Sparine), acetyl promazine (Nontensil), prochlorperazine (Stemetil), trifluoperazine (Stelazine), triflupromazine (Vespral), pecazine, mepazine (Pacatal), thioropiazate dehydrochloride (Dartalan), perphenazine (Fentazin).

Method. Every long stay patient resident

in Runwell Hospital at any time between 1st January, 1952 and 31st December, 1958 was traced and indexed. A long stay patient was defined as one with a stay exceeding 2 years. The evidence for using a period of stay of this character as a measure of chronicity has recently been reviewed by Brown(3). The long stay patients were divided into two groups—those treated at any time with tranquillizers as listed above and those not so treated.

Three long stay female wards were studied retrospectively by counts from ward report books using a method previously described(4, 7). The prescription of drugs on these wards was obtained from ward drug books which present a monthly summary of prescriptions. The wards were 1) "disturbed"—where behaviour problems and disturbed, combative patients were usually

significance, that drug treated long stay patients are those who were: 1. Most recently admitted rather than the longest term admissions (1a—See "Total" columns). 2. "Mobile" (in the sense that they had history of at least one previous admission and discharge at Runwell Hospital before the current 2-year stay) rather than "static" (1b—See "Total" columns). 3. Under 50 years of age in Jan. 1952, rather than over (or more generally—younger rather than older) (1c—See "Total" columns). 4. Suffering from schizophrenia and not from epilepsy or organic dementia (aged 65 or over on admission) regardless of sex. In addition females with mania were tranquillized while males with sub-normality and females with paranoid states were not so treated (1d—See "Totals" column).

Recent admission, "mobility," and youth are shown to be good prognostic factors, as far as discharge is concerned, regardless of treatment (Table 1). In general, therefore, the "best" patients, as far as prospects of discharge are concerned, are chosen for treatment.

Effects of Treatment: 1. Prospects of Discharge of Long Stay Patients. A higher

proportion of non-tranquillized female long stay patients was ultimately discharged than tranquillized patients while there were no differences between the male groups as a whole (Table 1). On the other hand, it has been shown that the tranquillized groups were more favourable in outlook than the non-tranquillized group.

In more detail it is seen that more non-tranquillized long stay males were discharged from the group admitted 1940-49 (Table 1a) and more non-tranquillized long stay males were discharged from the under 40 age group (Table 1c). The excess of non-tranquillized females discharged is from the "mobile" group rather than the "static" (Table 1b); and from both under 40's and over 60's (Table 1c).

Diagnosis shows no difference between the groups (Table 1d).

2. *Re-admission.* Recent evidence (6, 9) suggests that maintenance tranquillizers fail to prevent re-admission. This study presents no information on this aspect and is only concerned with the results of intramural hospital treatment.

As has been reported from other hospitals (3) there is at Runwell a significant rise in the rate of re-admission regardless of treat-

ment, in patients discharged between 1955 and 1958 as compared with those discharged between 1952 and 1954 (Table 2).

Comparing those discharged after drugs with non-tranquillized patients discharged in the later period (1955-58) when most tranquillized patients were discharged (Table 3) there is no difference in re-admission rate between the two groups. The rise in re-admissions is not therefore due to tranquilizers, per se, while neither do tranquilizers in hospital prevent re-admission.

3. Ward Behaviour. Unfortunately, the ward reports from 1952-54, inclusive, could not be traced for the "disturbed" ward: nevertheless, the pattern from the start of tranquillization can be seen (Table 4). Emergency and regular sedation drops as tranquilizers are prescribed to numbers of patients never previously sedated. ECT continues to be used during the period studied. The numbers of escapes, casualties, reports of noise, and patients in bed appear to fall. Reports of uncertainty, restlessness and overactivity rise, possibly with destructiveness. Smashing, incontinence and impulsiveness are little affected. In the non-disturbed ward again regular sedation falls, while again tranquillization rises to numbers never before sedated. The proportion on tranquilizers is less than on the disturbed ward. Apart from this, virtually no trends are seen. On the "hospital adjusted" ward the picture is similar, but fewest of the cases are tranquillized. There is a slight rise in the numbers on village parole, and a definite rise in the numbers of discharged patients, reflecting the use of this ward for medium and short stay patients as well as the long stay group in later years.

As far as ward behaviour here is concerned, in summary, "disturbance" is not affected in a clear way, but increased "uncertainty" and restlessness, possibly due to akathisia are seen. Nevertheless, "disturbance" invites treatment, while the best adjusted wards are least treated. When tranquilizers are used they replace other sedatives, but involve more patients than those previously sedated.

DISCUSSION

Brill and Patton (1, 2) have studied New York State mental hospitals, presenting conclusions which are somewhat at variance with those above and claiming that a reduction in hospital population has been due to tranquilizers.

A difference in results in itself would not be surprising as Kramer and Pollack (5) have shown that the pattern of care in New York differs even from most other parts of the United States. Certainly, many of the clearly presented tables in this paper, e.g., regarding restraint and seclusion, show practise and trends widely different from those established in Britain.

Shepherd, *et al.* (8), studied hospital statistics from another British hospital, and concluded that the "impact of pharmacotherapy proved to be very small." The proportion of patients with affective disorders seen by this hospital between 1954 and 1957 and treated with tranquilizers was 21% and the proportion of discharges with affective disorders who received tranquilizers was 19%. The figures for schizophrenia were 39% and 32% respectively; for organic, senile and epileptic states, 16% and 14% and for neurotics and psychopaths 25% and 24%. These figures and findings are very similar to those presented above.

Linn (6) in another American hospital shows tranquillized admissions in comparable years are discharged in similar proportions to non-tranquillized cases whether or not hyperactive. The advent of tranquilizers was, however, associated with an increased chance of discharge for all cases attributed to staff optimism. In the hospital studied by Linn, there was a decrease in provocative behaviour after tranquilizers were introduced.

In conclusion, it should be stressed that their clinical administration shows tranquilizers to be potent pharmacological agents. This paper does not set out to dispute this fact, but merely presents evidence to show that their current administration in one hospital (which, however, there is no reason to believe is therapeutically atypical in the administration and dosage of these drugs) does not produce better results in terms of discharge, *etc.*,

than those methods of treatment—mainly nursing care and occupation in the long stay group—against which they are in fact compared, nor a marked change in ward behaviour in relation to methods of treatment previously and less extensively employed.

SUMMARY

A retrospective study of a long stay population from 1952-58 shows the patients chosen for tranquillizers in the long stay group are those with the best outlook as far as discharge is concerned. Nevertheless, tranquillized long stay patients when compared with non-tranquillized patients do not have a better prospect of discharge and may indeed to some extent have a lesser prospect. Hospital treatment with tranquillizers does not alter the chance of re-admission of discharged long stay patients. Ward behaviour, apart from some aspects of "disturbance," is little influenced by tranquillizers which are themselves possibly associated with the introduction of

new symptoms. Disturbed wards invite treatment and on them, as on other wards, tranquillizers have replaced other sedatives, with the numbers of patients ultimately treated exceeding the numbers previously sedated.

TEACHING PSYCHIATRY IN A MILITARY SETTING¹

WILLIAM J. DICKERSON, LCDR(MC), AND
RANSOM J. ARTHUR, LCDR(MC)²

Psychiatric education in the military setting is developing at a rapid pace, but too often without thoughtful planning of the curriculum.

The goal of a military residency program should be to prepare a superior general psychiatrist who is additionally equipped to handle problems specific to the military. The military psychiatrist is confronted with a wide range of problems. He faces such varied challenges as the control of an acutely disturbed young fighting man, aiding a responsible officer numbed by depression, giving medical care to ill dependent and courtesy treatment of a foreign high official.

Heightening competition for residency candidates, expanding military needs and increasing public and military awareness of psychiatric services emphasize the need for attention to armed service residency programs. The inherent advantages and assets of the military setting must be fully employed and deficiencies must be recognized and faced. Some features of planning and maintaining a curriculum at the U. S. Naval Hospital, Oakland, are presented to serve others as a guide and to encourage a critical appraisal of the military residency program.

Deficiencies Inherent in a Military Residency Program. The most frequently voiced complaint, that the patient population is rigidly restricted in age and sex, is misleading. This charge ignores the vital services which military psychiatry offers to veterans, senior officers, civilian employees, dependents, and foreign military personnel.

Certain deficiencies, although less apparent, cannot be ignored: the long term care of chronically ill psychiatric patients is not generally undertaken in the active service hospital. The required administrative duties decrease the time available for teaching and clinical care, and the system of periodic

transfer of medical officers removes members of the teaching staff to other duty stations. Research scientists have been relatively unavailable for teaching, consultation, or assistance to residents and staff. Finally, unexpected additional duties may encroach on the resident's time for learning.

Advantages Inherent in a Military Residency Program. On the other hand, certain advantages for psychiatric education are contained in the military structure. Navy psychiatric facilities are integral parts of general hospitals, rather than isolated units. The psychiatrist is therefore responsible for the patient's total care, but has available for referral or consultation specialists in other branches of medicine. Similarly, the psychiatric resident has an opportunity in residency training to develop skill as a consultant to other physicians. The military training hospitals are well located near large cities which have outstanding professional communities. Thus professional exchange is facilitated between the military physician and his civilian colleagues.

The military psychiatrist has an unusual freedom from the incidental limitations to treatment. He is empowered to admit a patient to the hospital at any time without compromise to his medical decision by such factors as hospital cost, risk to the patient's employment or loss of his wages. Consultations, psychological testing, additional laboratory tests and collaborative social service interviewing of the family are available without additional charge to the patient and provide multi-dimensional information for the psychiatrist. A follow-up of the patient is often possible throughout his tenure of duty. In the best tradition of teaching hospitals, patients with interesting findings are presented in teaching rounds and conferences for the residents.

The psychiatrist in a military setting enjoys a particular opportunity which is relatively infrequent in civilian residencies. He often can observe the very early manifesta-

¹ The opinions or assertions contained herein are the private ones of the writers and are not to be construed as official or reflecting the views of the Navy Department or the Naval Service at large.

² U. S. Naval Hospital, Oakland, Calif.

tions of a psychiatric disorder. Pre-induction screening and annual physical examinations insure that all active duty personnel remain free of the disqualifying symptoms of mental illness at enlistment and each year thereafter; the military structure demands a high degree of job performance, social conformity, and military obedience; and even a slight deviance provokes medical attention long before such care might be sought or required in civilian life. Within the armed forces referral to a psychiatrist is immediate and mandatory at the discretion of the attending medical officer. Thus the psychiatrist sees patients much more promptly than in any non-military setting where detection and referral are not so quickly accomplished.

Similarly, the opportunity afforded the military psychiatrist to observe individuals under stress has few parallels in civilian life. These stresses range from the obvious hazards of military training or combat and the untimely disruption of families to the more subtle demands upon a young serviceman with problems of maturation and emancipation from parents.

Certain Navy programs, such as Operation Deep Freeze, submarine duty, space explorations and top secret projects, require preselection evaluation of officers, enlisted men and civilian participants. In this way the Navy psychiatrist examines large numbers of emotionally healthy individuals and attempts to match men with various relatively healthy personalities to exacting and unusual tasks. For example, he interviews prospective Annapolis midshipmen, screens men to be entrusted with defense secrets, eliminates those with unsuitable personalities for wintering-over in the polar stations, and evaluates men embarking on dangerous or arduous duty. He learns that the enforced confinement of small group living, as at the polar stations, is better endured by the rather isolated introvert than by the "hail, hearty and well met" extrovert, who eventually antagonizes others. This contradiction to the premium awarded "popularity" by contemporary society is a valuable lesson to the young psychiatrist.

The Educational Program. The direction and coordination of the educational program is paramount. It is essential that a

senior medical officer be designated to such duty, full time, to insure leadership, mesh many individual efforts, and maintain high quality of teaching. In addition, he is also responsible for achieving a philosophy of teaching; therefore, the director should be selected with great care. He must work diligently to fulfill these requirements, and perhaps most importantly to infuse by example a continuing dedication to the program, keen intellectual interest, and pride in professional achievement. To provide substance to the total program, the junior staff must willingly accept the added responsibility of teaching the resident staff. The Berry Plan³ has made possible a junior staff of high qualification who have been trained at outstanding civilian centers. The resident thereby has a close working contact with staff psychiatrists who represent various approaches rather than the monolithic point of view of some institutions. As in any academic setting, the junior staff members are best entrusted with planning and executing portions of the curriculum both for the advantage to the educational program and for their own development as teachers. They perform a prime function of individual supervision of residents. By their professional sophistication, interest and proficiency they enhance teaching discussions and help enforce a precision of thinking for beginning students. In the military residency program there is often a limitation of senior psychiatric staff. This deficiency can be overcome by the use of senior civilian consultants if care is exercised in their selection and assignment.

The limited size of the consultant staff forbids the inclusion of individuals who are not enthusiastic teachers. Fortunately there are eminent psychiatrists who out of loyalty to the Armed Forces are willing to make additional sacrifices to be consultants to the military hospital. These consultants complement staff teaching of general psychiatry, psychotherapy and psychoanalytic principles, psychopharmacology, clinical neurology and neuroanatomy and provide teaching in neuropathology, forensic psychiatry and those highly specialized topics not

³ The Berry Plan has permitted the delay in calls to duty for selected individuals until completion of civilian residency.

generally taught by the regular staff.

Funds are also available for single consulting visits by guest speakers, to augment the required program through lectures on special topics germane to psychiatry, for example, such diverse topics as the intellectual climate in which psychoanalysis was formed and the analogies between high speed computers and brain mechanisms.

The department's own teaching can be supplemented by the various lectures and seminars at nearby teaching institutions. Designated staff arrange invitations and promulgate announcements. Residents and staff are encouraged to attend and are allowed time from regular duties for this purpose.

Individual supervision is the most important element in teaching psychotherapy and the understanding of intrapsychic process. Thus, supervision is the prime teaching responsibility for the staff. Residents attend individual tutorial sessions weekly to discuss in detail their individual therapy of patients in order to become progressively more skillful in psychotherapeutic interviewing. Periodic case presentations, continuous case seminars and treatment reviews further broaden the resident's experience in psychotherapy.

There is little opportunity for the psychiatric resident in the Navy to participate in research full time. However, funds for modest research efforts, primarily clinical, are available for residents and staff alike. Each resident is expected to complete at least one research project during his 3-year training period. In addition residents occasionally participate as clinicians in Navy-wide studies such as the present investigation of small group behavior under stress or isolation. Residents as well as staff are included in certain studies undertaken within the department, *e.g.*, an investigative study within the Child Guidance Clinic of certain problems of service families, a drug study of hospitalized depressed patients, and an attempt to correlate certain EEG abnormalities with specific behavior patterns.

Building a Residency Program at Oak Knoll. The Neuropsychiatric Service of the U. S. Naval Hospital, Oakland, Calif., may serve as a good example of the practical

implementation of some of these principles.

Faced with increasing competition for the limited number of candidates for residency, the psychiatric service must make a determined effort to offer a forceful educational program that fulfills the resident's needs and emphasizes learning rather than service. The resident must be carefully distinguished from the staff, so that each can be charged with specific responsibilities. Entitled to the systematic presentation of specified areas of psychiatric knowledge, the resident's assigned duties should not preclude his attendance at teaching sessions. Instruction must be provided and the needed time insured.

The primary interest of the superior officers at Oak Knoll has been supported by the Head, Neuropsychiatric Branch, Bureau of Medicine and Surgery, in the assignments of teaching staff, the provision of educational funds, and in continuing encouragement. There has been an effort to gather a staff of teachers and of residents who prefer a formalized academic program within the military setting. By publicizing this intent it is hoped to discourage the uninterested and attract a select group within or entering the service who share these interests. Prior screening within the department and subsequent selection by the Bureau has tended to accumulate just such a professional cadre.

The senior psychiatrists at Oak Knoll have achieved maximal use of this increased staff by including teaching as a primary duty and by allocating adequate times for both supervisory and didactic teaching. All staff are assigned some teaching responsibility, and a few selected individuals are given greater educational duties, *e.g.*, one medical officer, previously a junior member from a university residency faculty, was designated a full time teacher and supervisor during his tenure at Oak Knoll. The officer in charge of training, after careful assessment, selects the individual staff for each of the varied teaching tasks. These range from the supervision of individual residents to lectures to student corpsmen.

Only through long term intensive treatment of a patient can the resident experience the practice of psychotherapy, a

unique training that can be gained in no other way.

Individual supervision of residents is limited to those staff who have completed formal training. These supervisors are paired with residents for a fixed period of time and must submit regular reports to the director of training. These evaluations provide information essential to the re-assignment of subsequent supervisors. Thus residents are exposed to differing approaches to psychotherapy but continuity is maintained. This continuity in supervision is a requisite to the learning of individual long term intensive psychotherapy.

Patients selected for outpatient psychotherapy are screened to insure good therapeutic candidates for whom long term attendance is possible before assignment to residents. As residents usually continue treating these few selected patients throughout their residency training, treatment time and supervision are allotted throughout each resident's individual assignments and rotations.

It must be recognized that certain necessary experiences can be acquired in the service residency only through affiliation with other institutions. In our program residents spend a part of their second year at the Napa State Hospital, where they can observe an extremely wide variety of psychiatric and other medical problems in a population of over 5,000 patients. There, residents care for patients with chronic psychiatric illnesses and receive additional instruction in the use of somatic therapies. The affiliation in the third year of residency consists of half-time attendance at the Berkeley State Mental Hygiene Clinic. There, residents obtain instruction in the evaluation and treatment of children and follow children in treatment under continuing supervision through a 9-month period.

Like these affiliations and participation in seminars and meetings at local centers, attendance at national meetings and specialty conventions is an important part of continuing medical education at all levels. Limited funds for such attendance require that doctors attend in rotation distant meetings of their choice. Each then reports to the entire group upon return. For local meetings interested department members

often attend as a group.

A close and active reciprocal liaison with nearby medical centers is important to the service teaching center. A wider professional acquaintance, knowledge of community facilities, awareness of specific advanced studies, and an opportunity for increased exchange is afforded the residents and teaching staff. The importance of such a liaison is fully recognized by the responsible senior officers of the Navy. Department staff members offered an appointment to the clinical faculty of the nearby medical school are permitted to accept such appointments and to devote one morning a week teaching senior medical students. In return university clinicians, teachers, and research scientists consent to lecturing or consulting at Oak Knoll. This liaison between the medical school and the naval hospital extends as well to the exchange of neuropathic and anatomical specimens, educational films and invitations to special meetings and lectures.

In our experience the expenditure of added effort and attention to the many details of a superior teaching program has been richly rewarding. The staff has responded to this professional stimulation with increased interest and enthusiasm. Morale is high. The residency program is attracting more and more applicants. The Department's other prime responsibility, patient care, has been strengthened rather than weakened by this attention to the Department's teaching commitment.

Thus, the accepted principle that patient care is improved in a center when medical education takes place is as true in the military hospital as in the civilian.

SUMMARY

Medical education in the military setting requires sound principles of modern teaching. The planning and curriculum of the residency in psychiatry at the U. S. Naval Hospital, Oakland, Calif., are reviewed to encourage a critical appraisal of such programs and to invite attention from non-military medical educators.

Deficiencies to be overcome include the encroachment of administrative duties on the resident's time and little experience in long term care of the chronically ill.

The full utilization of certain inherent features, such as freedom from some economic restrictions and participation in uncommon opportunities, provides an advantage over the non-military residency.

The use of consultants, responsibility for the educational program, and professional liaisons require specific attention.

Improvements recognized by the authors are presented.

ABSTRACTS

STREPHOSYMBOLIA IN CHILDREN WITH NEUROPSYCHIATRIC DISORDERS

ALEXANDER MARKS, M.D., AND JOHN C. SAUNDERS, M.D.¹

*Certain children manifest disorder in language development, a syndrome that has been described as congenital word blindness(1), specific reading disability, bradylexia, development dyslexia, visual agnosia and strephosymbolia. Strephosymbolia, the term we prefer, is a syndrome of difficulty in learning to recall a word with sufficient accuracy to recognize it, as in reading, or to reproduce it as in writing. It occurs independently of a child's intelligence.

This disorder of perception results in each object appearing as a mirrored reversal or inversion; also, there is an awareness of stimuli without meaning. Spontaneous mirror writing is an early sign of the disorder. Strephosymbolia commonly appears in children under five and usually disappears before school age. Failure to progress in reading and writing may indicate strephosymbolia.

Strephosymbolia occurs in delinquent and schizophrenic children as well as in normals. We decided to study the incidence in children with neuropsychiatric disorders for further insight into the process. We studied 19 childhood schizophrenics and 20 children with primary behavior disorders (6 girls and 33 boys, ages 6 to 13). Each child was presented with a blank piece of paper and a pencil and was asked to print his name. Next, the following words were dictated and he was asked to write them in a column beginning at the left margin of the page: cat, dog, boy, man, see. The child who failed to write to dictation was instructed by spelling the word, letter by letter, and if the child could not do this, he was given a printed card with the previously dictated words for copying.

After this dextrad writing form the child

was asked to repeat the above, initiated from the right margin of the page to attempt to induce mirror writing which would indicate latent strephosymbolia. Finally, he was asked to repeat the whole test using the opposite hand to his preferred one. Children who could neither spell nor write the alphabet were given a card with the letters, b d p q m w n u t f g to copy.

Two or more reversed symbols in any phase of the test were considered indicative of strephosymbolia. Further testing, however, is essential to determine if this criterion is valid in children with neuropsychiatric disorders. Of 6 left-handed children, 2 could spell, 1 could not spell, but could write the alphabet and 3 could neither spell nor write the alphabet. Of 33 right-handed children, 18 could spell, 9 could not spell but could write the alphabet and 6 could neither spell nor write.

From this preliminary study of 39 children with neuropsychiatric disorders, we found 3 of 19 or an incidence of 16% of spontaneous mirror writers in schizophrenia and in the primary behavior disorders, 2 of 20 or an incidence of 10%. The incidence of induced mirror writers (latent strephosymbolia) was 8 of 19 or 42%, and 14 of 19 or 73% respectively for the schizophrenia and primary behavior disorders. None who were able to spell to dictation were spontaneous mirror writers.

Many theories attempt to explain the etiology of strephosymbolia and there are data that may be interpreted as supporting each. The psychoanalytical theory relies on 3 factors for characterizations: fear, avoidance of looking, and hostility primarily toward the same sex parent and failure to identify with the same sex parent(2). The recent study by Walters, *et al.*(3), indicates that the psychoanalytical hypothesis of strephosymbolia cannot be supported. Another theory is based on neurophysiological results, auditory, ocular and neu-

¹ Research Facility, Rockland State Hospital, Orangeburg, N. Y.

We appreciate the cooperation of Dr. E. R. Clardy and Dr. J. S. Prichard.

rological. The neurological factors hold the dominant position as studies continue to support the original concepts of Morgan and Orton(1, 4) that strephosymbolia represents a developmental retardation in one specific function and this physiological deviation is due to a delayed development of unilateral cerebral dominance.

The signs and symptoms of strephosymbolia are highly variable from one individual to another and appear to be transmitted by heredity. Genetic investigations by Hallgren(5) and more recently by Norrie(6) in twins show that heredity is a decisive factor. Hermann postulates an inherited impairment of the sense of direction in space(7).

Gates believes that the dominance of the left eye is more important in these children than the dominance of the left hand(8). Photographic studies of ocular movements during reading show that these children make irregular movements back and forth with many pauses of fixation, whereas a normal child makes few pauses and moves his eyes in a steady progression from left to right. Critchley gives an interesting explanation for the disorder resulting from stored visual and kinesthetic memories associated with the process of learning to write (9). In a normal person, the visual memories associated with the writing process control the reversed patterns; in those affected with strephosymbolia there is not only a lack of dominant visual memories but a coexistence of correct and reversed muscle movements. This condition like most states of coexistence leads to a lack of understanding, resulting in misspelling, mirror writing, and the reversal of symbols. Kennard, *et al.* (10), reported 70% of disturbed children showed abnormal EEG patterns, that is, a general dysrhythmia; others have commented on the retention of the immature EEG patterns far beyond the age expectancy in children with primary behavior disorders.

The I.Q.s. of most of the children in this study are below normal, but it seems probable that psychometric tests give an erroneous estimate of their intellectual capacity. It has been reported and continues to be observed, that the schizophrenic child has a slower rate of maturation, both physical

and mental. This may explain the continuation of the strephosymbolia beyond the usual age for most children.

The most interesting question in this study is the probable relationship between the incidence of primary behavior disorders and strephosymbolia. Orton has described 4 psychiatric reaction patterns in children with strephosymbolia. Type I is a content, apathetic state with acceptance of the condition and no particular feeling of inferiority. Type II is a mild paranoid reaction resulting from being expected to keep pace with classmates. Type III is submerged with an overpowering sense of inferiority probably from association with siblings of above average abilities; when conditions are explained, these individuals are aware of their high intellectual capacity and grateful that the condition is recognized. Type IV is an emotional blocking; that is, there is blocking of intellectual output upon demand, and this could be produced voluntarily. If Orton's 4 types of psychiatric reaction patterns can be associated with the primary behavior disorders, then an etiological factor (strephosymbolia) may be established in these childhood disorders which potentially could be alleviated or prevented. Our preliminary data are sufficient to aid in establishing a correlation between emotional disorders and strephosymbolia, and in this area our investigations are continuing.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinion of the Journal.)

THE ECONOMY PROBLEM FOR THE CENTRAL NERVOUS SYSTEM

J. B. COLLINSON, D.P.M.¹

A number of models have been proposed to demonstrate methods by which various aspects of central nervous function—notably perception and learning—might be carried out. Latterly, concern has been expressed at the number of functional units, “cells,” or neuron analogues which would be necessary in such models to carry out signal classification or pattern recognition of all patterns theoretically possible by use of any given number of inputs, in such a way as to be analogous to processes of perception and learning in the organism (6).

For a number of inputs, n , to some pattern-recognition or signal-classification apparatus, each input to be capable of distinguishing k levels of intensity, the number of central units necessary for the separate registration of all theoretically possible subsets of the input ensemble is $(k+1)^n - 1$, disregarding any capacity of the system for registration of other than simultaneous patterns of input. If now k is taken to be no more than 10, and it is borne in mind that the number of nerve fibres in, say, one optic tract is of the order of one million, the number of central units necessary to carry out the proposed programme is readily seen to be very considerably greater even than Eddington's proposed estimate of 10^{79} for the total number of electrons in the physical universe, and even if allowance is made for considerable redundancy in each sensory modality, and for the possibility of registration of events on a sub-neuronal scale, a number of this order is clearly not to be entertained.

Now it is well known that the most

economical method of identifying any one member of a specified set is by a method of successive dichotomies, or by a “high-entropy decision process” (1). By such a method, any one of the set of $(k+1)^n - 1$ possible patterns discussed above may be specified by reference to at most $\log_2(k+1)$ subsets. If k be as great as 100, the ratio of necessary central units to input units then becomes approximately 6.7:1, and allowance for redundancy among the input units, and for the possibility of registration of events on a sub-neuronal scale, would reduce this ratio still further.

The findings of psychoanalysis (3), genetic psychology (9), comparative ethology (8), and conditional reflex studies (notably in regard to stimulus generalisation, or irradiation, and differentiation by simultaneous excitation and inhibition (7)), as well as experimental psychology (5), and indeed, common experience, all lend plausibility to this view that perception and learning proceed by successive discriminations; it has the further advantage that it is consistent with the highly elegant, supple, and general speculations of Hebb (4). Such a procedure is, moreover, equifinal, in the sense that an item may be specified by the same number of steps in different ways; equifinality is said to be characteristic of complex adaptive systems (2).

Nothing is here said about the precise nature of the discriminatory processes in fact involved in existing biological systems or organisms, nor is it implied that any such process is, in fact, theoretically the most economical. These questions may properly fall to be answered within the framework of such behavioral disciplines as those mentioned above.

DIFFERENTIAL SUCCESS RATES OF PSYCHOTHERAPISTS WITH "PROCESS" AND "NON-PROCESS" SCHIZOPHRENIC PATIENTS

BARBARA J. BETZ, M.D.¹

Studies by Whitehorn and Betz(1-5), focussed on conditions influencing favorable clinical outcome in psychotherapy with schizophrenic patients, have demonstrated 1) that some psychiatrists (designated A doctors) consistently have higher success rates than others (designated B doctors), and 2) that A doctors could be distinguished from B doctors on the basis of certain personality characteristics. Differences were demonstrated in clinical attitude and style. Also, by the use of the Strong Vocational Interest Inventory it was possible to show that A doctors' interests were like those of Lawyers, but not of Mathematics-Physical Science Teachers; whereas the reverse was true for B doctors whose interests were found to be like those of Mathematics-Physical Science Teachers but not Lawyers.

The conclusion that the personality of the therapist is a crucial factor influencing outcome in psychotherapy with the schizophrenic patient was drawn from these studies. An alternative explanation—that the success differential between psychiatrists is based on differences in the patients, those treated by the A doctors being, in some way, clinically "easier" cases—has needed to be ruled out. Careful attention to this question has made this explanation seem unlikely.

Recent evidence, indeed, indicates that

differential success rates between psychiatrists who vary in personality characteristics are most striking with "more difficult" rather than with "easier" cases. A comparison was made of the success rates of two groups of psychiatrists treating schizophrenic patients in two diagnostic categories: "process" and "non-process." This diagnostic designation was made by Dr. Christian Astrup, from Gaustad Hospital, Oslo, Norway, who recently completed an independent, diagnostic review of over 200 case records at the Phipps Clinic (following Langfeldt's distinction between true schizophrenia—"process," and schizophreniform psychosis—"non-process"). Seventy-three of these patients (36 "process" and 37 "non-process") were in the present study.² They were treated by psychiatrists who could be divided into two groups on the basis of their score level on the Strong Vocational Interest Inventory scales for Lawyer, and Mathematics-Physical Science Teacher (scale score 40 was used as the cut-off point). Thirty-three patients were treated by group A psychiatrists and 40 patients by group B psychiatrists. The patients' discharge status, "improved" or "unimproved," as recorded in the medical record, was used as the dependent variable(6).

¹ Director of Psychiatric Education, Spring Grove State Hospital, and Assoc. Professor of Psychiatry, Johns Hopkins Medical School.

² In selecting these patients' length of treatment (at least one month), type of treatment (psychotherapy only) and period of treatment (prior to 1954, so that the ataractic drugs were not a factor) were controlled.

TABLE 1

Comparison of Improvement Rates of Schizophrenic Patients, Diagnosed as "Process" and "Non-Process," Treated by Group A and Group B Psychiatrists

CONDITION OF DISCHARGE	TOTAL (N=36)		"PROCESS" PATIENTS TREATED BY PSYCHIATRISTS IN			
			GROUP A		GROUP B	
	NO.	%	(N=14)		(N=22)	
Improved	15	42%	11	71%	4	18%
Unimproved	21	58%	3	29%	18	82%

* $\chi^2=10.47$.01<p<.001

CONDITION OF DISCHARGE	TOTAL (N=37)		"NON-PROCESS" PATIENTS TREATED BY PSYCHIATRISTS IN			
			GROUP A		GROUP B	
	NO.	%	(N=19)		(N=18)	
Improved	21	57%	13	68%	8	56%
Unimproved	16	43%	6	32%	10	44%

Table 1 shows the findings when clinical outcomes of patients diagnosed as "process" and "non-process," treated by A and B psychiatrists are compared. As shown in this Table, a reliable higher success rate is found for A than B psychiatrists (71% vs.

18%) with the "process" patients, generally regarded as the more serious diagnostic category. This success differential is largely eradicated with the "non-process" patients. These data support the validity of the conclusion that differential personality factors in psychiatrists are causally related to differential "treatment success with schizophrenic patients. The unique potency of the "Lawyer" and the "Mathematics-Physical Science Teacher" variables in influencing the patient's therapeutic response is again demonstrated.

PRELIMINARY REPORT ON PHENOXYPROPazine

NORMAN W. IMLAH, M.B.¹

Phenoxypropazine (Drazine)² is (1-Methyl 2-Phenoxyethyl) hydrazine hydrogen maleate, a monoamine oxidase inhibitor chemically related to other drugs in this group. It is the first drug of this kind to be developed in Britain for clinical use.

In this investigation 24 patients were included initially and 20 completed a 6-week trial. All were outpatients, seen at weekly intervals. At the end of 6 weeks each were rated on a 4-point improvement rating scale. Side effects were recorded.

One case was withdrawn with side effects and 3 failed to maintain attendance. The 20 completing cases were 16

female and 4 male. Age range 29-60 years, mean age 44.4 years. Duration of illness 1 month-2 years.

Twelve cases had retarded endogenous depression; 7 cases had agitated involutional depression; 1 case was a depressive reaction to severe stress. Thirteen cases had a history of previous breakdown, 8 successfully treated previously by ECT. Seven cases had specific antidepressant therapy for the current illness without benefit.

All patients started on 10 mgm. phenoxypropazine b.d.; 13 remained on this throughout. At the end of the third week 5 were increased to 10 mgm. t.d.s., and 2 decreased to 5 mgm. t.d.s. No other drugs were given apart from barbiturates at night.

Results. The final rating was as follows: recovered (symptom free) 6; minor symp-

² I wish to thank Smith & Nephew Pharmaceuticals Ltd. for supplying Drazine for this trial, and Dr. W. Williams of Smith & Nephew Pharmaceuticals for his co-operation and advice during the investigation.

toms only 6; improved 2; no change 6.

Improvement began in 3 cases before the end of the first week of treatment, and in the remainder during the second week. Maximum benefit was apparent by the end of the fifth week.

Side Effects. The case discontinued on account of side effects reported "diarrhoea on the second day of treatment, stopped the drug on the sixth day after which diarrhoea ceased; 5 other patients reported side effects, all of minor severity and mainly transient. They were: nocturnal limb jerking 3, severe headache after alcohol 2, mild dizziness 2, nausea 1, dry mouth 1, nocturnal frequency 1.

DISCUSSION

An observed improvement in 14 of 20 cases of depression indicates that phenoxypipazine may bear favourable comparison with other active antidepressants. As there are no other clinical reports available it remains to be shown whether similar

views are found by other observers.

The impression of therapeutic effectiveness of the drug is supported by a relatively short latent period before effect, and comparatively mild side reactions. The latent period varies between 5-12 days. Side effects were less severe and less frequent than those encountered with other antidepressants. In particular there seemed to be considerably less hypotensive action than with other MAO inhibitors.

In consequence of this favourable preliminary impression a more intensive investigation has been undertaken.

SUMMARY

A preliminary clinical investigation of a new MAO inhibiting antidepressant, phenoxypipazine, is reported. Of 20 cases, 14 were improved, and in 12 cases the response was highly satisfactory after 6 weeks. Side effects were comparatively few, and with one exception, mild. Hypotensive activity was slight.

AMITRIPTYLINE-PERPHENAZINE¹ IN THE TREATMENT OF SCHIZOPHRENIA

R. E. KENNEDY, M.D., AND J. J. MILLER, M.D.²

The effectiveness of various dosage combinations of amitriptyline (Elavil) and perphenazine (Trilafon) in hospitalized psychiatric patients has previously been reported(1). As of Jan. 1963, 1,000 patients in diverse diagnostic categories have been treated in this hospital with both these drugs. The series is a continuing one.

Early in the study, this was a clinical trial in search of a design. Kessenich(2), who spoke of similar problems with drug testing in neurology, questioned the necessity of double blind studies or the use of placebo controls in the investigation of serious ailments. Interestingly enough, schizophrenia recently has been characterized as being, from many points of view, the

most terrible of all diseases(3). Kessenich further suggests that it might be permissible to utilize previous experience of an investigator as a control against which he might compare his results with new treatment. In this study, we are comparing amitriptyline-perphenazine treatment with other methods that formerly were used at Rollman in the treatment of schizophrenia.

This hospital dates only from 1955, relatively early in the period of pharmacotherapy in psychiatry. During the first few years, the majority of schizophrenic patients received a phenothiazine, or reserpine, but ECT was considered the bulwark of treatment, particularly because patients usually cannot be retained for more than 90 days. By 1959, perphenazine had become the phenothiazine of choice. When the less toxic MAO inhibitors began to appear, these were added to treatment. Nevertheless, ECT continued to be used

¹ Triavil—Merck, Sharp and Dohme.

² Rollman Psychiatric Institute, Cincinnati, Ohio.

The entire staff, under the direction of C. O. Ranger, M.D., contributed to the treatment of the patients reported in this study.

extensively, especially for schizophrenia.

In May 1961, amitriptyline was tried in combination with perphenazine, replacing the MAO inhibitors. It was soon apparent that the new combination produced excellent results. Fifty schizophrenic patients admitted between July 1 and Dec. 31, 1961, were treated with amitriptyline-perphenazine. The rate of satisfactory remission was 84%, but 30% received ECT in addition to the drugs. This represents a substantial gain over previous experience at this hospital(4). As time went by, doses tended to be increased, and ECT was found to be superfluous in many instances. From Jan. 1, 1962 to June 30, 1962, 87 more schizophrenics were added to the series. The rate of satisfactory remission in this group rose to 88%, and at the same time, only 11% were given any ECT. Currently, almost no ECT is being used, and results promise to be better, since more attention is now being paid to dosage, to identification of tablet evaders, and to detection of possible concomitant thyroid disorders.

The outstanding feature of amitriptyline-perphenazine treatment is that almost immediately patients begin to gain hours of refreshing sleep, if high enough doses are administered.³ Sleep, indeed, appears to be

³ Results were better with high doses. The 24-hour dose of amitriptyline was usually 200 mg.; that of perphenazine 64 mg. or more. Benztrapine (Cogentin) was added in doses of 0.5-1.0 mg. to prevent drug parkinsonism.

the pivotal factor in recovery. Sedatives no longer need to be given, and may even be contraindicated. The quality of sleep associated with sedatives is, in our experience, very different from that obtained from amitriptyline-perphenazine. Some patients report vivid dreaming with the latter, but not after⁴ taking barbiturates or "barbituroids."

Rond(5) quotes from an American physician of a century ago, who referred to want of sleep as almost a certain precursor of mental derangement. If this be so, then restoration of lost sleep certainly could be considered indicated in the treatment of schizophrenia.

SUMMARY

One-hundred and thirty-seven hospitalized schizophrenic patients received amitriptyline-perphenazine for periods seldom exceeding 90 days with a remission rate of about 86%. A possible rationale for the treatment is offered.

CONTROLLED EVALUATIONS OF SEVERAL TRANQUILIZING AGENTS IN ANXIOUS NEUROTIC OUTPATIENTS¹

K. RICKELS, M.D., L. SNOW, M.D., C. BAUMM, M.D., AND J. MOCK, M.D.²

We report here results in the evaluations of 4 newly developed pharmacological agents : amphenidone (Dornwal) (200 mg., q.i.d.), I.S. 813 (Clarmil) (300 mg., q.i.d.), Mead & Johnson 5055 (neopentyl allyl bar-

bituric acid, Nevental) (100 mg., q.i.d.) and McN-X-181 (ethyl-methyl-valeramide) (400 mg., q.i.d.).

In all four studies, a double blind controlled cross-over method was used. The patient's emotional status was evaluated and change recorded by the Physician Rating Scale, The Absolute Overall Scale (0-7), measuring degree of psychopathology, and the "Relative Overall Scale" (-3/+3), recording whether the patient felt the same,

¹ All 4 studies were supported by USPHS grant MY 2934. Medication was supplied by Maltbie Lab., McNeil Lab., Mead & Johnson, and Wallace Lab.

² From the Dept. of Psychiatry, University of Pennsylvania, and Philadelphia General Hospital.

better, or worse as compared to the visit two weeks ago.

Anxious neurotic patients referred to the Psychopharmacology Clinic of the Hospital of the University of Pennsylvania participated in these studies (62% white, 65% female, mean age 38.3). Duration of illness was evenly distributed for all 4 studies, with an average duration of over 1 year.

All patients were allowed to adjust dosage within a given range, upwards as well as downwards. Returned capsules as well as inquiry into drug usage were used to eliminate obvious drug deviators. Patients were placed either on placebo or one of the active agents for periods of 2 weeks (4 weeks for the amphenidone study). Each patient served as his own control, being treated on one active agent and placebo.

While several psychiatric residents participated in these studies, the same research nurse was involved. Patients were first seen by the research nurse, completed their forms, and then saw the physician for an average of 10 to 15 minutes. Patients were told that we had some drugs available which we thought might help their "nerves," and that they had to take each drug for at least two weeks in order to learn something about its efficacy. Medications were prepared in pink No. II capsules and were prescribed as "2 capsules q.i.d." This allowed for flexibility, *i.e.*, to increase up to 3 capsules q.i.d. or decrease to not less than 6 capsules daily.

Only "completed patients" will be discussed. Attrition rate, however, did not differ significantly for each study and was 31% for all studies.

The following number of completed patients participated in each study: 30 patients on amphenidone and placebo, 32 patients on I.S. 813 and placebo, 32 patients on McN-X-181 and placebo, and 34 patients on Mead & Johnson 5055 and placebo. Data were analyzed by analysis of variance, student's t-test, and, where parametric statistics were not applicable, by sign test and chi-square. Sub-scores could only be analyzed by non-parametric statistics because of skewed distributions.

Side Effects: While only occasionally drowsiness was reported with I.S. 813 and amphenidone, 75% of patients on 5055 complained of drowsiness and sedation. The most disturbing side reactions were produced by McN-X-181. Patients reported "tingling and numbness in legs," "funny feeling in the head," "dizziness and blurring of vision, drowsiness" and one patient suffered a mild edema of the lower extremities.

Clinical Improvement: Table I gives difference scores as improvement indicators.

TABLE I

OVERALL RATINGS OF IMPROVEMENT
(Drug-Placebo Differences)

	Amphenidone (Dornwal) N=30		I.S. 813 (Clarmil) N=32		McN-X-181 N=32		Mead & Johnson 5055 (Nevental) N=34	
	△ D-P		△ D-P		△ D-P		△ D-P	
	2 wks	4 wks	2 wks	2 wks	2 wks	2 wks	2 wks	2 wks
Physician ** Questionnaire	-.08	+.80	+.31		-.10		-.44	
Absolute Overall Scale (0-7)	--	--	-.20		+.19		-.45	
Relative Overall Scale (-3 to +3)	+.45	+.13	+.15		+.48		+.39*	
Patient Questionnaire	-4.15	-1.41	--		--		--	

* Significant at the 5% level (one-tailed).

** In all measures but the "Relative Overall Scale", a minus (-) sign indicates improvement.

These scores were derived by subtracting change produced by placebo from change produced by each of the 4 active agents. Only one Overall measure showed significant differences between one of the 4 drugs and placebo. Furthermore, data not presented here, including an analysis of the Clyde Mood Scale subscores as well as Physician questionnaire clusters and items, failed to demonstrate significant drug-placebo differences for 3 of the 4 drugs. Only Mead & Johnson 5055, the barbiturate derivative, showed drug-placebo differences for the Clyde Mood Scale subscores. Patients became significantly less energetic ($p=.10$), less aggressive ($p=.01$), and less jittery ($p=.05$). Summarizing our findings, one may say that Mead & Johnson 5055 produced mildly better results than the other 3 agents, however, at the expense of sedation.

TWILIGHT SLEEP PREMEDICATION IN EST

LAWRENCE H. GAHAGAN, M.D.¹

Twilight sleep, induced by scopolamine and a barbiturate, is an effective premedication for the frightened, agitated or resistive EST patient. Such premedication makes it possible to prevent—or at least alleviate—the anxiety which is otherwise so often associated with this treatment.

It is especially important to avoid anxiety in a procedure, such as EST, which is administered as a series of treatments. Mounting fear not only adds to the patient's misery, but it may also cause him to discontinue treatment or to refuse a further course of EST, if his illness recurs.

About 15 years ago, we began using light twilight sleep for calming disturbed patients, particularly those who were noisy or resistive. Recently, we have extended the use of twilight sleep, and now administer it almost routinely for premedication in hospitalized EST patients.

Technic: about one hour before EST, the patient receives scopolamine hydrobromide 0.6 mg. (1/100 gr.) by intramuscular injection and also a barbiturate, usually amobarbital (amytal) sodium 0.2 gm. (3 gr.) by mouth. Occasionally the barbiturate dose is doubled, or the barbiturate may be given intramuscularly.

By the time of EST, the patient is drowsy, tranquil and cooperative. Before applying the electric stimulus, an intravenous injection of an atropine-barbiturate solution, freshly prepared, is administered. (An appropriate reduction in the atropine-barbiturate dosage is made in view of the scopolamine-barbiturate premedication.) The atropine-barbiturate injection is immediately followed by an injection of succinylcholine (anectine) chloride from a separate syringe through the same needle. After about one minute, the electric stimulus is applied.

No instances of undue excitement or troublesome delirium resulting from the scopolamine-barbiturate premedication have been observed. Such undesired reactions can occur, but they are unlikely in the

absence of pain. We emphatically agree with Goodman and Gilman(1) that "the *disadvantages* of scopolamine are considered negligible by those who have had experience with the drug" (author's italics).

It should be repeated that both scopolamine and barbiturates are prone to cause excitement and delirium only when pain is present(1). For this reason, the warnings of the obstetricians and surgeons about the complexities of twilight sleep are hardly applicable.

As Dille(2) points out, "scopolamine is an excellent drug for the production of amnesia and loss of interest in any surrounding activities." In EST, scopolamine has some added advantages: 1) it has a potent inhibiting effect on secretions; 2) it is an antinauseant; 3) it stimulates respiration and counteracts the respiratory depressant effect of pentobarbital(1).

On the other hand, the vagal depressor effect of scopolamine is relatively weak in comparison with atropine(3). We have not yet determined whether scopolamine, as administered, will regularly prevent EST-induced cardiac arrhythmias of vagal origin. In playing safe, we continue to administer a small dose of intravenous atropine sulfate, usually 0.6 mg. (1/100 gr.) to assure an adequate blockade of the cardiac vagus (4, 5). As mentioned, the atropine-barbiturate solution is administered intravenously about one hour after the scopolamine-barbiturate premedication and shortly before the application of the electric stimulus.

SUMMARY

The patient's acceptance of EST is greatly facilitated by twilight sleep premedication. Light twilight sleep is readily induced by scopolamine and a barbiturate, which are administered about one hour before EST.

THE EFFECT OF POTASSIUM ON PHENOTHIAZINE-INDUCED EXTRAPYRAMIDAL SYSTEM DYSFUNCTION

G. BROOKS, M.D., L. WEAVER, Ph.D.,
C. L. RAVARIS, M.D.¹ AND M. MacDONALD, M.D.²

While treating a group of male patients with fluphenazine, LaPolla(1) made the empirical observation that the administration of 1.5 gm. of potassium orally exerted a beneficial effect on extrapyramidal system (EPS) dysfunction. A controlled study to test this observation was undertaken.

METHOD

Sixteen schizophrenic and 4 manic-depressive patients with a mean age of 42 years were selected. Females were chosen because of the greater incidence of EPS dysfunction(2). All patients were receiving psychotropic drugs. These drugs were terminated and, during the 2-week initial period, all patients were placed on 5 mg. of fluphenazine (Prolixin) and 2 mg. benzotropine methanesulfonate (Cogentin) once daily. This was done to minimize the withdrawal effects so often encountered with abrupt withdrawal of phenothiazine medication(3) and to obtain baseline data on clinical status, psychomotor performance, and serum potassium levels.

Clinical examination for EPS dysfunction and psychomotor testing were done thrice weekly. Fasting serum potassium determinations were performed at the end of the first two weeks and at the conclusion of the study.

Following the two-week stabilization period, the patients were assigned to bal-

anced experimental and control groups on the basis of clinical ratings and psychomotor test performance. Over the next three-week experimental period, both groups received fluphenazine on the following schedule: week I, 5 mg. daily; week II, 10 mg. daily, and week III, 20 mg. daily. A matching placebo replaced the daily Cogentin tablet. The experimental group received 15 milliequivalents (1.25 gms.) of potassium (K-Triplex, Lilly) in 2 ounces of lemonade t.i.d. The control group received a matching placebo.

With the exception of the research psychologist, all participants on the study were blind to group assignments. Ward personnel were not aware of the purpose of the study.

RESULTS

At the end of the stabilization period, 5 patients showed a mild-to-moderate degree of cogwheel rigidity, or resistance to passive stretch, or both. Psychomotor performance was, of course, equal since the groups were equated on this dimension.

At the end of the experimental period there was a definite increase in the incidence and severity of EPS dysfunction in the experimental group, involving 7 of 10 patients. The control group had only 3 of 10 patients so involved. In most instances, the increase was due to the exacerbation of previously existing symptoms. The overall incidence of 50% is in accord with previous experience with piperazine phenothiazines at moderate dose levels. The failure to observe a greater evidence of EPS dysfunction may reflect a selective factor since these patients have had long previous treatment with various phenothiazines.

There was no significant difference between the two groups on psychomotor test

¹ Dept. of Psychiatry, College of Medicine, University of Vermont.

² Dept. of Pharmacology, College of Medicine, University of Vermont.

The research was performed through the clinical facilities of the Vermont State Hospital and supported in part through USPHS Grant MY-1752.

Fluphenazine (Prolixin®) was supplied by E. R. Squibb and Sons and potassium (K-Triplex®) was supplied by Eli Lilly and Co.

performance during the experimental period. Serum potassium levels, at both periods, were within normal limits.

It is concluded that this study presents no evidence that supplemental oral potassium will reduce the incidence or severity of extrapyramidal motor system dysfunction secondary to the administration of

phenothiazine medication.

MENTAL ILLNESS AND VISUAL ILLUSION

CHARLES KORENYI, M.D.¹

Ames in 1951(1) described the visual illusion experienced by normal human subjects during demonstration of the rotating trapezoidal window. Under identical conditions most urban European and African subjects have the visual illusion, *i.e.*, the trapezoidal window oscillates instead of turning clockwise. However, the majority of African rural subjects, never having contact with western culture, do not have this visual illusion. It has been concluded that the knowledge of architecture plays a role in the occurrence of this illusion(2). It seemed possible that illusory perception might be altered in some forms of mental illness, and perhaps have a diagnostic or other value.

METHOD

Selection of patients: The first group consisted of all schizophrenics admitted to Creedmoor State Hospital with no history of previous hospitalization, tested on a continuous basis during a 12-month period. The number of patients tested was 110, 53 males and 57 females; they had an age range of 15-51. The second group consisted of chronic psychotics who were hospitalized for a long period of time; 251 patients were tested in this group, 210 males and 41 females, within the age range of 31-90. Volunteers from the hospital and institute staff made up the third group of 25 controls, 12 males and 13 females, within the age range of 16-60.

¹ Senior Research Psychiatrist, Creedmoor Institute, Queens Village, N. Y.

The editorial assistance of John R. Whittier, M.D., the technical assistance of Edith Feehan, R.N., and Amy Klier, R.N., and the cooperation of Hans P. Laqueur, M.D., are gratefully acknowledged.

The procedure for demonstration of the trapezoidal window was the following: the subject was seated in a dark room and the apparatus was placed on a table at a distance of 20 feet, at the subject's eye level. Both of the subject's eyes were uncovered. He was instructed to watch carefully the movement that he would see. First the rectangular window was shown, and after 3 revolutions, the examiner asked "How does it seem to you to be moving?" After obtaining a report for the rectangular window, the trapezoidal window was shown in the same way. The examiner recorded the answer as "yes," "no," or "uncertain," meaning subject had the illusion, did not have the illusion, or was uncertain.

RESULTS

Ninety-seven percent of the acutely ill schizophrenics, 90% of the chronic psychotics, and 96% of the controls, had the visual illusion. This finding is similar to that of Allport *et al.*(2): 84% for the African urban group and 80% for the European urban group.

SUMMARY

The Ames rotating trapezoidal window was demonstrated to 110 acute schizophrenics, 251 chronic psychotics, and 25 controls. The ratio of subjects experiencing the visual illusion was found similar in each group: 97%, 90%, and 96% respectively. It is concluded that mental disorder does not alter this form of illusory perception.

CASE REPORTS

MANIA ASSOCIATED WITH THE USE OF I.N.H. AND COCAINE

FRANCIS J. KANE, JR., M.D., AND TERRY W. TAYLOR, M.D.¹

Mental disturbances have been reported in the past accompanying the use of isonicotinic acid hydrazide(1) and cocaine(2). The occurrence of separate manic attacks separated by an interval of 30 years associated with the use of these drugs seems worthy of report.

A 49-year-old married white professional man entered the Psychiatric Inpatient Service of the North Carolina Memorial Hospital on 7/23/62, with a one-week history of bizarre behavior characterized by unusual suspiciousness, ideas of reference, unusual verbal aggressiveness, unusual expenditures of money, insomnia, marked motor hyperactivity, and visual hallucinations (snakes). Mental status revealed an alert, markedly hyperactive man with marked pressure of speech. He gestured constantly, paced continuously, and showed marked changes in mood from elation to depression, and tearfulness. There was no evidence of hallucinations at this time. The patient had many ideas of reference and was quite paranoid about his family. He was oriented in all spheres, and both recent and remote memory were intact. He abstracted proverbs well. Physical examination at that time was essentially within normal limits. History revealed ingestion of 100 mgs. I.N.H. q.i.d. and PAS 15 gms. daily for suspected TBC. He received chlorpromazine medication orally in doses of 400 milligrams which over a period of days brought him to a calmer state. Since it was felt that this syndrome might be in some way connected with his I.N.H. medication, he also received pyridoxine 100 milligrams daily. He was discharged from the hospital on 8/21/62, much improved.

On 9/13/33, the patient had been admitted to a state hospital with a mood disorder diagnosed as manic depressive psychosis, manic type. This had followed one week of prescribed use of cocaine extract intranasally for the relief of acute sinusitis. He was discharged from the hospital on 3/2/34, much improved. In the interval he has been a hard working successful professional man who has enjoyed good health and has served with distinction

in his community and in the military service in the Pacific in World War II under conditions of extreme hardship. A follow-up 8 weeks after discharge reveals that the patient is doing well at this time.

The occurrence of mania associated with the use of I.N.H. has been reported at least once along with a variety of other clinical syndromes(1). Psychoses with chronic hallucinosis and Korsakoff psychosis of several years' duration have also been reported, these being looked upon as evidence of organic cerebral impairment(3). Others have reported considerable emotional instability and persistent loss of recent memory associated with the chronic use of I.N.H.(4). Severe spastic paraplegia with depression has also been reported(5).

The probable common underlying problem in all the above is the interference with basic neurophysiological processes involving the use of pyridoxin, the metabolism of which is markedly impaired by hydrazide compounds(6). This interference depletes brain gamma-amino-butyric acid which has a non-specific depressant effect on nervous tissue. Vitamin B-6 co-enzymes are also involved in metabolic processes in the production of the principal central nervous system neurohormones, norepinephrine, and serotonin(7). The clinical reports cited above seemed to have occurred prior to the use of prophylactic pyridoxin, and several patients were reported retreated with I.N.H. while receiving B-6 prophylactically. Our patient was not receiving prophylactic pyridoxin, so it seems plausible to suspect that marked C.N.S. over-stimulation may be the result of interference with vital cerebral metabolic systems.

Cocaine has been found to potentiate enormously the action of the neurohormones, epinephrine and norepinephrine(8). This potentiation of norepinephrine gives rise to a central adrenergic stimulus similar to that provoked by L.S.D.(2). This patient

¹ Dept. of Psychiatry, Univ. of North Carolina.

would seem to underline the difficulty of attributing to one type of stress the potential for producing psychosis since personal psychological stress plus impaired cerebral function seemed to have been co-factors in the development of this patient's illness.

SUMMARY

A patient is reported who showed similar attacks of mania separated by an interval of 30 years associated on each occasion with the use of a drug which causes marked C.N.S. stimulation. It would seem, for this patient, at least, that the profound disturbance of C.N.S. function sometimes associated with these drugs served as an additional severe stress causing personality disruption and a manic illness. Since many compounds of this kind are being used increasingly for the treatment of mental

illness, it may be that we will see an increasing number of these syndromes.

REGIONAL ILEITIS IN DEPRESSED PATIENTS

BERTRAM S. MERSEREAU, M.D.¹

Regional enteritis or "Crohn's Disease" has received little attention in psychiatric literature. Crohn's monograph² does describe various investigations in the psychosomatic area, but these have been generally inconclusive and in many instances seem to exclude psychological influence. In discussing the possible role of psychological factors, Crohn comments as follows: "True, many cases of ileitis have been rescued from psychiatric institutions, but that is only because the diarrhea was regarded as nervous, and the true source of the illness was completely missed."³ The meaning of this statement apparently is that the enteritis was purely an incidental finding unrelated to the particular psychologic characteristics of the population.

In the following two cases of hospitalized psychiatric patients the diagnosis of regional enteritis was belatedly established.

¹ Instructor, Dept. of Psychiatry, State University of New York, Upstate Medical Center, Syracuse.

² Crohn, B. B., and Yarnis, H.: *Regional Ileitis*. New York: Grune & Stratton, 1958.

³ *Ibid.*: p. 29, by permission.

Both were males, in the military service, 23 and 35 years of age. The younger man experienced his first bouts of diarrhea during times of stress such as basic training and specialist school. Subsequent bouts tended to be related to post-discharge civilian-life stress situations of work, courtship and marriage. The older patient experienced unusual diarrhea shortly after the death of a son and at a time when he was scheduled for a tour of sea duty. At times it had seemed to observers that the patients were depressed because of the intermittent distressful diarrhea. Each had been hospitalized for psychiatric symptoms. The diarrhea was accompanied by cramps and general malaise which had led to the suspicion of an organic gut disorder. Repeated extensive medical-roentgenological evaluation had failed to reveal organic pathology. In each case the diagnosis of regional enteritis was finally established within a few months of former normal examinations. In both there had been pre-occupations with the body status. The elder patient had always been free from definitive disorders, but he considered himself to have been "in poor health as long as I can remember." The younger patient had suffered more clear-cut problems of congenital upper alimentary canal stricture, childhood capricious ap-

petite, life-long dermatitis, and adolescent and adult obesity.

In each case diarrhea and abdominal cramps appeared at a time of considerable stress associated with anxiety and depression. In each the anxiety and depression continued into an intermittent chronic state and continued to be closely associated with cramps and diarrhea.

Follow-up of the elder patient revealed persistent depression and bodily concerns follow-

ing convalescence from definitive surgical treatment of the gut lesion.

These cases seem to suggest that particularly stressful life experiences may have contributed in some way to development of the enteritis. Implicit in this report is the warning that unsuccessful search for suspected organic disorders is no guarantee against their future discovery.

ANOREXIA NERVOSA AND GONADAL DYSGENESIS (TURNER'S SYNDROME)

FERRIS N. PITTS, JR., M.D., AND SAMUEL B. GUZE, M.D.¹

It is the authors' purpose to record the first instance of an association between anorexia nervosa and Turner's syndrome.

S. B. weighed 5 lbs. at birth,* after an uncomplicated 8-month gestation. She was the only child of Jewish immigrants from Eastern Europe. The mother and several relatives of both parents were less than 5 feet tall. The maternal grandmother had experienced a psychotic depression of 2 years' duration; recovery immediately followed EST in a psychiatric hospital. The paternal grandfather had diabetes mellitus. The family history was otherwise unremarkable. At delivery the mother was 38 and father 46 years of age; the pregnancy occurred after 12 years of sterile marriage.

At birth the patient was "small, active, with good color; nuchal skin very loosely webbed; dorsum hands and feet firmly edematous; eyes in hypertelorism position; palate has high arch; hair line very low on webbed neck; ears low-set." The edema of the hands and feet had disappeared by age 3 weeks. Repeated follow-up evaluations revealed delayed growth as determined by the Baby Wetzel Grid. Her general development and intellect were considered normal; she sat at 7 months, pulled up at 9 months, walked at 13 months, used first words at less than 12 months, and was using simple sentences by 18 months. Full Scale IQ's ranged from 95 to 108. Blood pressures were normal in all extremities and there

was no evidence of cardiac murmurs or enlargement. At age 5 she was short and stocky (33 in. and 37 lbs.). She gained and lost weight rapidly in 2-5 pound fluctuations, but by age 13 she was quite corpulent (53 in. and 87 lbs.).

At age 7 her pediatrician recorded that she had "areas of alopecia areata" and at 7½ "hair still falling out." (The mother now states that "she was pulling her hair out even then.") At age 8 epiphyseal roentgenography revealed ossification compatible with her chronologic age. An attempt was made to stimulate growth with methyl testosterone.

At age 11½, the epiphyseal roentgenographic age was 12 years. CBC and urinalysis were normal. The 24-hour urinary FSH excretion was 5 mouse units. A cuboidal vaginal epithelium was demonstrated. Vaginal, buccal, and blood smears all revealed absence of female chromatin bodies. Testosterone linguets (5 mg.) and thyroid (60 mg.) were given daily to stimulate growth. At this time she was "although extroverted and active in sports, upset about problems; wants to be taller, concerned about her size and role, wears padded brassiere." The record reveals that there were 3 episodes of repeated emesis for 24 hours during a 2-3 month period when testosterone and thyroid were first given.

By age 13 her growth rate had not increased despite thyroid and testosterone therapy; however, these medications were continued 10 months longer during which time it became clear that growth had ceased at 53 inches, her present height. At 13 she had a tonsillectomy and adenoidectomy. At 14 a "Z type" plastic repair of the webbed neck was performed. Both she and mother were concerned about her growth failure and the absence of sec-

¹ Dept. of Psychiatry and Neurology, Washington University School of Medicine, Renard Hospital, St. Louis 10, Mo.

We are indebted to Dr. Max Deutch and Dr. Paul Zentay for permission to review their clinical records.

ondary sex characteristics. At 13 she was seen by her pediatrician for "depression at social rejection—is not invited to parties and 'not in on anything'." Psychiatric consultation was advised but refused.

At 13½ she weighed 87¼ lbs., was 52½ inches tall, and demonstrated concern at her obesity; therefore, a 1000 calorie diet and 10 mg. dextroamphetamine daily were added to daily thyroid and methyl testosterone. In 6 weeks she lost 11 lbs. and was advised to discontinue both Dexedrine and diet. She was "afraid she'd look fat and funny," however, and continued to restrict dietary intake. In 8 more weeks she lost 10 additional pounds to 65¼—a total loss in 14 weeks of 21½ lbs., or approximately 25% of initial body weight. She attained this weight loss by restricting her intake drastically, exercising excessively, using cathartics to produce diarrhea, and regurgitating the occasional meal that hunger forced her to consume. When her parents became concerned about her weight loss, she resorted to lying, hiding food, and concealing her actual caloric deficit. At this time a 24-hour urine contained 3.9 mg. of 17 keto steroids, 4.1 mg. of 17 hydroxy cortico steroids, and 9.2 rat units of FSH (normal adult 8-50 units). A sulfation factor value was 0.2455 units (normal 0.8 to 1.18). As no pituitary growth hormone was available at that time, she was begun on Methandrostenolone (Dianabol, Ciba) tablets, 5 mg. daily. Her mother complained that the patient had diarrhea and repeated vomiting after gorging herself. Alopecia was again noted. This symptom had reappeared simultaneously with nail biting, thumb sucking, and habitual face-rubbing. She was "very nervous" and gave a history of frequent abdominal pain and recurrent nausea. She stated that "everything I used to do looks bigger than it is and I'm so upset I can't stop biting my nails, pulling my hair, and worrying about everything." Medications were discontinued.

The psychiatric consultant noted that while she "had had several problems, both medical and emotional, prior to 6 months ago, it was only then that the acute difficulties appeared. Formerly, she would minimize her short stature and tell her mother 'you should be glad it's not polio.' Then she became worried about her appearance, went on a diet, and became self-critical. In school she had been compulsive and anxious about her work for the first time; her grades are reflecting her efforts and have gone from C to B. Her mood has been moderately depressed and her behavior includes a wish to be close to the mother, appearing guilty away from home, being sub-

normally assertive at school and with her friends and, of course, being self-critical about her appearance." Within a week she was back in the pediatrician's office saying that she was still distressed: "It's not my size, I don't know what it is." Her weight had fallen to 53 lbs., and immediate hospitalization was advised to deal with the severe malnutrition and dehydration.

From this point until the present, 30 months later, she has spent over 50% of her time as a psychiatric inpatient. There have been 11 separate admittances to 4 different hospitals for periods of 4 days to 9 months. Each has been prompted by severe weight loss and dehydration. Her weight has been 38-50 lbs. on admittance and 65-85 lbs. at discharge. She remained alert and active despite the weight loss and dehydration. She confounded open floor management by hiding food, vomiting secretly, stealing other patients' cathartics, lying about her activities and goals, secretly gorging 2 liters of water just prior to daily weighing, *etc.* She gained weight promptly on a closed ward; however, when discharged the same process would begin again and in a short while severe weight loss would be evident. She is now hospitalized.

Turner's syndrome is a genetically determined disorder characterized by retarded growth with normal epiphyseal development and adult dwarfism; stocky body build; broad shield-like chest; short, webbed neck; lymphedema of dorsum of hands and feet which disappears in the first few weeks of life; digital valgus; hypotelorism; high-arched palate; frequent cardiovascular anomalies and hypertension; and infantile female external genitalia without development of primary and secondary sex characteristics through puberty. In addition mental deficiency is supposedly more common than in the general population (1-3). These patients ordinarily have either 45/XO sex chromosomes or have a form of 45/XO/46/XX mosaicism, although there are rare instances of 46/XX or 46/XY karyotypes (1). The webbed neck apparently is seen with the absence of sex chromatin bodies (3) and the 45/XO karyotype. Our patient quite obviously meets the diagnostic criteria for Turner's syndrome; indeed, she lacks only the non-essential features of cardiovascular anomalies and mental deficiency.

The marked weight loss after initial dieting in an adolescent female with obsessions and phobias about food establish the diagnosis of anorexia nervosa in our patient. Primary amenorrhea, a manifestation of gonadal dysgenesis, precluded the development of the secondary amenorrhea some authors(4) consider an essential diagnostic feature of anorexia nervosa.

SUMMARY

A patient with Turner's syndrome (ovarian dysgenesis) and anorexia nervosa is

reported; available data from birth to age 18 are summarized.

POST-HYSTERECTOMY PSEUDOCYESIS OR PHANTOM VISCERAL ORGAN

A. J. MALERSTEIN, M.D.¹

Bodenheimer(3) mentions casually having seen one patient post-hysterectomy with symptoms of pseudocyesis. His report is included in Bivin and Klinger's(2) classical study of the literature on pseudocyesis. Otherwise, neither Bivin and Klinger nor Rutherford(6) include any cases of pseudocyesis post-hysterectomy.

Hoffman(5) reviewed 51 references dating back to 1872. He concludes phantoms of the penis, breast or facial parts are infrequent and points out phantom teeth have been reported. Critchley(4) reported breast or ear phantoms are uncommon, while eye, rectum and larynx phantoms are common. Ackerly, Lhamon and Fitts(1) reported 11 cases of phantom breast symptoms in 55 breast amputees. They stressed that in cases where the phantom was not painful they had to ask the patient to elicit any symptoms of a phantom. They allude to the possibility of visceral phantoms. Szasz(7) reports two patients who, after vagotomy, had healed ulcers by x-ray, but continued to have ulcer pains relieved by milk and water.

Our patient, a married woman in her late twenties, mother of three, had had repeated hospitalization for pernicious vomiting of 2 years' duration. For 2 years prior to the onset

of her vomiting and commencing shortly following hysterectomy (for back pain, dyspareunia, and metrorrhagia), she was tense, bored, restless, suffered from insomnia, had fainting spells, and poured her energies into an extra job, housework, and providing meals for boarders.

The onset of vomiting followed a meal in a restaurant. The patient's physician diagnosed the condition as food poisoning. The patient had been obese since the age of 9 or 10. It dawned on her after her first episode of vomiting that one way of losing weight without giving up eating was to stick her finger down her throat. She induced emesis in this manner for about 10 days, but following this she continued to vomit without conscious control at a rate varying from many times a day to occasional periods of a few days free from vomiting. Her vomiting in its severest form resulted in several hospitalizations, during which she would respond well over a period of two to three weeks of sedation, I.V. fluids, and extensive workups. The workups revealed no positive findings. When I saw her she appeared very thin and older than her chronological age.

By the time she started therapy many secondary gratifications were derived from the symptom. The patient had symptoms other than vomiting (mainly phobic) as well as some character problems. The vomiting was variously determined, *e.g.*, related to the eating habits and attitudes of the family. However, I will confine myself to culling out only that material which I feel supports my thesis that this

¹ 2305 Van Ness Ave., San Francisco, Calif.

woman had an unconscious fantasy that she was pregnant.

The sight or smell of food made her vomit. Yet she craved homemade ice cream, and watermelon, the two foods she craved when pregnant with her first child. During the course of therapy she was about to be anaesthetized prior to surgery for a nonfunctioning ovarian cyst and she told the intern her breasts were sore. At one point during psychotherapy she said, "I know it's crazy, but I felt life in my belly." At times she had cramping abdominal pain which radiated to her back.

There are more data available that would suggest how the choice of a fantasy of pregnancy would interweave into this patient's history and serve specific functions for her. However, these have been omitted.

Since seeing this patient, Dr. Bernard Weil informed me that he had a patient who continued to have periodic "menstrual cramps" post-hysterectomy. A friend who read this paper prior to publication had periodic "pre-menstrual" cramps, depres-

sion and feelings of heaviness which lasted for 6-7 months after hysterectomy. She never spoke of her symptoms to her physician. If post-surgical symptomatology on a phantom visceral organ basis occurs more often than would ordinarily be supposed, it may constitute an explanation of some of the post-operative complications with which the surgeon is confronted.

COMMENTS

EUTHANASIA

"Is life no more than the heart-beat and respiration?" In those words *The Lancet*¹ asks, and answers somewhat ambiguously, one of the most difficult, painful and tragic questions the doctor is called upon to answer.

The question refers to the combined labour of doctors and nurses to prolong life in the case of a patient in irreversible coma due to extensive destruction of the cerebral cortex following head injury or other causes. In such a case the consciousness has been obliterated, the mind is gone, the person has ceased to exist. What is left is an automaton in the familiar human form subsisting through the activities of the lower brain centers. Such an existence may be continued for months or even years. "Is it really prolonging life," *The Lancet* asks, "or merely prolonging dying?"

There are, of course, two sides to such an issue. The rule to which the doctor dedicates his life and which society trusts him to follow is to save life and keep it going at all costs. In this respect a sharp distinction traditionally exists in the evaluation of human life and that of other animals. The factors leading to this distinction in which human kind has been indoctrinated from times immemorial make an interesting and worthwhile, if somewhat discouraging study which, relatively speaking, still has a long way to go.

But the best of rules may have exceptions, and the physician may find himself in a dilemma that may be resolved only by "turning a blind eye on general rules." *The Lancet* editorial ends: "A clinician who persistently seeks to sustain a parody of life may end in serving nobody and nothing

except pride in his own technical competence."

The question of preserving life of the body without the person is only one of those with which the physician may have to deal. The case of incurable disease accompanied by great suffering is another. Here sedation adequate to relieve intolerable pain is the obvious indication. Sometimes a patient who is quite aware of his helpless situation takes matters into his own hands; and we recall Seneca's opinion as to the individual's right to decide whether he will continue to live in his own house of flesh.

Over the years medical thinking about euthanasia appears to have been changing. *New Medical Materia*,² a monthly commentary on medical and socio-economic problems, recently presented graphically, following a wide survey of medical opinion throughout the United States, a cross-section of the views of American doctors on two questions:

1. *The case of a patient in great pain without hope of relief or recovery;*
2. *An infant born with serious abnormalities and with no chance of a normal life.*

In the first situation 31.2% of all doctors surveyed felt that euthanasia was justified. Classified according to religion the figures were: Protestant 38.5%; Catholic 6.7%; Jews 38.8%.

In favour of euthanasia in the second situation: 32.8% of all doctors: Protestant 40.7%; Catholic 6.2%; Jews 48.8%.

Accompanying these charts *New Medical Materia* also published a cross-section of opinions both for and against euthanasia in these two situations, expressed verbally by doctors participating in the survey. These opinions illustrate the perennial division between religious and non-religious thinking.

NEWS AND NOTES

NEW YORK CITY COMMUNITY MENTAL HEALTH SERVICE.—The cost of mental illness in the United States is highlighted by the budget estimate by Dr. Marvin E. Perkins, Commissioner of Mental Health Service, New York City, for fiscal year 1963-64. It totals \$34,166,203, representing an increase of \$6,040,032 over the budget for 1962-63.

Dr. Perkins also notes that a decade ago the direct and indirect *national* cost of mental illness was estimated to be \$2.4 billion. The corresponding figure as of today was not given.

DR. FRAZIER GOES TO BAYLOR UNIVERSITY.—As of January 1, 1963, Dr. Shervert Frazier became Professor of Psychiatry and Chairman of the Department at Baylor University Medical School, Houston, Texas. Before going to Baylor, Dr. Frazier had been a member of the Department of Psychiatry at the College of Physicians and Surgeons, Columbia University.

ACADEMY OF PSYCHOSOMATIC MEDICINE.—The Academy will hold its second symposium on "Anxiety and Depression" at the Marlborough Blenheim Hotel, Atlantic City, N. J., June 15-16, 1963, beginning at 8:30 a.m. on June 15.

Topics will include: Psychiatric Education of the Non-Psychiatrist, The Multiple Roots of Emotional Illness, The Psychopharmacology of Depression, *etc.*

For further details, please write to the program chairman, Wilfred Dorfman, M.D., 1921 Newkirk Ave., Brooklyn 26, N. Y.

DR. BLAIN JOINS PENNSYLVANIA HOSPITAL STAFF.—Morris Cheston, Esq., Chairman of the Hospital's Board of Managers, announced that as of April 1 Daniel Blain, M.D., director of mental hygiene for California since 1959, takes up his new position

as director of psychiatric planning and development at the Pennsylvania Hospital.

Dr. Blain will head a commission for the study of psychiatric services of the Hospital and the Institute in relation to the community. Members of the committee include Dr. Lauren H. Smith, head consultant for medical development of the Institute, Dr. J. Martin Myers, medical director of the Institute, certain other members of the medical staff of both divisions of the Hospital and representatives of non-medical persons in the community.

CENTRAL NEUROPSYCHIATRIC HOSPITAL ASSOCIATION.—During the meeting in Chicago March 14 and 15, 1963, the Association, which is made up of 19 private psychiatric hospitals, elected the following officers for 1963-64: President, Ralph S. Green, M.D.; President-Elect, B. Cullen Burris, M.D.; Secretary-Treasurer, George T. Harding, Jr., M.D.

DR. GREENBLATT GOES TO BOSTON STATE HOSPITAL.—Dr. Milton Greenblatt, a native of Boston, and who for many years has been closely associated with the Boston Psychopathic Hospital, which, when it was opened by E. E. Southard in 1912, was administratively a division of the Boston State Hospital, becoming in 1920 an independent institution, has been appointed superintendent to the Boston State Hospital. Dr. Greenblatt takes over this new responsibility as of April 1, 1963.

CORRECTION.—Through a printer's error the first line of the next to last paragraph on page 1002 in the April 1963 issue of the Journal appeared incorrectly. The line should have read "Another interesting parallel between the . . ."

BOOK REVIEWS

THE LIFE AND WORK OF SIGMUND FREUD.

By Ernest Jones; edited and abridged by Lionel Trilling, and Steven Marcus. (New York: Basic Books, 1961, pp. 541. \$7.50.)

The purpose of an abridgment, to retain in shortened form the essential content, the spirit and style of the original, has been admirably fulfilled. The task of the editors of the abridged biography (541 pages) has not been an easy one. Documentation and identification of sources taking much space in the original edition have been omitted; likewise the surgeon's notes about treatment of Freud's neoplastic disease.

Occasionally something of greater importance has been omitted. The chapter on Freud's initial and later abandoned "theory of the mind" is in this reviewer's opinion interesting enough to have been retained. One would also like to find Jones' estimate of Freud's personality, written originally shortly after Freud's death, and partially reproduced in Volume 2 of the 3-volume edition. It also would have enhanced the value of the abridgment if at least the chapter on religion in Volume 3 had been retained. This chapter shows clearly the profundity and the courage of Freud's atheism, his views on the relationship between religious ritual and neurotic mechanisms and his identification with Moses which in his later life took the place of the earlier Hannibal identification.

The elimination of most of the letters does no harm but it might have been worthwhile to include Freud's letter to Marie Bonaparte in which he states his belief that major psychoses cannot be treated by psychoanalysis, and predicts somatic therapy for this group of disorders.

The abridgment would have gained by the elimination of the inaccuracies and misspellings of names in the original edition. The name of the German general who at the end of the war saved Paris from the destruction ordered by Hitler, and to whom therefore the entire civilized world is indebted, was von Choltitz, not von Cholbitz. The psychiatrist who was drowned in his effort to prevent the suicide of King Ludwig II was von Gudden, not von Gudelers. (Gudden's name continues to be remembered by those even slightly familiar with neuroanatomy by Gudden's Commissure.) In writing to Pfister, Freud commented on Pfister's analysis of the Count of Zinzendorf, not

Zizendorf. The outstanding novelist whom Freud read was not G. F. Meyer, but Conrad F. Meyer. The quotation from Goethe in Freud's letter to Einstein should read: "Im Vorgefuehl," instead of "ein Vorgefuehl." Jones is at odds with the Latin language and forms the atrocious adjective "sexicum," and Trilling and Marcus have perpetuated this monstrosity in their abridgment.

Freud's art collection shown in one of the excellent photographs should not have been designated as primitive art since obviously it consists chiefly of Egyptian, Assyrian and classical pieces.

The present volume is divided into 3 books which correspond with the 3 individual volumes of the original. Book 1 covers the formative years and the great discoveries (1856-1900), Book 2, the years of maturity (1901-1919), and Book 3, the last phase (1919-1939).

Although Freud has expressed himself against being made the subject of a biography, the biographical material is exceedingly ample. Jones describes both Freud's life and work on a basis of complete familiarity and states that his respect and admiration for Freud's personality and his achievements were immeasurably great. Jones believes that his own hero-worshipping propensities had been worked through before he encountered Freud. In this belief he is quite obviously wrong. As a matter of fact Jones' attitude towards Freud is frankly idolatrous, and lends a personal note to the book. For critics of Freud or of psychoanalysis Jones has no understanding nor mercy. He speaks of "ill natured people," and of "distortion" and of "mendacious legend." He does not forget to record Kretschmer's early rejection of Freud's teaching, but omits to mention that later Kretschmer integrated the essentials of Freud's thinking into his own.

If one would ask what on the basis of this biography emerges as the outstanding feature of Freud's life and character, the answer would be the enormous complexity of the personality and the heroic design of his life. The heroic attitude, evolved in childhood, was never abandoned and carried on to the last. The boy identified himself with Hannibal, the tragic semitic hero. This identification which in conjunction with other factors undoubtedly was instrumental in forming Freud's heroic attitude also led to peculiar, almost immature inhibitions. On his first visit to his beloved Italy

Freud stopped at Lake Trasimeno, the ground of one of Hannibal's most famous battles, but did not proceed to Rome, just as Hannibal had not succeeded in reaching Rome. When Freud eventually entered the eternal city it was an exhilarating triumph (as if Hannibal had succeeded). It was at the same time that Freud with the urging of friends and the help of patients could bring himself to make a determined and successful attempt to achieve professional rank. Freud's stay in Rome furnishes another proof of how unobjective this heroic genius could be. He admired to the utmost the relics of ancient Rome. He detested the Papal Rome because of his dislike of any religion, and particularly of the "lie of salvation." At the same time he admired Michelangelo, apparently forgetting how much Michelangelo had been part of Papal Rome.

Similar immaturity and prejudice is evident in Freud's whole-hearted condemnation of and dislike for America. He blamed American food for his nervous indigestion which on occasions plagued him all his life. He criticized the bathrooms in America and called America: "A mistake, a gigantic mistake."

Never, however, did he lose his love for England, English history and literature.

And there is the true heroism in the never ending search for truth against all obstacles, feeling bitterly the rejection by his colleagues. In this diligent search he did unhesitatingly sacrifice earlier theories if this became necessary. The search for truth was coupled to a virtually religious faith in reason, its ultimate power and victory. While Freud believed that he was as objective and scientific as his admired old master, the physiologist Brucke, he did not hesitate to subscribe to Jones' suggestion of a formation of a committee to watch over "my creation," when the defection of some of his disciples had shown that even from within the movement the dogma was not unassailable. The members of the committee were bound together by the gift of Greek intaglios which were fitted into rings. Freud wore one with the head of Jupiter. What a strange group this committee was. Jones tells how the idea of its formation occurred to him on the basis of his past preoccupation with Charlemagne and his Paladins. The other members will hardly evoke such heroic associations. Ferenczi ended in a homicidal paranoid psychosis, hallucinating that messages came to him from across the Atlantic. A letter of censure which Freud sent to Ferenczi still makes interesting reading. This was the man whom Freud originally had called his Paladin and secret Grand Vizier. Then there was Abraham who allowed himself to be oper-

ated only on a day fitting the numerological calculations of Fliess, Freud's friend of the early period. And Rank who sent a young American home to practice psychoanalysis after 6 weeks' training. When Jones expressed his disagreement Rank shrugged his shoulders saying: "One must live." Of Brill Freud once said: "Brill is behaving shamefully, he has to be dropped."

Jones having been part of the committee and part of the movement seemed to be almost unaware how much the various neurotic immaturities contrast with features of greatness and the profound depths of insight which led to the discovery of the unconscious.

Part of Freud's basic heroism reveals itself in his intellectual courage and the capacity to admit and face the evil of life, to bear the 18 years of extreme pain, "a little island of pain floating in a sea of indifference," suffering repeated surgical procedures with unparalleled fortitude. How strongly Freud held on to the heroic ideal under most adverse circumstances is evidenced, when the old chronically ill refugee on his way from France to England dreamed that he was landing at Pevensy. He explained to his son that this was the place where William the Conqueror had landed. Years before he had said: "I am nothing but by temperament a conquistador."

Next to the heroism and the passion for truth Freud's absolute honesty and integrity as well as his simplicity appear as outstanding characteristics.

In certain aspects Jones is possibly unsuccessful, lacking deep enough knowledge of German language and culture. While he praises Freud's style his discussion of Freud's truly magnificent gift as a writer is very brief. He omits practically completely Freud's cultural background, mentioning Schopenhauer briefly and C. G. Carus not at all.

The description of Freud the neurologist is thorough and interesting. Freud was far ahead of the majority of his colleagues when in his studies on aphasia he expressed the opinion that centers were nothing more than nodal points in the general network. The introduction of the medical use of cocaine, the work on infantile cerebral paralysis, the gold chloride stain, and even the early work on Reissner's cells in petromycon which Freud proved to be spinal ganglion cells are thoroughly described. Bernard Sachs who later was such a bitter enemy of Freud praised the work on infantile cerebral palsy as masterly and exhaustive.

The book by Jones has to be evaluated in 4 different categories: 1. As a biography in the narrower sense it is exhaustive. The author

knew Freud intimately, knew his family very well and had access to all important material. He has worked this into an extremely well told and fascinating story.

2. As a character study the book is influenced by the author's idolatrous attitude. Jones sees Freud probably in many ways as Freud saw and desired to see himself. Sources other than Freud's and his closest followers' writings have been neglected.¹

3. Jones mostly sees in Freud the heroic scientist, not the intuitive thinker, writer and seer. He is hardly ever aware of the unbridled phantasy which at times dominated the thinking of the man who as a physiologist and neurologist had tried to apply strictest self-discipline. Jones never stresses sufficiently to what great extent Freud's edifice has been built on introspection. A famous Academic Lecture comes here to mind, and needless to say, even the most serious critics of Freud find no hearing in Jones' book. To what grotesque results Freud's phantasy could lead becomes evident in his letter to Thomas Mann written in 1936. This letter is only to be found in the 3-volume edition.

4. Finally Jones also gives a fairly thorough history of the movement, and even of the Verlag (this fourth category could be eliminated from future 1-volume editions without loss).

In this reviewer's opinion the main value of the book rests in the extensive biographical narration. In critical understanding of Freud's creation and its impact Jones' voluminous work has been clearly surpassed by Erich Fromm's brief and lucid study. As stated at the beginning of this review, the abridgment has achieved its purpose to the full extent and is a notable achievement within itself.

ALFRED GALLINEK, M.D.,
Columbia Presbyterian Medical Center,
Neurological Institute, New York, N. Y.

MOHAVE ETHNOPSYCHIATRY AND SUICIDE: THE PSYCHIATRIC KNOWLEDGE AND THE PSYCHIC DISTURBANCES OF AN INDIAN TRIBE. By George Devereux. (Washington: Smithsonian Institution, Bureau of Am. Ethnology, Bull. 175, 1961, pp. vi + 586, 10 plates. \$3.25.)

The Mohave Indians, now mostly resident on a reservation in Arizona, have been the sub-

ject of a long series of scientific papers by the distinguished anthropologist George Devereux. These papers have described various aspects of Mohave culture which are relevant to the interests of a psychoanalytic anthropology: Mohave sexual customs, Mohave dreams, Mohave profanity, Mohave pregnancy, etc. The present volume undertakes to present the material on Mohave mental disorders and Mohave psychiatric beliefs and practices. It is based largely on material collected during several extended field trips in the 1930's; it is of methodological interest to mention that at this time in Devereux's scientific career, he remarks, he was sceptical if not hostile to psychoanalysis. Thus the psychoanalytic framework of interpretation which characterizes the present volume does not imply a pro-psychoanalytic bias in the collection of the primary data (although, perhaps, by psychoanalytic principles, an anti-psychoanalytic bias might achieve a similar result!).

The volume is divided, fundamentally, into four parts: 1) a preliminary presentation of Mohave ideas, in the context of their traditional world view, concerning mental disorder and its treatment; 2) the presentation of case materials (well over a hundred individuals are represented) classified according to traditional Mohave categories; 3) discussion of these and other case materials classified according to "occidental" disease categories; and 4) an extended presentation of case materials, with associated discussion, of the several types of suicide recognized by the Mohave. It may be noted that Devereux introduces his work with the claim that it is "the first systematic study of the psychiatric theories and practices of a primitive tribe . . . a kind of 'Mohave textbook of psychiatry,' dictated by Mohave 'psychiatrists' to the anthropological field worker." The claim is valid: while there are many partial accounts of the psychopathology and psychotherapy of primitive peoples, none approaches this monograph in thoroughness of detail based on original field work. Read in the context of Devereux's and others' ethnographic accounts of traditional as well as reservation Mohave life, the volume is undoubtedly a fundamental source in ethnopsychiatry.

The evaluation of the volume with regard to its methodological, interpretive, and theoretical content, is not easy. There are technical shortcomings, chargeable not so much to the anthropologist as to the circumstances of ethnological field work: the case materials, for instance, were in many cases not derived from first-hand observation but from descriptions provided by the anthropologist's several prime

¹ It is interesting to note that a recent publication (*Sigmund Freud's Akademische Laufbahn im Lichte der Dokumente*. Josef Gicklhorn and Renee Gicklhorn. Wien: Urban & Schwarzenberg, 1960.) reveals facts which are entirely different from what already has been considered uncontroversial, historical truth.

informants; and the case materials, with the associated commentaries of the informants, are (laudably enough) the backbone of the study. The interpretation of a given phenomenon mingles, sometimes in uncertain proportion, inferences about Mohave culture and basic personality structure and deductions from both psychoanalytic theory and Mohave ethnography. Thus it is difficult to evaluate the degree to which Mohave "theories" of psychodynamics are on the one hand, conscious cultural formulations which duplicate, in some respects, occidental psychiatric theory, and on the other hand are simply local expressions of a pan-human psychodynamic pattern. But the richness of the case and interview materials, and the interest of the theoretical suggestions and insights contributed by the author, make quibbling over methodology an ungrateful talk. Devereux's work is recommended as essential reading for any anthropologist or psychiatrist interested in the forms of mental illness, and practices of psychotherapy, of non-western peoples.

University of Pennsylvania.

MELANCHOLIE ZUR PROBLEMESCHICHTE TYPOLOGIE PATHOGENESE UND KLINIK. By Hubert Tellenbach. (Berlin: Springer-Verlag, 1961. DM 39, 80.)

The modern 'anthropological' approach to psychiatry holds a special appeal for an important group of German-speaking psychiatrists. Some of its merits and defects are exhibited by this monograph in which the author, one of the younger generation, has made an attempt to take a new look at the old and fundamental psychiatric problem of depression. Dr. Tellenbach's study is essentially clinical with strong philosophical connections. From anamnestic data relating to 119 depressed patients seen at the Heidelberg Psychiatric Clinic in 1959 he attempts to elucidate the sequence of phenomena which lead into states of depression which he views as restricted modes of living. The patients' pre-morbid personalities exhibit a constitutional rigidity; in 'pre-depressive situations' they flounder in a form of vital stasis; at the onset of the illness they are overwhelmed by morbid doubt. The dynamics of this sequence are discussed speculatively in terms of the special meaning attached by the author to the word 'endogenous.'

As an exercise in 'understanding' psychology the clinical thesis is presented with subtlety and some erudition. Dr. Tellenbach is well

enough acquainted with the roots of his subject to provide an interesting historical introduction and his bias towards Zutt and von Gebsattel does not blind him to the contributions of Kraepelin and Lange. Nonetheless, the study remains more stimulating than convincing. Much of the clinical reasoning turns on the specificity of the phenomena described and their relationship to each other. This cannot be clinched by the case-history method of argument, backed up as it is by an acrobatic use of language in which the word tends to follow the concept. The reader must be prepared to master the meaning of terms like *Ordentlichkeit*, *Inkludenz*, *Remanenz* and *Endokinese*, and to grapple with such key sentences as the following: "Die Seinsart des Endon—wie auch die der grossen Endogenität der Natur—ist transsubjektiv und deshalb metapsychologisch, transobjektiv und deshalb metasomatologisch." He is left wondering to what extent new and elaborate labels are being affixed to old and familiar bottles and, noting that all but 8 of the 197 references are in the author's native tongue, he may perhaps recall the unanswered question posed by the late Dr. Mayer-Gross: "Why can one express this form of psychiatry only in the German language?"

MICHAEL SHEPHERD, D.P.M.,
London, England.

LA TERRA DEL RIMORSO. By Ernesto de Martino. (Milano: Il Saggiatore, 1961, pp. 439.)

Tarantism, which traditionally is defined as a disorder characterized by an uncontrollable desire to dance under the influence of musical arias (tarantellas) following the supposed bite by a spider, was apparently very common in the 16th and 17th centuries in the region corresponding to the heel of the Italian peninsula (where the city of Taranto is located). In the past centuries there has been very little mention of it so that it was believed by many to have entirely disappeared. Ernesto de Martino, a distinguished Italian ethnologist already known for some very important contributions to cultural manifestations of Southern Italy, has led a research team (composed of a cultural anthropologist, a psychiatrist, a social worker, and a musicologist) on a field investigation of tarantism in several towns around Taranto. About 20 subjects suffering from tarantism have been followed and their manifestations carefully recorded, not only verbally in the text but also in many illustrations and on a phonograph record of the tarantellas which add

value and clarity to this publication. Furthermore, the author has presented a detailed historical survey of the literature on tarantism, stressing in particular the contributions of those (such as the great physician, Giorgio Baglivi) who have studied this subject in the past. In discussing the various aspects of the ritual on tarantism (the craving for colors and water, the crisis marking the passage from immobility to phrenetic dance, the symbolism of the spider and the identification with it on the part of the patient, the cyclic reappearance of the phenomenon in coincidence with the time of the harvest), he has made an attempt to place them in the historical and geographical context of the tradition of the healing role of the dance and music in the Mediterranean areas. While pointing to the derivations and affinities between tarantism and the Greek Dionysiac mysteries (which also provided relief to emotionally disturbed people through a stronger cathartic abreaction), he warns against a fallacious "reduction" to a general type of cultural pattern or to surviving elements of previous cultures.

For our purpose, the description of the behavioral expressions—and, in general, of the personality—of the subjects is of particular importance. In spite of the attempt made by de Martino to secure the cooperation of specialists in different disciplines relating to human personality, their contribution to the book is definitely a very insufficient one in comparison to the rest of the book. The few Rorschachs administered to the subjects are reported only partially, and the conclusion reached is that "It is impossible to pass a judgment neither on the intelligence nor on the personality of these patients, and even less on their 'normality' or 'abnormality.'" Similarly, the psychiatrist of the team, after having rejected as oversimplification the statement that tarantism occurs in people particularly predisposed and that its meaning is to permit the release of anxiety and conflicts through the stereotyped ritual, oscillates between a psychiatric (anxiety hysteria, delusion) and a cultural interpretation of it. Perhaps a better position from a psychiatric viewpoint is reached in the first part of the book where the emphasis is put on the unconscious guilt feelings of the patients affected by tarantism and on the ways of discharging them (hence the title of the book—*La Terra Del Rimorso*, namely, "The Land of Remorse" where "remorse" is understood both in its usual as well as in the literal meaning of "biting again"—Latin *rimorsus*). On the whole, this last part of the study particularly reflects the hurry (three weeks) with which the field investigation has been conducted and, in gen-

eral, the discrepancy between the wealth and depth of the ethnological material and the scarcity of the clinical material. This inadequacy is not overcome by the brilliant style—though too philosophical and too existentially oriented—used by the author throughout the text. One wonders whether it would not have been more effective to study even very few cases longitudinally, *i.e.*, on the basis of a very careful and anamnestic history and of a deeper individual relationship, thus possibly throwing light on the previous emotional experiences of each subject. Perhaps this approach would have helped to answer the basic questions which, I am sure, are in the minds of many psychiatrists: What was the early development of these individuals? What kind of experiences did they go through in adolescence and later on? What previous contacts with tarantism had each individual? Is the basic personality of these subjects functioning cyclically? and so forth.

These considerations, however, do not intend to be a criticism of the study; on the contrary, in view of the scarcity of well-prepared psychiatrists and psychologists in a country like Italy, where there has been no time to integrate properly the psychodynamic theory of behavior into the culture of the country, this remains a very important contribution to culture anthropological studies. Furthermore, it is one of the few dedicated to an aspect of our western culture and its connections with its Greek antecedents, rather than to alien cultures.

GEORGE MORA, M.D.,
Poughkeepsie, N. Y.

THE GYNECOLOGIC PATIENT: A PSYCHO-ENDOCRINE STUDY. By Somers H. Sturgis, with Doris Menzer-Benaron, et al. (New York and London: Grune & Stratton, 1962, pp. 240. \$7.75.)

This book presents a study of the gynecological patient on the basis of the total physiological response to disease. Services have been organized at Peter Bent Bingham Hospital, Boston, so that in addition to a thorough endocrine investigation, close co-operation between gynecologist and psychiatrist permits a basis for study and the control of certain functional disturbances emphasizing psychological features which have often received only cursory consideration.

With some reason the senior author points out that the young gynecologist or surgeon is often so impressed with the importance of surgical techniques that he fails to give any

consideration to fundamental reactions on the part of the patient which, if controlled, may well obviate too active treatment and so modify the use of measures which may set up a chain of reactions to the detriment of the long term welfare of the patient.

The first section of the book deals with functional disturbances such as amenorrhea, dysmenorrhea and premenstrual tension while the second section presents the emotional reactions which may be associated with the treatment of conditions having a demonstrable pathological basis. It is emphasized that the complete recovery of the patient may be complicated because of the failure to appreciate these important factors.

The book presents a series of case reports with endocrine and psychiatric summaries and a summation of the problems which have been so illustrated. There can be little doubt as to the value of this rather unique style. It is certain to leave a new conception of the importance of fundamental factors which have contributed to the problem presented by the patient and how they may affect the measures to be adopted for the restoration of her health in mind and body.

THOUGHT AND LANGUAGE. By *L. S. Vygotsky*. Ed. transl. by *Eugenia Hanfmann*, and *Gertrude Vakar*. (New York: M. I. T. Press; New York and London: John Wiley, 1962, pp. xiii + 168.)

A most challenging and difficult book to review; perhaps its review belongs to the later psychological historian and political scientist; or, at the moment, to the author of the introduction, Jerome S. Bruner, who makes a very good case pro Vygotsky.

Vygotsky is dead, since 1934. His brief span (some ten years) of urgency in the field of psychology (particularly "cognitive" psychology) provides a link between Ach and the Wurzburgers, on the one hand, whom he obviously espoused, and the "more modern" experimentalists like Luria; possibly including the late Kasanin as a relatively modern U. S. A. clinician.

Political Science would, I am sure, question the statement (on the American jacket of the book) that Vygotsky's thought "has been a major influence on modern Soviet psychology." However that may be, I (the reviewer) cannot recognize his influence on present-day U.S.S.R. psychology. So, I leave it to later historians.

The early paragraphs of this work stress the

importance of the inter-relation of thought and word. Did not Socrates wrestle with this same problem? Or was it not the same?

Vygotsky then tries to interpret Piaget, which intrigues Piaget to say (in a supplementary statement to the volume) "I didn't quite mean that, but he makes me think again." This supplement is the best reward for buying the book!

The chapter headings are as follows: 1. The Problem and the Approach; 2. Piaget's Theory of Child Language and Thought; 3. Stern's Theory of Language Development; 4. The Genetic Roots of Thought and Speech; 5. An Experimental Study of Concept Formation; 6. The Development of Scientific Concepts in Childhood; 7. Thought and Word.

This is where we came in.

I'm not so sure where we came out. Except that I am glad the editors and translators have produced this volume. Vygotsky was a great man. His sponsors were not of his own choosing. Only history can acclaim or disclaim him.

W. LINE, PH.D.,
Toronto, Ontario.

MENTAL ILLNESS IN LONDON. By *Vera Norris*. (New York: Oxford University Press, 1961, pp. 317. \$9.50.)

This volume presents statistical analyses of the operation of two observation units and the three mental hospitals receiving their patients from about half the geographic area of London, with 1.6 million population. It includes a five-year follow-up of patients by means of official records which can indicate whether or not readmission to hospital has occurred. The mental hospitals received patients from the observation units as well as from other sources; the observation units received patients from general hospitals and other referral sources. The statistical analyses in the volume are not overly complex and are clearly set forth. They are worth careful perusal as an introduction to the complexities of recording the movement of human beings through a social system over a period of time and of the necessity for the avoidance of the pitfalls that await the unwary investigator of such phenomena.

Dr. Norris concluded that diagnostic practices in psychiatry were not so inaccurate and unreproducible as to be useless. Overall, diagnosis was the same (using a relatively rough, 11 group classificatory scheme) in the observation unit and the mental hospital receiving the patient, with identity varying from the high of 85% for schizophrenia to a low of a little more than 40% for "Disorders of Behavior and

Character" (disregarding the miscellaneous group). While it is heartening to encounter a defense of the usefulness of classification in psychiatry again, it must be admitted that the differences between one and another group diagnosing the same patient are still large enough to make the interpretations of comparative statistics a very chancy thing. Furthermore, comparison of results of treatment or management is possible only if the differences are very large if one is to be reasonably certain that diagnostic practice cannot explain them rather than differences in therapy.

The follow-up results are, in general, discouraging and Norris felt they by no means justified the optimistic opinions so frequent in recent years. It is not on this book that the English estimate is based that hospital beds can, over the next decades, be greatly reduced. Norris found that even in the most hopeful group of psychotics, the manic-depressives, success in the sense of no readmission to hospital was not outstandingly good, with 40% undergoing readmission within four years of discharge.

The work pays unusual attention to death associated with the psychiatric illnesses and the data are instructive. Even in manic-depressive psychoses the crude death rates are about seven times that of the age-corresponding general population. The observation units obviously receive very ill patients with many dying in the first few days or weeks; indeed these deaths before transfer are interpreted as a relief to the mental hospitals where the cases would otherwise have to be admitted. One wonders whether it might not be even more economical to allow them to die in the general hospitals rather than be transferred at all. In general, Norris lends emphasis to the fact that death rates are definitely higher in the presence of psychiatric illnesses. Of course, they are highest in the organic psychoses.

The book contains a chapter on the uses of statistical studies in administration. It comes to the inescapable conclusion that the present situation and prospects are intolerable and that, while improvements must be made in patient care, the real hope for the future lies in research on better ways of prevention and treatment. The arguments in favor of heavy expenditures in research efforts are certainly impressive.

One cannot call such a book as this inspiring but it is certainly one that deserves very careful study; it is an antidote to uncontrolled optimism in our field.

PAUL V. LEMKAU, M.D.,
The Johns Hopkins University.

BASIC ANXIETY. By *Walter J. Garre, M.D.*
(New York: Philosophical Library, 1962,
pp. xv + 123. \$5.00.)

The mother who not so rarely experiences the infant as an encumbrance is the significant person in its life. Feeling that its existence is threatened by the significant person, the infant "will fear death." "The anxiety that the infant must feel to some degree at least I call the 'basic anxiety.'" The author considers "this basic anxiety . . . the key to personality adjustment, the focal point of our difficulties in orientation, the cause of our diseases and maladjustments, and in fact the central point in the adaptation of humans to life."

Although the author uses the term "unadulterated anxiety" in passing he does not seem clearly to discriminate anxiety and fear. He also writes repeatedly about the child when according to his leading idea one would expect him to deal with the infant. Nevertheless this is an interesting treatise which may do no harm. The author seems to be haunted by his concept as though it were a clue to a framework of human life in which everything could find its predestined place.

His discussion is one of many interpretations. One wonders whether he does not think that he is explaining facts.

EUGENE KAHN, M.D.,
Houston, Texas.

BASIC ENDOCRINOLOGY FOR STUDENTS OF BIOLOGY AND MEDICINE. By *J. H. U. Brown,*
and *S. B. Barker.* (Philadelphia: F. A. Davis, 1962.)

The authors have written an excellent textbook covering the essentials of endocrine gland functions. Primarily oriented to students in physiology or medical courses, the material is essentially a presentation of normal human endocrinology. Biochemistry, synthesis and metabolism of the hormones, their specific physiologic effects and the normal interrelations of the endocrine glands are presented clearly and concisely. Some of the common disturbances of glandular function, cited as evidence for hormonal effects, contribute to the student's understanding of the normal state. However, the authors have explicitly and successfully avoided compiling a textbook of clinical endocrinology.

Sections covering hormone assays and other indices of endocrine activity are simply and precisely presented. Suggested experiments illustrative of endocrine physiology should prove valuable to both teachers and students.

Some of the schematic simplifications of

complex biochemical interrelationships are not completely successful. When diagrammatic presentation is possible only at the expense of extensive omission of modifying data, it might better be avoided in order not to introduce questionable hypotheses. This small criticism, however, detracts little from a valuable book, well printed in an inexpensive format.

R. C. MELLINGER, M.D.,
Henry Ford Hospital,
Detroit, Mich.

THE GROWTH OF SELF-INSIGHT. Edited by John M. Dorsey. (Detroit: Wayne State University Press, 1962, pp. 220. \$5.00.)

The book constitutes Volume X of the Leo M. Franklin Memorial Lectures. It consists of a symposium by John M. Dorsey, Lectureship Chairman for 1959-60, and four co-authors, on Human Individuality. Bernard Mayo, professor of history, University of Virginia, contributes "Jefferson's Faith in Human Integrity." Wilbert Snow, Poet of the Maine Coast, gives "Individuality in the Work of Ralph Waldo Emerson." Milton Rosenbaum, Albert Einstein College of Medicine, discourses on "The Whole Individual, a Health View." Harold A. Basilius, professor of German, Wayne State University, discusses "Goethe's Conception of Individuality and Personality." Editor Dorsey presents an essay on "The Growth of Self-Insight." His intimate, inimitable style makes for difficult reading. Within that diction, however, is outlined a medical and psychiatric philosophy which is deeply personal Dorsey. He combines the basic best of psychoanalysis, existentialism, intuitionism, solipsism, and individualism. The palatability of his philosophy is still a little rough in spots; its digestibility somewhat refractory at times; but, these approaches mastered, its assimilability is achieved. Dorsey truly gives substance to the words of Herodotus: "The destiny of man lies in his soul."

The medical philosophy recorded in the little volume well deserves a place in the professional literature of today.

THOMAS J. HELDT, M.D.,
Detroit, Mich.

MODERN CONCEPTS OF HOSPITAL ADMINISTRATION. Ed. Joseph Karlton Owen. (Philadelphia: W. B. Saunders, 1962, pp. 805.)

There were seventy-two contributors to this text, some with long years of experience, others comparatively new to the field of hos-

pital administration. The various facets of hospital administration are broadly covered in an interesting and informative manner. Some of the subjects are not dealt with in any great detail but they are all well covered, written with apparent enthusiasm, conviction and presented with a common sense approach. There are several subjects that have not been considered in other texts that are well timed for current interest and needs. Amongst these are Community Planning; The Hospital Insurance Programme; Physical Medicine and Rehabilitation; Care of the Mentally Ill; Home Care; Formal Education for Hospital Administration; Current Trends in Administration.

There are, as one might imagine, statements made to which exception may be taken. This is, of course, to be expected and is thought provoking and helpful.

This is a book which in my opinion one will find extremely useful, no matter what one's level of responsibility in the field of hospital administration may be.

Toronto, Ontario.

THE FUTURE OF PSYCHIATRY. Ed. by Paul H. Hoch, and Joseph Zubin. (New York: Grune & Stratton, 1962, pp. 271. \$8.75.)

In a field like psychiatry, where knowledge is fragmentary and constantly changing and speculation abounds, the task of predicting future developments can well make the stoutest hearts quail. As Greenblatt in his excellent contribution to this symposium puts it: "... any attempt to peer into the future at this point involves judgments about a sea of unknowns that frighten one into abject humility."

Ideally such a task should be given to the young, whose imaginations are still fresh and who have the rashness of youth. But their lack of experience would give their words little weight, so one turns perforce to "authorities" who will be heard with respect. To become an authority takes time, so, as might be expected, about half the contributors to this volume are over 60. This may be related to the book's rather conservative tone. On the sound premise that prediction of the future must rest on knowledge of the present and past, most of the contributors offer historical or contemporary surveys of their own bailiwicks or review their own work. With a few notable exceptions, however, they avoid predictions or tack them on as perfunctory afterthoughts. The contributors cover biological, psychological, social, and educational approaches. The expert in any par-

ticular field will learn little from the paper on that field, but taken together these surveys perform the valuable service of bringing the reader up to date in areas not his own.

They reveal that knowledge of the biological basis of psychiatry is increasing at a fantastic rate. The development of microtechniques in neuroanatomy, neurophysiology, and biochemistry is yielding increasingly detailed understanding of the relations between structural and functional properties of the nervous system, subjective states and behavior. Microtechniques are also revolutionizing the study of human genetics. The data garnered by old and new methods are analysed by electronic computers that can handle vastly more information than ever before. These are rapidly unearthing new relationships in all aspects of human functioning—social and psychological as well as biological.

New techniques for gathering and processing data have stimulated the development of new conceptual schemes such as information theory and cybernetics. Rioch, in a richly thoughtful and well documented presentation, describes how these offer new ways of thinking about biological and psychological processes of much greater specificity and power than anything available in the past.

While many contributors stress that we are on the threshold of vastly increased understanding of human functioning, none adequately tackles the question of the possibilities of control of human behavior that will inevitably result from this increase in knowledge. Some suggest therapeutic possibilities, but all seem to avert their gaze from the noxious ones. This probably reflects the general unwillingness of scientists to tackle the unpleasant ethical implications of their activities.

The future of the sociological and psychological aspects of psychiatry looks far less spectacular than that of the biological ones. Computer techniques, in which Zubin and Pasamanick, especially, place great hopes, while slowly adding to our store of information in these fields, have yielded no major breakthroughs as yet. However, it is comforting to note that not even the most enthusiastic proponents of biological approaches believe that they will render sociological and psychological ones obsolete.

Since methods of prevention and therapy in psychiatry rest more on social and psychological than on biological information, their future does not seem to hold any major innovations either. In the meanwhile the effectiveness of preventive psychiatry remains in doubt and proposed programs, such as those offered by

Funkenstein and Farnsworth, lack a solid basis.

It seems probable that psychotherapeutic practice will be increasingly influenced by the growing recognition of the importance of social factors in psychiatric illness and treatment. The trend towards working with patients' families and others in their environment will almost certainly increase, as will the development of the social organization of psychiatric services in hospitals and communities. This implies incorporation of a variety of personnel in psychiatric treatment programs.

These developments add weight to the concept of psychotherapy as a learning process which helps the patient to correct maladaptive social communication patterns or to develop those which he lacks. As a result, psychiatrists will probably do less and less psychotherapy themselves, and function more as leaders of treatment teams or as practitioners of the new biological therapeutic interventions lying just over the horizon.

Whatever the future may hold with respect to specific advances, one conclusion, succinctly stated by Gruenberg, seems amply supported by this interesting volume: "... psychiatry in the next twenty years will become more and more influenced by empirical findings and our treatments will be selected on the basis of systematic study more and more frequently in contrast to the swings of fashion."

JEROME D. FRANK, M.D.,
Baltimore, Md.

TREATMENT OF THE CHILD IN EMOTIONAL CONFLICT. Second Edition. By H. S. Lippman. (New York: McGraw-Hill, 1962, pp. 367. \$9.50.)

* Several new subjects have been added to the second edition, including a chapter on reading disabilities and a chapter on group therapy. In addition, the author has up-dated case history reports from the first edition, giving a valuable follow-up on the effectiveness of the therapies employed.

The book is clearly written and the author has generously used case histories to illustrate and emphasize the therapeutic processes. It is to some degree uneven, undoubtedly due to the analytic and therapeutic interests of the author, who has recognized this in his preface, where he states that he has not tried to illustrate all the conditions studied in a child guidance clinic, but attempted to present a point of view towards therapy rather than a comprehensive picture of child guidance services.

Certain sections are excellent, for example,

those dealing with the neurotic child, school phobias, depressions, group therapies and reading disabilities. By comparison the sections dealing with the organic disturbances, mental retardation, and convulsions are less adequate.

Despite these minor criticisms this is a book that should be read by every physician, psychologist or social worker who is or will be involved in the treatment of children with emotional disorders.

WILLIAM A. HAWKE, M.D.,
Toronto, Canada.

DEPRIVATION OF MATERNAL CARE: A Reassessment of its Effects. Public Health Papers #14. (Geneva: World Health Organization, 1962, pp. 165. \$2.00.)

The hypothesis that maternal deprivation in early childhood accounts for much delinquency in after years is examined and the evidence on which it is based appraised by six "distinguished workers in child psychiatry and allied fields." The referee, as represented by the Preface, finds for the defence but many readers will find much food for thought in the well informed, highly informative, logical analyses by Margaret Mead and Barbara Wootton, both set forth in impeccable English free from technical terms and with deeply sympathetic but unbiased interest. This publication should make salutary and timely reading for those who are now handing out dogmatic advice regarding thalidomide victims. But there is a wider and more general field including WHO itself: the volume demonstrates clearly that students sent to this continent to learn public health should not go back with their text-books, note-books and heads filled with what we believe, have and do, but should return equipped to study the problems as they are in their native circumstances, define them, measure them, absolutely and relatively, and find solutions compatible with those circumstances and perhaps nearer the truth than those we might dictate for them.

NEIL E. MCKINNON, M.D.,
University of Toronto.

COMPARATIVE NEUROPATHOLOGY. By J. R. M. Innes, and L. Z. Saunders. (New York: Academic Press, 1962, pp. 859. \$32.00.)

This monumental work fills a need for a comparative and authoritative text of comparative neuropathology in English. Beautifully edited and profusely illustrated it contains a wealth of information valuable not only to veterinary pathologists but to all engaged in

the study of the diseases of the nervous system. With the exception of one special chapter on the neurological diseases of monkeys most of the material is organized according to the etiological factors. However, special chapters are devoted to the cerebrospinal fluid and to the disease of skeletal muscles, the hypophysis, the spinal cord and the peripheral nervous system. Wild and domesticated animals, as well as laboratory animals, are considered.

Extensive bibliography brought up to 1960 is included after each chapter.

In spite of its high price, this important book is a must not only for libraries of universities, research institutes or neuropathological laboratories, but also for private collections of all neuropathologists.

J. OLSZEWSKI, M.D.,
Professor of Neuropathology,
University of Toronto.

DETERMINANTS OF INFANT BEHAVIOUR. Edited by B. M. Foss, foreword by John Bowlby. (London: Methuen; New York: John Wiley, 1961, pp. xv + 308. \$6.75.)

This is a record of the proceedings of a Tavistock study-group on "mother-infant interaction" [sic] held at CIBA, London, in 1959. John Bowlby was the convenor, who succeeded in bringing together an important contributing and participating membership. Dr. Foss, as rapporteur for the seminar, and editor of the report, is to be congratulated on all the important characteristics underlying the purpose of the seminar and its public communication of outcomes.

The study group was built around seven prepared papers, presented by Ambrose, Blauvelt, David, Gewirtz, Harlow, Rheingold and Rosenblatt, respectively: The Development of the Smiling Response in Early Infancy; Mother-Neonate Interaction: Capacity of the Human Newborn for Orientation; A Study of Nursing Care and Nurse-Infant Interaction; A Learning Analysis of the Effects of Normal Stimulation, Privation and Deprivation on the Acquisition of Social Motivation and Attachment; The Development of Affectional Patterns in Infant Monkeys; The Effect of Environmental Stimulation upon Social and Exploratory Behaviour in the Human Infant; Early Socialization in the Domestic Cat as based on Feeding and other Relationships between Female and Young.

Discussion and improvised contributions, including a very important discussion of the film "Monique," are included.

It is not quite as much of a mixture as it

sounds, when expressed as above.

The scope and intent of the seminar are clear. Other study-groups will follow. The evaluation of the process and of the series must await further outcomes. At this stage one can welcome the meeting of minds and their researches from so wide a variety of disciplines, contributing to the same end. Naturally, there will be an unwitting clash of philosophies of *early* human development—which is quite nicely ameliorated by the final comments of Bowlby, who has demonstrated his wisdom in this regard, and to whom the behavioural scientists might well look for continued leadership.

In summary, the book is a very valuable contribution—largely from experimentalists and clinicians. One can hope for the eventual inclusion in the process of a social-scientist as philosopher.

Toronto, Ontario.

ESSENTIALS OF PAEDIATRIC PSYCHIATRY. By R. Meyer, M. Levitt, M. L. Falick, and B. O. Rubenstein. (New York: Appleton-Century-Crofts, 1962.)

The title of this small book, *Essentials of Paediatric Psychiatry*, is somewhat inaccurate because it is by no means a resume or summary of current paediatric psychiatry. However, the purpose is defined in the preface—"to provide the paediatrician with understanding of both the normal psychiatric development of children and their emotional problems and to clarify his own role in relation to them. No effort has been made to present a complete picture of human development." The authors explain that they have selected issues and viewpoints which represent their own preoccupations and that they have left a great deal out of the book as it was not planned to be either eclectic or extensive. One would agree with this as the book does not present a full picture of human development, but tends to emphasize psychoanalytic concepts and to minimize the constitutional and maturational aspects of development.

Little advice is given to the paediatrician about the direct handling of the child and his role is mainly restricted to environment manipulation, particularly the counselling and support of parents. The reason for this is the feeling of the authors that the paediatrician who must be involved in physical examinations and direct medical intervention cannot also play a very different role in the psychological treatment of the child. Therefore one would suspect that most paediatricians would

find that this book does not answer many of the questions which arise in their daily practice.

Several sections of the book the reviewer felt were particularly well written, including the chapters on brain damage and mental retardation which clearly present the criteria necessary for clinical diagnosis. Several statements warrant emphasis—that the EEG frequently leads to equivocal results and rarely gives a definite answer to the question of brain damage; that the major function of psychological testing seems to be corroborative rather than diagnostic; that psychological testing does not provide a diagnosis of any disorder in the absence of other confirmatory findings, historical, case material, clinical observation, etc.

The section dealing with asthma appears to be written objectively and approaches the relationship between asthma and emotional factors critically and competently. The chapter dealing with the emotional reaction of children to hospitalization is also well documented and presents an objective and critical review of the subject.

Unfortunately there are other chapters which do not appear to be of the same quality. For example, the discussion of reading disabilities tends to ignore the maturational aspects of development which play such a large part in reading disabilities and focuses on those emotional problems which may be involved.

The section dealing with treatment is limited to approximately 12 pages which will probably not meet the needs of most paediatricians. However, considerable time is spent on the question of referral to the psychiatrist, which should be useful.

Some Certain sections have a psychoanalytic orientation and may be somewhat unacceptable to the paediatrician, who may find it difficult to accept the statement that increased frequency of urination is a manifestation of anxiety, or may be associated with the struggle against masturbatory impulses and fantasies, or an expression of castration anxiety. One would also wonder about the statement that in enuresis conditioning devices are sometimes effective but fail to deal with underlying causes and can thus only lead to transitory inhibition or new symptomatology.

In conclusion, one might say that this book presents an adequate idea of development as currently recognized by the psychoanalytic school. However, this limitation prejudices its practical value for the practicing paediatrician.

**GEORGE RONALD HARGREAVES,
O.B.E., M.Sc. (LEEDS), F.R.C.P. (EDIN.)**

(1908-1962)

Many members of the APA must have met Dr. Ronald Hargreaves, either during the war, when in 1943 he visited around the army posts in this country and those in Canada, or on his more recent visits as Professor of Psychiatry at the University of Leeds, England, or perhaps at Geneva when he was Head of the Mental Health Section of the World Health Organisation. All of us therefore will have been grieved and shocked by the news of his sudden death on the 18th December, 1962, in Queen Square Hospital, London, at the age of 54, following an operation for an aneurysm which was causing pressure on his optic chiasma.

Ronald Hargreaves was one of perhaps half a dozen people in the world who made a major impression in the field of social and preventive psychiatry, and he was someone who could ill be spared.

Ronald Hargreaves was a Yorkshireman, though none of his time since early boyhood had been spent in Yorkshire until he returned to Leeds as Professor. After school, he took his medical course at University College, London, and then at University College Hospital Medical School, where he did very well. His perceptive contemporaries at the Medical School recognised that he possessed the most original mind amongst the students of his time. The sudden death of his father caused Hargreaves to postpone house appointments at his own hospital in order to earn money for the education of the younger ones in the family. He worked at Hill End Mental Hospital, St. Albans, and as clinical assistant to Dr. Bernard Hart, University College Hospital. His interest in the neuroses took him to the Cassel Hospital, and then to the Tavistock Clinic, where he was appointed a full physician in January 1938.

At the outbreak of war it was decided that a certain group of psychiatrists should

be called up as soon as possible to service in the army, and Hargreaves was one of these. During the six months of waiting for that call up he did an immense amount of reading. He read Fortescue's *History of the British Army* and, still more remarkable, procured and read the training manuals of every arm of the fighting services, in this way equipping himself with background knowledge for the work he was about to undertake.

R. Hargreaves was blessed not only with outstandingly good intelligence, but also with a phenomenal memory; and when, around Christmas time 1939, he actually came into the army, he knew more about the army's history and difficulties and background than most regular officers knew.

The work which Hargreaves did in the army, first of all as a specialist in Northern Command, and then at the War Office, was quite outstanding, and indeed, made by far the biggest contribution to the development of all the social psychiatric activities that were developed during the war. It was his experiments and work which led to the rather overdue development of a proper selection service for all men coming into the army, and later all officers who were to be considered for commissions.

Hargreaves had not merely read the history of the British army, he had also read and mastered Tom Salmon's masterly work in Volume X of the U. S. Army history of the 1914-18 war. This served as a Bible to British army psychiatry, just as later the British army was able in return to be of some help and guidance in the enlargement and development of psychiatric services in the U. S. army.

Hargreaves was distinguished by many things, but certainly by a healthy determination to see the right thing done, if at all possible, and it was fortunate that he very quickly won the complete confidence

of the General of the Northern Command, who later became Adjutant-General of the British army (Sir Ronald Adam).

In 1943 he came over with Brigadier Rees, who was the Consulting Psychiatrist to the army, on a visit to the U. S. and made a tour, along with General Brock Chisholm and some of our Canadian colleagues, to the Canadian military posts as well as those of the U. S. army. They got permission for William Menninger, then Consultant at Atlanta, to go with them, and teased him much about being just a clinician when there was a war on, with the result that Colonel Menninger (as he then was) found himself whilst in Canada let in for all kinds of soldierly activities which he had only envisaged before, but which gave him increased insight into the life of the combatant soldier and officer.

Hargreaves' visit to America on that occasion was of value to him, in that he saw many things that might be copied in the British army, some that he did not want to copy, and at the same time it established for him many excellent friendships which persisted through the years with psychiatrists and others in the U. S. A.

When the war ended, Hargreaves was appointed O.B.E., though many people thought he should have had a higher decoration for his immense contribution to the health and welfare and morale of the British Army. He then took on the job of Senior Medical Officer to the great international firm of Unilever, where he was faced with many problems not altogether dissimilar to those in the British Army, but in an industrial setting. With some heart-searching, he allowed himself two years later, in 1949, to be taken out of this job, to undertake, at Dr. Brock Chisholm's request, the work of first Chief of the Mental Health Section of WHO in Geneva. Here he again did a brilliant job, of quite a different kind. His erudition and knowledge, his interest in every branch of medicine (for he was never at any time limited to psychiatry or to analytic procedures) created very firm foundations for the mental health work of the organisation. The Expert Committee meetings which he organised produced reports, for the writing of which he was largely responsible, which have had

a lasting influence throughout the world in upgrading the concept of psychiatry and the therapeutic community and community services.

I remember very well sitting in his room in Geneva one day (for I was often there) discussing the joint operations of the World Federation for Mental Health and WHO. During an hour's talk five or six people came into the room, and would have withdrawn quickly, seeing that he had somebody with him; but he beckoned them in, and they had just come to return some books he had lent them, of which they had read the special pages or parts which were relevant to their particular problem, and wanted to tell him of the kind of plans they had formulated for their sections in other branches of medicine, on the basis of discussion with him. Consequently, on what was about the smallest budget of any section of WHO, Hargreaves produced an enormous amount of good work, because the other sections—public health, nursing, education, health education, *etc.*—ran projects which, because of the influence and advice of Hargreaves, became in fact mental health activities; but they ran on their own budgets and not on his. This has always seemed to me to be a very impressive activity, and one which many of us could try in our own circles to copy.

The illness of his wife prevented him from travelling as much as he would have liked, but whenever he did travel he left behind him a wealth of good feeling and a great deal of wisdom, and he was enabled to encourage the arrangements for consultantships and fellowships to be given to countries where they could do the maximum good.

After five years at WHO, Hargreaves decided to apply for, and was appointed to, the Chair of Psychiatry at Leeds University, where he did a remarkably fine job in building up a sound, very high grade team to work with him, excellent education, very good relationships with his colleagues in the faculty and, what is perhaps just as important, very good and helpful relationships with other faculties, like Education. It was impressive, when talking to some professors from other faculties at the Memorial Service in Leeds recently, to find

some of them were deeply moved by his loss.

One could write almost indefinitely about Ronald Hargreaves. He was a very good artist, an excellent cook, a wonderful raconteur, as many people will remember. A very modest man, he was always concerned with the good of the job for which he was working rather than for himself. He was in fact a very rare person. I hope that in the future there will be many more who resemble him in some of his qualities and char-

acteristics.

Ronald Hargreaves had four children. Three are in training for special jobs. Eva, his wife, who had been a very skilled anaesthetist in the days when she was at hospital, died after a long series of operations last summer, so that now our sympathy goes to the children who are left, and to his brother, who is a general family physician.

John R. Rees, M.D.

BENJAMIN KARPMAN, M.D. (1886-1962)

Ben Karpman's death leaves a void in the ranks of psychiatry that may never be adequately filled. However friendly or unfriendly one's attitude, it cannot be gainsaid that he was among the most articulate and dedicated champions of the psychiatrically "dispossessed"—the criminal, delinquent, sociopath and sexual offender.

I had gone to St. Elizabeths in the summer of 1937 to study psychiatry and, hopefully, to become a psychoanalyst. Soon after my arrival, I was introduced to Ben in the library. He was the first "psychoanalyst" I had ever met outside the books that I had been reading since high school. When he learned I had read Steckel's "Peculiarities of Behavior" while in college, it was the beginning of a firm friendship. Ben offered to psychoanalyze me but the method he proposed did not seem to me to be comparable to what I had read. He suggested that I abstract his case material and then he would discuss the material with me and thus teach me analytic theory. We compromised by agreeing to meet in the library before the general staff conference each day for a quick chess game. In this way, he later pointed out, we were both behaving as "psychopaths" for we would hide the chess men and the board in the stacks. There was little that did not engage Ben's interest and curiosity, and at that time he published an article in the *Psychoanalytic Review* on the "Psychology of Chess." To have a dog and to be interested in dogs led to the article "The Psychopathology and Psycho-

pathological Reactions in Dogs."

Ben was unquestionably a controversial figure. I think he enjoyed controversy and had a particular genius for "upholding the opposition" to provoke others into questioning their concepts. Over the many years that I knew him he never failed to amaze me with his encyclopedic knowledge of the psychoanalytic literature and his precise and specific recall. As my own knowledge of psychoanalytic literature, and of Ben's contributions as well, deepened over the years of our association, I would sometimes catch him in what seemed to me to be a deliberate misquotation. Occasionally, with a chuckle and twinkle, he would admit to an outrageous statement intended to be provocative. On one occasion I jokingly accused him of not only misquoting Freud but of misquoting Karpman.

Many undoubtedly would accept that personally Ben was a warm, generous and kind friend. What others, not so familiar with him, did not realize was his very keen sense of humor, his tremendous fund of anecdotes and his capacity to laugh at himself and others.

While I disavowed many of Ben's techniques, I admired his dogged persistence in working with the most difficult type of patients and his enormous energy that enabled him to work 16 to 18 hours a day until the last few years of his life. He even welcomed weekends because then he could work steadily, without interruption. I believe that there are few people who would

be willing to emulate his therapeutic career.

Although not a man of appreciable means, he was known for his generosity over many years. Whenever a collection was made for any worthwhile purpose, Ben Karpman always made a substantial contribution. He was generous to his University and to the residents that he loved, even those, like myself, who frequently disagreed with him. In the tradition of Maimonides, he was very helpful to patients in their transition from hospital to community, without hope or expectation of recompensation.

Ben's lifetime spanned the development of modern psychodynamic concepts in psychiatry. In the 20's he was analyzed by Steckel (I was never sure whether it was 10 or 400 hours). Ben was as *bona fide* a psychoanalyst as any others of his day and time, although he never became a member of the American association. The late Clara Thompson, first President of the Washington-Baltimore Society in 1930, told me that he was several times invited to join, but he always preferred to go his own way.

Ben was born in Slutzk, Russia, August 8, 1886. He came to this country as a young man and had his college and medical

training at the University of Minnesota, receiving his M.D. degree in 1920. His entire professional career was spent at St. Elizabeths Hospital. He made several trips abroad for post-graduate training at the University of Vienna in the 20's, and for analysis. For a considerable period, he served as Chairman of the Department of Psychiatry at Howard University School of Medicine. He was the only, or one of the very few, psychoanalytically trained individuals who chose to spend his career in a mental hospital. He worked for more than forty years in his office in Center Building and published more than 110 papers, monographs and books.

I suppose that to the many who knew him over the years at St. Elizabeths, and to the future residents and staff members, his office will long be known as "Dr. Karpman's office" whatever use is made of it. It was in this office that he suffered a heart attack on May 23, 1962 and died early the following morning. He leaves a wife and two children, his son is a physician.

His like will not soon be seen again.

Bernard A. Cruvant, M.D.

CORRESPONDENCE OF THE A.P.A. FOUNDERS¹ROBERT E. JONES, M.D.²

The correspondence between the founders (see Appendix) of the American Psychiatric Association and its first secretary, Dr. Thomas S. Kirkbride, has never before been reviewed and summarized, yet these letters indicate the flavor of psychiatric practice in 19th century America and reveal the character of the men who managed 13 of the 20 mental hospitals then in existence.

The Historical Library and Museum of the Institute of the Pennsylvania Hospital contains approximately 5000 autograph letters(2) written from 1843 to 1865 to Dr. Kirkbride, including at least one letter from each founder except Dr. Samuel White, the first vice-president of the Association and eldest of the group, who died a few months after its founding. Only 40 letters from Dr. Kirkbride to the founders survive, preserved as press copies in two volumes of his letters, dating from 1842 to 1849. The surviving Kirkbride letters conveniently cover the period preceding and immediately following the establishment of the Association, giving some idea of the flow of correspondence and the exchange of ideas.

Dr. Kirkbride was, as well as a founder, an energetic supporter and sustainer of the Association(3). He served as its first secretary for 8 years, then as vice-president for 7 years (1855-62), and as president for 8 years (1862-70). Being the first secretary, much of the correspondence deals with the business of the Association: arranging time and place of meetings, accommodations for members, and introduction of new members.

In general, the Kirkbride correspondence was conducted in a sincere, friendly, respectful manner. The men obviously had high regard for one another and felt an *esprit de corps* among themselves in caring for the "class of unfortunates," as Francis

T. Stribling called the insane. Isaac Ray referred to the group as "brethren"; John S. Butler nicknamed them the "Old Originals." The correspondence reflects the fact that they were sensitive men who considered that they had a high calling. They had a sense of humor and could joke about regional differences, or about themselves as "mad doctors" or "insane doctors." None, of course, called himself a psychiatrist, although Pliny Earle came close by calling them "rich psychiaters." The letters are full of cordial invitations to visit one another, enquiries after one another's health and family welfare, sympathy during illness, and gratitude for visits, errands, and information.

THE FOUNDING

In the spring of 1844 Dr. Samuel Woodward, Superintendent of the State Lunatic Hospital at Worcester, Mass. called at the Pennsylvania Hospital for the Insane to see Dr. Kirkbride, the Superintendent. Dr. Kirkbride, however, was not at home, and Dr. Woodward continued his journey south to visit Dr. Francis T. Stribling of the Western Lunatic Asylum in Staunton, Va.

Dr. Stribling must have greeted Dr. Woodward with a very stimulating idea, for on June 15, 1844, Dr. Kirkbride wrote to Dr. Stribling:

During my absence I regretted to hear that Dr. Woodward had come on to see me, but have since understood that he will give us a visit on his return. Before this you will probably have seen him as he intended going as far as Virginia and Ohio.

As respects a convention of the Medical Superintendents of Insane Hospitals, I agree with you that much benefit might result from such a meeting, particularly as respects the statistics of such institutions. There are some difficulties in the way, however, and preparatory to a meeting it appears to me that all should be aware of the matters likely to be discussed and have some idea of what plans are likely to be proposed for general adoption.

¹ Supported by a grant from the Hall-Mercer Hospital, Pennsylvania Hospital Division.

² Psychiatric resident, Institute of the Pennsylvania Hospital.

To be efficient, the action of such a convention should as far as possible embrace all the asylums of character in the country. Should Philadelphia be selected as the place for meeting, I should be very glad to do everything in my power to make all who attend perfectly at home and to see to any preparatory arrangements that may be required.

Again on July 5th, 1844, Dr. Kirkbride refers to the meeting in a letter to Dr. Stribling :

... As respects the meeting of Superintendents of Insane Hospitals I need hardly say that I shall take pleasure in joining them in any deliberations likely to promote the good cause in which we are all engaged. The time and place mentioned by you will of course be particularly convenient to me, and perhaps as you suggest it would be difficult to arrange any preliminaries previous to the assembling of the convention.

I was much disappointed and not a little surprised that Dr. Woodward did not call out to see me on his return, particularly as he scarce took a glance at our establishment on his way South, and as I had hoped from what he then said that he would have spent a few days with us on his way home.

Finally on Aug. 22, 1844, Dr. Kirkbride addressed Dr. Woodward :

I received your letter of the 17th inst. yesterday, and shall take great pleasure in making the arrangements you suggest, relative to the meeting of Physicians to Hospitals for the Insane to be held in Philadelphia in October next. I had already concluded to make an arrangement with Mr. Jones for any accommodations we might desire, and no better place for first getting together could be designated.

The meeting to which these letters refer occurred on the evening of Oct. 15, 1844, when at the invitation of Dr. Kirkbride, a group of 13 physicians, all of them superintendents of hospitals for the mentally ill, met in the parlor of his residence called The Mansion, on the grounds of the Pennsylvania Hospital. There they formulated some preliminary plans which were confirmed the following day when the group met at 10 o'clock in the morning at the Jones Hotel, which stood on Chestnut Street above 6th. At this Philadelphia hostelry the

official organization took place of the Association of Medical Superintendents of American Institutions for the Insane (a title which in 1892 was changed to the American Medico-Psychological Association, and in 1921 to the American Psychiatric Association).

On the evening of Oct. 20, 1844, the Association adjourned to meet in Washington, D. C. in May 1846. The members felt that their meeting had been a success. Dr. Samuel Woodward, who was elected the first president, wrote to Dr. Kirkbride :

... The time spent in Philadelphia was one of the most profitable and agreeable seasons that I have ever enjoyed. I trust much good will come from the convention and hope the ardour manifested at the meeting will not be suffered to cool so as to prevent full and able reports on all subjects assigned to committees.

And years later, in 1854, Ray wrote to Kirkbride :

As nature abhors a vacuum, so do I abhor that utter non-communication which frequently follows such a pleasant reunion of friends as we enjoyed last week, and so I indite you a letter, albeit not much prone at epistolary performance. Those bright sunshiny days which we pulled at your delightful place, and which received additional sunshine from the cordial hospitalities of yourself & family, will always be marked with white chalk in the calendar of my memory. Such pleasant episodes in the monotonous story of life, I love to dwell upon, and my heart yearns towards those whose kindness chiefly made them so. The museum, the donkey, the walks, the brook, the trees—will always be associated with the savour of a sweet remembrance, while the noble establishment itself, consecrated by so many glorious memories, justifies a little pride of country, and enlarges my reverence of the goodness yet in man. If our yearly conventions had accomplished nothing more than to make us acquainted with one another, and with other institutions beside our own, creating feelings of personal regard and mutual sympathy, I should think they had not been in vain.

RESTRAINTS

A few days after the Association adjourned (Oct. 30, 1844), the new secretary sent an abstract of the meeting to Dr. Amariah Brigham, State Lunatic Asylum,

Utica, N. Y. Dr. Brigham had sent a copy of the *American Journal of Insanity*, now the *American Journal of Psychiatry*, which he had just begun editing that year, to Dr. Kirkbride, and had received from him a note of thanks (July 12, 1844). Dr. Brigham became worried about the statement which the Association had adopted concerning restraints, as the following letter shows, which Dr. Kirkbride addressed to Luther Bell at the McLean Asylum.

November 13, 1844

My dear Sir,

You will probably recollect that just before the close of our convention, the following resolution was written by you, on behalf of the Committee on Restraint &c, and adopted by the Convention, viz., "Resolved that it is the unanimous sense of this convention, that the attempt to abandon entirely the use of all means of personal restraint is not sanctioned by the best interests of the Insane."

Upon looking at this resolution subsequently it appeared to me that the language was liable to criticism and might lead to unjust inferences as to the views of the convention. I copied it however and forwarded it with the proceedings for publication in Dr. Brigham's Journal as directed by the convention. I now find by a letter from Dr. Brigham which I have just received that he is particularly anxious either that this resolution should not be published or its phraseology altered—he is unwilling that we should at this day commit ourselves so decidedly on the subject and objects particularly to the word *attempt* inasmuch as we do always (he says) make the attempt to dispense with restraining apparatus, before we resort to its use; and that those who say they dispense with all restraint would ridicule the idea that we would not attempt to do what they really have accomplished.

As near as I can judge from Dr. Brigham's letters, he would prefer a resolution something like this, "that the entire rejection of every species of restraining apparatus, under all circumstances is not sanctioned by the best interests of the insane."

Of course I have no authority to make any alteration in the proceedings, and unless you as Chairman of that committee are willing to make some change, it would perhaps do better not to publish this resolution at all. I believe we agree entirely on the subject of restraint and I am confident you can word a resolution that would remove all cause for uneasiness.

Have the goodness to let me know your views on this matter at your earliest convenience.

Dr. Kirkbride dispatched a request to Dr. Brigham to hold publication of the statement until he had had a reply from Dr. Bell, who agreed to the wisdom of altering the wording.

During this same year, Dr. Kirkbride was interested in designing and improving his own restraining apparatus, as he reveals in a series of letters to Pliny Earle at the Bloomingdale Asylum.

July 15, 1844

Thy letter of the 24th I received a day or two since, and will have a dress made and sent to thy direction as requested. I shall send it with the necessary straps and buckles which are essential to its efficiency . . .

July 17, 1844

I today send a bundle containing one of our canvass dresses. I regret having been so long in obtaining it, but regular tailors do not like to sew the material and the one I send is not what I prefer. My directions are that they should be secured by small hard *twine* instead of thread, and a small belt to be sewed in at all the points where patients commonly begin to tear. The strap with the back buckles and the small padlock are necessary parts of the dress . . .

July 8th, 1844

It will give me pleasure to order for you the *bed apparatus* (I like that term better than "straps," commonly employed & to which I have a real aversion) but I am satisfied those heretofore made are unnecessarily large and strong, particularly for females and unless you are in a hurry will only order (one) just now as I hope to make some improvements in them, as soon as I can get a little leisure to tend to their construction.

August 9, 1845

I have had two lock buckles, with a key, made for (the bed apparatus) and put on the side straps, which completely prevents a patient from loosening himself, even with his hands unconfined. The cost is 1.25, so that the entire cost is 6.25.

Dr. Kirkbride seems to have filled an order for restraining apparatus which he shipped to Dr. Stribling:

April 22, 1844

With this note I send to Mr. McCanby as requested in your letter of some days since—

one of our bedsteads complete with a wrench for turning the screws by which the bottom is held firmly in its place—one "bed apparatus" which as you will readily observe may be changed in size by means of the straps passing under the broad piece of leather upon which the patient reposes—one "canvas dress" with lock buckle strap for the waist and a (?) strap and small padlock for the neck, both of which are to be covered so as to be entirely concealed from view, and one set "canvas sleeves," which are also to be secured, when in use, by the same kind of belt and neck straps, as the canvass dress just referred to.

He also supplied Stribling with information about the douche :

March 22, 1843

As respects our *douche*, it is simply a leaden pipe (about $\frac{3}{4}$ inch) connected to the main water pipe and either brought into the shower bath box, or else carried over one of the bathing tubs, the supply of water being regulated by a cock attached at such a point as may be convenient. I have such a repugnance to violent means and to seeing an insane man boxed up in any contrivance for restraints, that I have not thus far arranged anything by which I could use the douche as recommended by Lauset if the patient was powerful and obstinately opposed to its employment. There is occasionally a case in which some such contrivance would be desirable, but the number I believe is small.

Thus, Dr. Kirkbride had fairly well formulated his own ideas about restraining apparatus before the Association took up the question and issued a statement.

REPORTS FOR THE JOURNAL

The business of the Association was handled by committees appointed at the first meeting, and most members were diligent in the preparation and presentation of their reports. Brigham, as editor of the Journal, was eager that the Committee reports should be well done. In a letter to Kirkbride he wrote :

May 27, 1848

But I hope Reports for next time will be more complete, so as to form good *monographs* on the subjects they treat. We have been too negligent in this respect . . . To illustrate what I mean—take the subject assigned to Dr.

Benedict. Now his experience & opinion (tho to an extent valuable) are not all we want—but he should find out by all practical means the experience & opinions of others and what cases are proper & what not for dormitories & why ! &c.

In 1849 Brigham had decided on a different system :

I have written to some & shall to all of our associates that they had better select their own subject (provided they do not like the one I designate) for Reports but to be sure to present a written Report on something.

In 1851, the young, scholarly John Galt wrote from the Eastern Lunatic Asylum in Williamsburg, Va.

I regret to find that circumstances prevent me from going to Philadelphia during the present month. The President of our Association assigned me the duty of writing on "The Propriety of keeping the insane and persons affected with other diseases in the same establishment." Not being able to attend the meeting of the Association, I transmit through the mail the required essay.

Pliny Earle, a prolific writer, nevertheless balked at being required to produce his reports :

I have enclosed the Report . . . I heartily wish it "bon voyage," and hope it, or its like will never be found on my table again. For some three months it has been lying here, a *great bore*—like the Thames tunnel, almost, under the London bridge—under the bridge of my nose ; and I rejoice in being well rid of it, when you get hold of another such tough customer please to carve it yourself. My carving knife is dull, and I don't like to lay out my strength upon incorrigibles.

The first mention in the correspondence of the *American Journal of Insanity* is a letter from Kirkbride to Brigham, editor of the Journal.

July 12, 1844

I have to thank you for the 1st No. of the "American Journal of Insanity" which was duly received and to assure you that it will give me pleasure to contribute in any way in my power to promoting its prosperity. The greatest difficulty I see in your plan is the wish to give it at the same time a popular and a

professional character—a difficulty which I feel confident you can come as near removing as any one—and I shall be truly gratified to find you are entirely successful.

Brigham reminded Kirkbride in a letter dated Mar. 3, 1845:

Recollect that all my readers are not Drs. & I must cater for many tastes. I will try to make it better & better—as it is I am assured it has done good & is well rec'd many who have through it had their attention first called to insanity.

Brigham at times found the Journal a financial burden:

I have determined to go on with the Journal though I fear to some pecuniary loss. I wish as opportunity presents you would tell your folks to buy it. I think they will get their money worth—also I must beg something from you for the Journal—do do send me some scraps you must have left over after your Reports—cases or anything else from you will do good—an account of your Hospital would do good & I wish I could have the beautiful print of it to send out bound up with the April number . . . I send a good many to Europe & all our U. S. and I wish to make known so excellent an establishment as yours.

CASES AND TREATMENT

The letters were written in an era when case histories of patients were not maintained and very few descriptions of patients are contained in the correspondence. The only case history in the correspondence is presented by Dr. Awl in a letter to Dr. Kirkbride:

July 1, 1858

Returning from New Orleans, I find my friend and patient ——— has been sent to your care. I had so recommended and am happy to learn they have followed my suggestion. She seemed to grow melancholy in Oct. last, after the loss by death of a much loved child. Depression of spirits and ill health, with occasional slight amendments, have continued for most of the time since until shortly before starting for your city when there were indications of returning health, slight indeed but sufficient to give us encouragement. The change appeared to follow the use of citrate of (illegible) with alum, which brought a

return of the menses, improved the condition of the bowels, and lead to a better state of general health. The suicidal propensity is strong and the suicide may be considered as hereditary, but I have little doubt of your success. The change from home associations to your cheerful institution, with the proper moral treatment and restoratives, will I think accomplish everything desired. A sister of hers was under my care in the Ohio Lunatic Asylum similarly affected, who perfectly recovered, which gives us the more hope.

Her husband desires me to say it may be proper to examine her trunk and with some care, as she is strongly determined upon self-destruction. He also requested me to ask you to write him a line as soon as may be convenient.

Most of the emphasis in treatment, at least in this series of letters, was centered on providing the proper therapeutic environment, attendants and recreation for the patients. Only a few medications are mentioned in the letters.

Several interesting passages describe the facilities available at the time. Dr. Kirkbride expresses his views about the acreage needed for the care of the insane in a letter to Dr. Luther Bell.

June 3rd, 1844

I have today received your letter of the 30th inst, and in replying to the questions contained in it, I have no hesitation in saying, that it is hardly possible to overrate the importance of having a large amount of land connected with every Insane Hospital, not only for gardening and farming purposes, but to enable a numerous class of patients to have the full benefit of exercise in the open air, (to protect them) from the excitement attending their coming in contact with persons who are to be found rambling in the vicinity of every large city. Gardening and farming are available for nearly all classes, and in my opinion ample opportunities for this kind of employment should be provided by every institution no matter what class of patients may generally be received. The lowest estimate I have been in the habit of giving is half an acre for every patient in a hospital, and I am confident what with less than fifty acres, an institution like the McLean Asylum must labour under some disadvantages. Connected with this hospital we have one hundred and eleven acres, of which fifty-one are surrounded by a stone wall 10½ feet high around the pleasure grounds of the patients,

the remaining seventy are used for farming purposes and we should be sorry to part with a single acre of either.

Awl mentions the deer park at the Pennsylvania Hospital.

I have inquired of the gentleman owning the park of deer and he informs me that his whole stock degenerated in the same way yours is doing. He thinks it owing to the confinement to narrow bounds and the tame pasture. Says the sheep and goats do no injury. He was obliged to give up the whole park and now has not a single one left of a very large flock.

Stribling had a somewhat idealized recollection of the Pennsylvania Hospital, as he wrote to Dr. Kirkbride:

August 6, 1867

I often think of you and in imagination see you engrossed as ever in your specialty, and everything around you looking bright and prosperous—your buildings, commanding as to the exterior, inviting within—your grounds ample and beautifully arranged, your attendants competent and faithful—your board of managers confiding and liberal.

The cost of treatment in the Pennsylvania Hospital is mentioned in a letter from Awl to Kirkbride, when he referred a patient on Dec. 4, 1849.

It is an institution exclusively for paying patients with fine accommodations varying in price from four dollars as high as friends choose to pay.

Brigham described the milieu of the Utica Asylum.

March 3, 1845

We have done and are doing much with our schools and have had a very pleasant winter with frequent exhibitions at which we have been singing, acting pieces, declamation &c. I have had hymns printed on cards to hold in the hand and thus have got more than half our household to sing after a fashion & to their satisfaction & enjoyment.

Earle was pleased with a new facility at Bloomingdale Asylum.

Dec. 9, 1848

During the past month we have been building a new Bowling Alley in the men's yard.

The edifice is 70 ft long and 14 wide, enclosed, wainscoted & windowed. It gives ample room for an Alley and a shuffleboard . . . I am happy to hear you are building a museum. Your institution will be a *bifors* for the Insane before long, not to say that it is not now.

Later, Earle was proud of his establishment at the Northampton Lunatic Hospital in Northampton, Mass.

Oct. 16, 1865

Our official year closed on the 30th Sept. and had been a successful one—for the latitude and longitude; far more successful than I feared at its beginning. We more than paid our expenses, and received more from pay-patients—or rather, *earned* more by them than in any earlier year of the hospital. We have made many improvements in details; which contribute largely to the good and quiet working of the hospital, and are now in a condition in which, if not comparable with you, we are, at least, not to be "sneezed at." So don't sneeze at us. And if Northampton has ever been a "bye-word" among you "crazy doctors," let it be so no longer.

The founders, then, were proud of their institutions and their care of the insane, as shown in a remark by Awl.

Dec. 4th, 1849

Travelling . . . may do good, but is neither as cheap or reliable as treatment in a well conducted asylum.

Epileptics were often included in the insane hospitals, and the most complete medical regimen described in the letters is provided by Dr. Woodward who answered a question about treatment of epilepsy which Dr. Kirkbride addressed to him soon after the initial meeting of the Association.

Nov. 21, 1844

I am glad that you have written to me on the subject of Epilepsy. As it seems I was misunderstood if the impression was received that I have cured three hundred cases. That is too large a number I have no doubt, although I am unable to say how many. I believe I said that I thought I cured one-third of the cases that I treated if not complicated with insanity, palsy, or other organic disease. I generally use the Nitrate of Silver in pills in combination with narcotic . . . You may recollect when in

Philadelphia the question was asked me what I thought of Iodine as a preventive of the *blue skin*. I replied that I had no confidence in it as I had used silver freely in probably one to two thousand cases & had never seen but two cases of blue skin. I did not mean to be understood so many cases of Epilepsy as I use the remedy freely combined with morphine in diseases of the heart, uterus, and intestines . . . I prescribe these remedies with some hope even when Epilepsy is complicated with Insanity.

ATTENDANTS

Dr. Kirkbride was always interested in the calibre of attendants chosen to care for the insane, as shown by the fact that he was made chairman of that committee at the original Association meeting. Apparently some of the attendants at the Pennsylvania Hospital were procured by Pliny Earle who wrote on July 24, 1846 :

Thine of the 20th is at hand. I sent the two applications to thee, not knowing whether thee wanted any more attendants at present and supposing that if thee did want more, thee would communicate with the applicants. Below is a copy of my advertisement in the Worcester.

YOUNG MEN

Wanted, as attendants on the Insane, at the Bloomingdale Asylum, New York, and the Pennsylvania Hospital for the Insane, Philadelphia.

SIX YOUNG MEN

active, intelligent, not addicted to the use of tobacco or alcoholic drinks, and possessing that essential element of the power of exercising good government over others—*the power of governing themselves*.

Such as have taught schools, and can bring good testimonials of their success in that business will have preference.

Applications, for both institutions, to be made by letter, and addressed to Pliny Earle, Physician to the Bloomingdale Asylum, New York.

I like the plan hinted at in thy letter requiring from applicants the loan of their shadows by which to judge of them.

"Poor Tom, who had a house to sell
Did round the country go ;
And that he might its virtues tell
He took a brick to show."

Isaac Ray, who later wrote a small handbook describing the proper character of attendants and other personnel at hospitals, also expressed his views in two letters :

19 May '58

The Crocker you speak of was an attendant here some 8 years ago, then fresh from the country, young & unsophisticated. He was intelligent, prompt & gentlemanly, but rather quick-tempered. He never handled a patient roughly, but occasionally spoke sharply, and, if I am not mistaken he was not always on good terms with other attendants. Still, he staid here as long as he cared to, & since then he has been in California, Minnesota, & the Lord knows where else—a sort of experience not calculated to improve him as an attendant. The fault I should most apprehend in him now, is, that he would be likely to know too much for an attendant, & not enough for a supervisor.

11 Aug '62

I have just addressed a letter to the Secretary of War in which, for reasons too obvious to you to need mentioning, I suggested to him the propriety of exempting from the recently ordered draft, attendants in hospitals for the insane. There seems to be in this matter of exemption, some division if not conflict of authority, between the state and the U. S. Without understanding it or inquiring into it, I concluded that it might do good & could do no harm, to address Mr. Stanton, and my object in writing you now is to suggest that you also address him to the same effect. A letter from you would have more influence with him, no doubt, than one from me of anyone else.

The wages of attendants were, incidentally, mentioned by Kirkbride in a letter to Bell.

Sept 14, 1844

. . . At present we are paying \$10 for male attendants and \$8 per month for female attendants—a sum that I consider too small to remunerate the proper kind of persons for the responsible duties they are called upon to perform . . .

KIRKBRIDE ON CONSTRUCTION

Because his interest in the field of psychiatry was construction of hospitals for the insane, much of the correspondence deals with design and building of a mental hospital.

tal, and Dr. Kirkbride set forth in these letters many of his ideas in the greatest detail. He desired that a hospital should have not only a pleasing exterior, but also the benefit of the latest developments in engineering. In this correspondence he showed particular interest in a system of forced ventilation, either by steam or hot air, in order to provide fresh heated air and to remove foul air.

Most of the founders addressed questions to Kirkbride about all aspects of hospital construction including: hot water heating, steam heat apparatus, a laundry drying system, pressing machines, manufacture of laundry soap, ornamental wrought iron window screens, doors and panelling, dormitories, verandahs, chapels. Ayl dis- cussed his plan for a new state hospital in Ohio, while Stribling consulted him in 1859 about a new hospital west of the Alleghenies. Kirkbride complied with all their requests and supplied advice on all aspects of construction and organization in the minutest detail. He even purchased and shipped materials for them, including bed spreads, magic lanterns, tivolì boards.

In 1853, the erudite Galt wrote to ask his opinion:

Sept 5th, 1853

Being engaged in writing an article relative to the propriety of treating the insane of each sex in the same or separate institutions, I have determined to seek the aid of your clear judgment, ability & great experience in the management of the insane.

Isaac Ray reported to Kirkbride his feelings about verandahs.

Jan'y /47

Accept my thanks for yr pamphlet on Construction of Insane Hospitals. I wish that every one who has had equal opportunities to form opinions on this subject which I regard as second in importance to no other connected with the care of the insane, would *publish* them & be willing to assume the responsibility of them. This is the only way in which any advance can be made, & this result is no less certain, though it may show considerable diversity of views. I see nothing of much importance in yr views from which I should dissent, except yr approbation of verandahs, as Dr. Woodward styles them. Of all contri-

vances connected with hospitals, none has appeared to me so utterly objectionable as these—cages, I call them. You may think I am unreasonably prejudiced, but I have some foundation for my views, I have been disgusted & sickened by the sight of the patients at Worcester, from the road, climbing up the bars, & making indecent gestures to the passers by.

Kirkbride, in his beautifully designed hospital where patients had single rooms, gave his opinion about dormitories or wards in a letter to Brigham:

... On the subject of associated dormitories it appears very evident to me that our friends in Great Britain are passing from one extreme to another, from having all single rooms to having nearly all collected in large dormitories. Since reading Dr. B's [Bell's] article, I have been looking very carefully over my own patients and think that one-third might thus be accommodated *without any disadvantage*, and about *one-eighth or one-tenth*, with some advantage. These last are a certain class of suicidal patients and some timid individuals, generally females, who have a dread of being alone at night. Our patients tend to be generally of a class who express the same feelings in regard to have a chamber of their own in the hospital, as they would if living at a hotel or ordinary boarding house.

Associated dormitories are not novelties in this section of the country. During my residence in the Penna Hospital in the city of Philada many years since, I had opportunity of observing them pretty extensively. For 20 years it was the custom to have at least one-fourth of the whole number they lodged, and the practice was continued until the patients were removed to this institution. The number in a room varied from 4 to 12 or 14. The experience there went so far as I can learn, to prove conclusively that for many patients there was no *danger* but at the same time so little advantage, that in constructing the new hospital all patients (except those with a special attendant) were provided with single chambers. The patients in the old hospital—the men at least, who lodged in associated dormitories had the "largest liberty" for insane men that I recollect to have heard of. They had no attendant with them, and for many years the doors leading from their apartment into the open air were never fastened. Those who became tired of being in bed during hot nights could get up, take a promenade in one

of the yards and return to enjoy a tranquil nap. One individual when unable to sleep, was often known to go down to the woodpile, and during a moonlight night saw more than a quarter of a cord of wood before retiring to bed (not a bad anodyne after all). And one gentleman of small stature but wonderfully powerful voice who still makes himself heard in this neighborhood when he had a vision of some fancied insult, would hastily dress, hurry down to the yard and after a few minutes of loud talk & violent gesticulations, quickly return to his bed without disturbing the slumber of his sound sleeping neighbors. The regular watchman of the institution was the only guardian of these patients for several years, and with all this . . . want of proper care, I do not recollect having heard of any unpleasant occurrence.

JURISPRUDENCE OF INSANITY

All of the superintendents had to contend with the ill-defined status of commitments, the legal rights of the insane, and the problems of insane prisoners. Earle was able to joke with Kirkbride about the situation in July 1865:

My dear "Mr. Chinklinde" alias "Dr. Kilpatrick"

Are you yourself or are you not? A friend sent me yesterday the April No of the "New York Social Science Review," which contains a discussion in a society evidently composed almost exclusively of foreigners, of the subject of Insanity. It is about the shallowest thing I ever did see.

One speaker says, "In Philada, where a large asylum of such a nature (private) is kept by a certain Dr. Kilpatrick, everything depends upon the Doctor's honesty. He may bury an innocent person alive if he chooses." Hem!

Many of the superintendents were called upon for their opinions in legislation for the insane, as Awl mentions:

June 19, 1846

I have also to review the laws of the state in relation to the subject of insanity. I got into this last scrape by recommending the subject to the consideration of the Legislature, which honorable body very good naturedly took it into their heads to think one good turn deserving of another and immediately conferred the duty on myself. It must therefore be done, though I have neither skill nor desire for drafting laws.

Oct 25, 1849

I hardly know how I am to get through & prepare for the Legislature, who I am sorry to say it is to be feared, will be about as pretty a set of Blackguards as Ohio produced last winter.

Kirkbride was aware of Awl's experience and recommended him to the governor of New Jersey:

Jan'y 18th, 1847

I have just had a visit from Governor Stratton of New Jersey and he is very anxious to avail himself of your labors in the revision of the Statutes of Ohio relative to Insanity &c.—and he desired me to write to you and to request as a special favor to him and to myself, that you would forward a copy of your devised law on the subject of the Hospital &c. provided the same is in print, as soon as you can after receipt of this . . . I had already told him your knowledge and experience and on the subject of State Hospitals would be peculiarly valuable to them, and on that account they would like not to act till they know what your legislature has done.

Isaac Ray, who published his *Jurisprudence of Insanity* in 1838, was recognized as the leader on the subject, but did not discuss legal matters at any length in his correspondence with Kirkbride.

THEORY

It is interesting to note that any speculation or theory in regard to mental functioning is absent from these letters and is mentioned only in an oblique way by Pliny Earle:

Aug 4, 1858

You know that Dr. Carpenter says that when we try to think of a thing and can't, the brain takes up the matter into *automatic* keeping, rummages and ransacks all its rusty, musty, and cob-webbed corners, and after thus working, unconsciously to ourselves, if it happens to find the said thing, it at once pops it out upon our recollection, while we are thinking, perhaps, of something as foreign as possible to it.

PUBLIC CASE OF IDIOTS

A letter from William M. Awl to Kirkbride makes a definite statement concerning the origin of public care for the mentally retarded:

Nov. 10th, 1857

My dear Friend Kirkbride

Breaking a long Silence, I invite your kind attention to the following facts & circumstances of which, I think, you cannot fail to have clear recollection, and which will be, I trust, of sufficient interest to receive from your hand a suitable corroboration and statement in reply at your earliest convenience.

We have an institution for Idiots in Ohio of which Dr. Patterson late of the Indiana Hospital for the insane is the Superintendent. He and his board of Trustees are about preparing their Annual Report, and the Doctor this evening came into my office with the request that I would furnish him with any facts that I might have in relation to the origin or first movement of a public nature that I had known to occur on the subject in the U. S. This he doubtless was induced to do in as much as I had previously mentioned that this action originated in the Association of Med. Superintendents, and that I myself was confident of it because I had there brought it forward.

Other parties it seems have been claiming the honor (if this discharging an impulse of duty may be so called) and on this account he thought it best to have the facts clearly stated to vindicate of course the truth of history. I accordingly drew up for him the following. "That the first public action on this interesting scheme of benevolence in the United States (in my opinion) was in the City of Philadelphia, Pa. during the month October 1844, and before the first meeting of the Association of Medical Superintendents of American Institutions for the Insane, of which Dr. Woodward of Mass. was the President and Dr. Kirkbride of Pa. the Secretary. That the importance and need of Asylums for the care in instruction of idiots in our country was at that meeting brought to the immediate notice of the Association by myself in a few introductory remarks. That I was followed by other members who also spoke upon the matter; and that a committee consisting of Drs. Brigham, Awl, & White was appointed, who at a subsequent session, held in the City of Washington in May 1846, made an able report thereon, to the same body. Doctor Brigham having been by my special request appointed chairman of the committee instead of myself."

These facts in this detail it is true do not appear in the proceedings of the Association as published in the Journal of Insanity. But the fact that there was such committee does, also that they made such a report through their

chairman the late Dr. Brigham. And of the whole of which proceedings, as stated, I now have as clear a recollection as if it all occurred but last week. I could not help knowing it vividly & perfectly, for I made a note of the subject as a proper one to claim our united attention before leaving home. I can yet recall almost the language I there used and I distinctly recollect another circumstance connected with the occasion . . . *The first public movement on the subject of institutions for the idiots in our country took place in neither Boston nor N. Y. but in your own good city of Phila. and before the first meeting of our association as I herein have stated it . . .*

INTRODUCTIONS : DOROTHEA DIX

Several of the founders sent letters of introduction to Dr. Kirkbride, introducing legislators, doctors, and others interested in insanity, asking Dr. Kirkbride to talk with them and show them his hospital. All three letters from Stedman in this collection are letters of introduction. Stribling introduced a doctor from California in 1853. Bell introduced Dorothea Dix, who was just beginning her campaigns on behalf of the insane. The association between Miss Dix and Dr. Kirkbride continued for many years on a basis of mutual admiration. However, in 1845 Kirkbride wrote to Bell :

During my stay in Boston our friend Mr. Dwight mentioned to me that it was publicly stated in the streets, that Miss Dix, had procured the pardon of twenty-seven insane convicts from the Eastern Penitentiary during the past year. I had no hesitation in saying that the statement was incorrect. Since my return I have made particular enquiries on the subject. I find on investigation that Miss Dix did solicit the pardon of *one* man from Montgomery County who was notoriously insane at the time of his conviction, and that one other insane man at the time of his conviction was pardoned by Govn. Porter during the past year. These are the only two cases of insane convicts pardoned during the past year. I am also authorized to say that it has never been the custom to pardon a convict on account of sickness or insanity, and that such occurrences have been exceedingly rare at any time.

I mention these facts that should you hear, as you probably will, the same statement, you may be able to state what are really the circumstances of the case.

Others of the founders knew Miss Dix and her work. Brigham wrote :

Mar 3, 1845

I see Miss Dix has been over your state & *memorialized* your legislature. I hope good will result from it & trust that her experience in this state may make her more courteous in observing & publishing. In this state I am afraid she did hurt by *coloring* & by not accurately observing. She was often mistaken & this has thrown a doubt over all her statements with many.

Stribling, in Virginia, had praise for her plans to use government land for hospitals, but thought that a States Rights attitude might prevent southerners from using her idea :

Sept 23, 1850

I was pleased to see that the Assn so cordially endorsed Miss Dix's national scheme. I sincerely trust that her praiseworthy perseverance may be fully rewarded.

Aug 21, 1852

We have just had a visit from Miss Dix which we prized much—only regretted she could stay with us so short a time. Her 10,000,000 bill you see has passed the Ho. of Representatives—it will I trust certainly pass the Senate. It is, however exceedingly doubtful whether it will at all benefit the Institutions in Va. as our state rights politicians oppose such disposition of the public lands—our legislature may & probably will reject the donation.

One of the secretary's duties was to write introductions for representatives of the Association to attend meetings in England. Doctor Kirkbride's file contains the following "Letter of Authorization for Bell to represent the Association at meeting in Great Britain."

At the meeting of "the Association of Medical Superintendents of American Institutions for the Insane," held in Philadelphia on the 16th day of October 1844, it was *resolved*

"That any member or members of this association who may be in Europe at the time for the meeting of the Convention of Physicians to the Institutions for the Insane in Great Britain, be authorized to represent this body at that meeting, and

that the President and Secretary furnish the proper credentials."

In pursuance of the authority granted by the above recited resolution, and by request of Saml. B. Woodward M.D., President of the Association, I hereby certify that Luther V. Bell, Superintendent and physician to the McLean Asylum for the Insane near Boston, Massachusetts, is hereby appointed a delegate from the said Association of Medical Superintendents of American Institutions for the Insane, to attend the next meeting of the convention of the Physicians to the Institutions for the Insane in Great Britain.

Kirkbride took advantage of Bell's trip to Europe to request information for himself :

December 11th, 1844

... I was certainly surprised to learn that you were to be our representative to the British Association, but can assure you that no one would have been more likely to have been selected, had the Association had the privilege of selecting from the whole body. I hope the trip will prove pleasant to you, and of benefit to your own health, as it can not fail to be advantageous to the institution, for which you undertake the voyage. You are so completely familiar with all the matters that interest us in common, that I know not how any suggestions of my own can enable you to add to the usefulness of your undertaking. I would just remind you however that you are the Chairman of the Committee on Restraints and Restraining Apparatus and that I am particularly anxious to know the true state of the "non-restraining" hospitals and the precise means they employ in certain cases that will suggest themselves to you. I should also like to know the precise character of their "padded rooms" and whether they can be kept perfectly sweet and the fixtures entire when patients are not only very violent but very filthy in their habits. You will get all the novelties in the mode of construction, ventilation, &c. You must keep a register of all you see and hear . . . that is worth remembering, for the benefit of the rest of us who have to remain at home.

Any new plans of hospitals—engravings of them or designs for the hospitals for the Insane, I wish you would do me the favor to secure for the library of this institution.

I should be glad if you would visit the new penitentiary near London, on the separate system and write me your impressions of the establishment and how it is working . . .

DIFFICULTIES : FIRE AND PLAGUE

Management of a hospital in the 19th century presented other difficulties to the founders than just patient care, as recorded by Awl :

Jany 23, 1847

I am just recovering from a horrible alarm of fire in our building—another example of the practicability of setting wood on fire by means of heated air. Nobody injured—very little damage done, but every one, including your humble servant, awfully frightened.

Mar 20, 1849

... Provided always the cholera is not about in some of the big cities. And by the by what do you think about this awful disease? How dreadful to have it break out in an institution! May God in his merciful Providence spare the Hospitals for the insane one & all. And may he prepare you & I and our Fellow Associates in the care of the insane, with strength of mind and body for whatever trials may await us.

July 7, 1849

With the cholera prevailing nearby in the city and state prison, and with the alarm that is causing attendant after attendant to leave his post, you cannot imagine how timely and welcome has been your very kind letter . . .

Aug 2, 1849

As yet we enjoy health in the Asylum and cannot be too grateful while the pestilence has been raging, as it were, around us. At this time there is a sizable decline in the city nearby & in most directions, especially West & South. The epidemic apparently passing over the Continent from the Southwest to the Northeast. In the Ohio Penitentiary within sight of our building it has been unusually severe & fatal & at Lexington in the Asylum very bad. How good & merciful our Heavenly Father in allowing us frail & sinful worms to escape whilst thousands of good & better are called to drink the bitter cup. And how should we pray that a Knowledge of this goodness may lead us to repentance whilst we exercise faith in the Lord Jesus Christ.

THE CIVIL WAR

In spite of the fact that the correspondence continued through the years of the Civil War, there are only two references to the war in these letters.

In May 9, 1861, Isaac Ray wrote to Dr. Kirkbride :

The truth is there is only one idea afloat in the public mind, and nothing else is cared for. Two of our Trustees have gone to the wars, and others are drilling. I don't intend going myself, but my son would go if he could persuade me that he could be more useful to his country there than here.

In Feb. 13, 1865, Pliny Earle wrote :

It seems that "Uncle Abe" can't settle his difficulties Quaker fashion. Well! Out of the whirlwind cometh the calm, and time will show which party shall reap most of the whirlwind.

PERSONAL NOTES

Among the solicitations and remarks about one another's general health, there are two interesting matters. First, Awl seems to have passed through a period of depressive ruminations about his condition :

May 27, 1847

The truth is I have been low-spirited, in feeble health and hardly able to get through with duty for some weeks . . . I once thought that if I ever should go crazy (and some folks I suppose think I should not have far to go) it would be my desire to go to Worcester. But I believe now I should as soon they sent me to Philadelphia as any place else in the world.—Provided always you remain superintendent—otherwise I do not go crazy at all . . . Such constant application of the mind as we are obliged to give our respective institutions is enough to wear the brains and body both out.

Aug 30, 1847

I am sensible of an uncommon weakness and a state of nervousness which at times makes me uneasy with a dread that something worse may be coming—what I don't know, unless it be palsy or something worse.

The second interesting item concerning the founders' health refers to the shooting (1) of Dr. Kirkbride by an apparently paranoid patient. Dr. Awl writes to Dr. Kirkbride :

Oct 25, 1849

I am in receipt of your very acceptable favor of the 19th inst and hasten to offer my congratulations for your truly Providential escape. The newspapers had furnished an account of the shooting but that only served to render us anxious and uneasy for your safety, thinking you had perhaps sustained

greater injury than was known to the public. But now the truth is known we are greatly relieved and thankful. The scoundrel deserving punishment of some kind—certainly to be restrained of his liberty and propensity to do evil. He belongs to a troublesome and mischievous class who are part mad, part knave, and rather more than two-thirds down right old-fashionedly wicked in heart and head. We too have had such and it is some doubtful if an Insane Hospital is exactly the right place for them. I hope the laws of your commonwealth will at least see that he gives you no further trouble.

Stribling wrote from Virginia concerning the incident :

Sept 23, 1850

Have you recovered entirely from the effects of your shot? Your escape must have been Providential! You & myself have I believe come nearer falling martyrs in the cause than any of our contemporaries—unless indeed poor Brigham may have fallen a victim to his zealous self-denying labors.

Thus, the correspondence covered the range of problems which confronted a 19th century American psychiatrist. In discussing all of these matters, the personal regard of one founder for another is always evident. For example, Awl says of Woodward :

June 6, 1848

Our friend Dr. Woodward I found in the enjoyment of his fame and every domestic comfort this life can afford. He attends to the practice of his profession rationally in a state of literacy, so as to make it both profitable and pleasant, a little more perhaps of the former than of the latter. I say pleasant because he does not ride nights nor much in bad weather, and much of his time is devoted to consultations. My time with him was spent very pleasantly & profitably and I still regard him as a great & good man. He appears to live a life of industry in order to be useful & having exhibited the evidence of righteousness by faith in a gloriously exalted Redeemer, his evening will doubtless descend without intervention of a cloud. Honorable & useful, it will be hard to find a more delightful man than our mutual friend Samuel B. Woodward.

In two letters, Earle compares Kirkbride to Confucius in his wisdom, who he felt would have made a good superintendent of

a mental hospital. Earle did not have such a high opinion of some other physicians and wittily wrote to Dr. Kirkbride on Nov. 9, 1857 :

If your corps of professors is not so large as that of other colleges, there is still a compensatory advantage for you in the fact that you will not make so many M.D.'s (Muddle-headed Dolts) as they do; and I trust that your graduates will not make such pretensions to universal knowledge as some of us M.D.'s do.

The founders occasionally gossiped about one another. Earle wrote to Kirkbride :

Feb 13th, 1865

As President of the Assn of Superintendents, thee asks me if I am married. As a correspondent of *The Am. Jour. of the Med. Sciences*, I answer: No. If the question had been put, and answered, in the personal *capacity* of each of us, the answer would have been the same.

Ray wrote about the Quaker Earle :

20 June 51

I can tell you nothing new in our line, unless it may be that poor Earle has been unsuccessful in his wooing; or rather, though he apparently succeeded, yet his success did not continue. There is talk about a mustachioed fellow in regimentals having eclipsed the Dr. in the eyes of his ladye love, but that of course must be scandal. I fear however she is not a docile follower of Wm Penn.

In the entire correspondence, there is only one example of heated tempers, when Brigham apparently felt that Kirkbride had not supplied him with material for the journal concerning the erection of the New Jersey hospital. Kirkbride replied (Jan'y 10th, 1846), "I may candidly say that there was something about your previous letter I did not exactly like." In his next letter on Jan'y 29, 1847, Kirkbride was sarcastic throughout and finished by saying,

As to the "cutting up," I have been too much of a surgeon in my day to object to cutting up or down if the case is properly selected and the operation done in good style. I know that even if it is disagreeable it may be useful and if I am to be cut up I would as leave have you do it as anybody else.

Two of the founders were apparently interested in poetry. Earle included a short verse in one letter, while Awl wrote to Dr. Kirkbride on Dec 5, 1857 :

As Cutter said, "I am out of the crazy business." An Editor now & then comes at me for something nevertheless, and when in the mood I occasionally for amusement comply—sometimes in prose and then again in verse as the fit may take me, keeping it very quiet to enjoy alone. Here is a small sample, which, as it is on a more stirring subject, you may hand to one of your city Editors to copy if you like, concealing of course my name. Some out here think it a hit—at the right point and at the right time, these very important essentials in popular composition. But of this you will judge. Let me hear from you & if the verses are printed send me a copy of the paper.

CONCLUSION

One hundred and ten letters from the founders of the American Psychiatric Association to its first secretary, and forty letters from Dr. Thomas S. Kirkbride to the founders, have been reviewed. The letters, dated from 1843 to 1865, cover the founding and early years of the Association and reveal the character of the "Original Thirteen" as well as their concerns and struggles. Probably the only founder who would have supposed that this correspondence would be preserved was Pliny Earle, who with his usual wit, wrote to Dr. Kirkbride :

August 9, 1862

N.B. Please preserve all my letters as models of philosophic, didactic, and aesthetic writing.

APPENDIX

FOUNDERS

Awl, William M. (1799-1876), Ohio State

Hospital, Columbus, Ohio ; 23 letters.

Bell, Luther, V. (1806-1862), McLean Hospital, Mass. ; 8 letters.

Brigham, Amariah (1798-1849), Hartford Retreat ; Utica State Hospital ; 8 letters. First editor of the *American Journal of Insanity*.

Butler, Joh. S. (1803-1890), Boston State Hospital ; Hartford Retreat ; 6 letters.

Cutter, Nehemiah (1787-1859), Pepperell Private Asylum, Mass. ; 1 letter.

ADOLF MEYER ON AMERICAN PSYCHIATRY IN 1895

GERALD N. GROB, Ph.D.¹

"You are on the dividing year of your first century of life," S. Weir Mitchell told a convention of superintendents of American hospitals for the insane in a famous address in 1894.

You look back with just pride as alienists on the merciful changes made for the better in the management of the chronic insane. It is to be feared that you also have cause to recall the fact that as compared with the splendid advance in surgery, in the medicine of the eye and the steady approach to precision all along our ardent line, the alienist has won in proportion little. This is partly due to the nature of the maladies with which you have to deal; but there are many other causes at work to retard the wholesome progress. Just that which is impairing the usefulness of the lesser specialties in medicine has been more gravely enfeebling your value, and retarding your development. I mean the tendency of isolation from the mass of the active profession.

Accusing his listeners of complacency, he lectured them harshly about their many shortcomings—a lack of interest in research, haphazard management of their institutions, the disinclination to train and utilize qualified medical personnel, and a lackadaisical attitude in general. Mitchell confessed that some of the problems facing the superintendents arose from factors beyond their control, but stressed that as a group they had to bear a large measure of responsibility for the existing state of affairs(1).

Mitchell's speech aroused much antagonism(2). It did so precisely because it told the truth. Mental hospitals in America had deteriorated considerably during the last third of the 19th century. Compared to other advancements in the medical field, treatment of the mentally ill had made little progress. Psychiatrists had become increasingly narrow and specialized and were growing more isolated from both the medi-

cal profession and the recent work in psychology that touched upon their specialty.

The stagnant situation of the 1880's and 1890's stood in sharp contrast to the progress made in the period preceding the Civil War. During the early 19th century, as a result of the liberalizing influence of Enlightenment thought and the general current of humanitarian reform, a significant beginning had been made in establishing a comprehensive hospital system based on rational therapeutic principles and open to all regardless of social or economic class. The dominant therapy of that time—moral treatment—reflected the hopeful and optimistic approach of those physicians and laymen who were concerned with the insane. Taking their cue from the pioneering work of Pinel and his contemporaries, American psychiatrists developed a therapy that emphasized kind, individualized care within a small hospital, occupational therapy, religious exercises, amusements, and games. The use of devices for mechanical restraint were partially repudiated as part of the treatment. Instead heavy emphasis was placed upon a healthy psychological environment for both the individual and group. So much enthusiasm and vitality went into these efforts to better the care of the insane and to develop a successful therapy that significant results were achieved(3).

Developments in American psychiatry after the middle of the 19th century, however, failed to meet the expectations of these early reformers. There were a number of causes for this failure. In the first place, the patient population resident in the many public institutions founded for the care of the insane continued to rise with each passing year. The natural increase in population, swollen by large numbers of immigrants, resulted in a proportionate rise in the insane. As a result, the efficacy of moral therapy, which was based in part upon individualized care, was sharply impaired. Many state hospitals, therefore, were transformed slowly from curative into custodial institutions.

¹ Dept. of History, Clark University, Worcester, Mass.

This investigation was supported by a research grant (M-3190) from the N.I.M.H., U. S. Public Health Service.

Secondly, as hospitals became places of confinement, they tended to become isolated from outside influences. Although a spirit of research and experimentation was a major characteristic of 19th century science, few American mental hospitals by the 1880's had anything that resembled even remotely a well-organized and integrated research program(4). Partially because of the problems arising from the ever-growing inmate population, many hospital superintendents fostered a narrow specialization that made them administrators who were untouched by many of the dominant intellectual and scientific currents of their own day.

Finally, the pessimistic direction that psychiatric thought took reversed the earlier optimistic attitudes. In the preceding half-century an important beginning had been made in accumulating knowledge concerning mental illness and developing an effective therapy. Pinel, for example, influenced by the French ideologist school (which argued that in science theory had to be based on the gathering and analysis of sufficient data), broke with the speculative philosophies previously characteristic of psychiatric thinking and insisted that all knowledge about insanity would have to come from extended observation of the external characteristics of insanity(5). Far more important than the nosological system that he formulated from extensive observations, however, was his introduction of a psychologically-oriented therapy predicated on the assumption that insanity was a curable disease. As a result of the work of Pinel and his followers, a spirit of hope and enthusiasm entered institutional psychiatry, which underwent a drastic transformation.

During the second half of the 19th century, however, the materialism that accompanied the development of science had a decisive impact on psychiatry. Medicine in general entered a period marked by an emphasis on a structural pathology. In psychiatry in particular the search for a physical or somatic basis for insanity resulted in a lessened interest in psychological phenomena. Psychiatrists tended more and more to disregard the psychogenic aspects of mental illness and to emphasize its somatic etiology. The theory of degen-

eration, for example, which coincided with the idea of evolution, was symbolic of the disillusionment with the older moral therapy. Similarly, the prevailing somaticism, reflected in the work of Wilhelm Griesinger as well as in the rise of neurology as an integral part of medical science, contributed materially to the loss in confidence in the ability to deal effectively with mental illness with a therapy that was psychological in nature. After all, if the basis of insanity was physical, of what use would be a psychological therapy? Thus the emphasis on a somatic etiology led to a form of therapeutic nihilism, for until it was possible to correlate lesions with abnormal behavior, no therapy—physical or otherwise—would be possible. One result of materialism between 1850 and 1890, therefore, was a lessened confidence in the ability of the physician to influence the course of mental illness.

American psychiatrists in particular were affected by the prevailing somaticism. Because their contacts with mental illness had usually occurred within the confines of an institution where patients whose prognosis was anything but hopeful (partially a result of the retrogressing impact of the internal environment of the hospital) had tended to accumulate, they were highly receptive to a physical interpretation of insanity. More and more a spirit of pessimism characterized institutional psychiatry in the United States. As Dr. John B. Chapin, superintendent of the Willard Asylum in New York and one of the leaders of American psychiatry, put it in 1877: "The majority of the insane are not likely to, and, as a matter of fact, do not recover. . . . In the judgment of the medical profession, further advance in our knowledge of the pathology of structural changes is best assured in the revelations which the microscope will furnish(6)." Especially representative of the loss of confidence was the work of Pliny Earle, whose book *The Curability of Insanity: A Series of Studies* (1887) was a bitter attack on the optimistic claims of his predecessors.

By the end of the 19th century, however, the impact of new forces—intellectual, social, economic—was being felt. In the intellectual sphere, for example, one of the

products of Darwinian thinking was the rise of an environmentalist ideology that sought to reform American society in order to eliminate or at least mitigate some of its glaring defects. The older deterministic outlook, exemplified in the philosophy of Herbert Spencer and William Graham Sumner, came increasingly under direct attack by various individuals who constituted the nucleus of the progressive movement of the late 19th and early 20th century. Basically the progressive outlook was characterized by an optimistic moralism and a belief that the individual could be changed by altering his social environment. Operating at many different levels in society and in many different fields, progressive reformers began to apply their ideas to develop programs of social control and reform(7).

Psychiatry too was affected by the intellectual and social ferment of this period. Increasingly the older pessimistic somaticism came under criticism as psychiatrists, influenced by environmentalist ideas, thus sought to modify their own discipline. Dissatisfied with merely performing post-mortem examinations of demented brains or expounding rules for the confinement of insane persons whose prognosis was largely negative, psychiatrists slowly but surely began to re-examine some of their traditional assumptions about man and the nature of mental disease. Initially a body of critical thought was enunciated by physicians who were not associated with state mental hospitals, as well as humanitarian reformers and social workers eager to introduce much needed changes into mental hospitals. The strength of the ideal of scientific research at the end of the 19th century, moreover, was such that there was a concerted effort in the United States to loosen psychiatry from its administrative foundations and bring it back into medicine. Newer developments in psychiatric theory were also in the process of shaking many time-honored ideas. The relative failure of the physical approach reopened interest in the psychological. In France, for example, a considerable body of work had been done on the neuroses. In Vienna Freud was embarking on a career that would virtually revolutionize older ways of thinking about

human behavior. Even Kraepelin's monumental work, despite certain pessimistic overtones, contributed to the ferment by taking psychiatry out of the dissecting laboratory and into the clinic of living patients. One result of all of these developments was a renewed interest in the efficacy of psychotherapy. Psychiatrists began to recognize once again the medical value of a constructive intellectual and emotional environment(8).

It was in such an atmosphere that Adolf Meyer began a career that would reserve for him a dominant place in the history of American psychiatry. Diverging partially from the dominant somatic school, Meyer began studying the totality of the individual's personality as well as his environment. Conceiving of mental illness as a maladjustment of the whole personality, he labored to break the hold of Kraepelinian nosology and to incorporate some of the findings of psychology and psychoanalysis into psychiatry. Although Meyer's "psychobiology"—as he called his system—was of an eclectic nature, it harmonized very well with the intellectual, social, and economic forces that were working for reform in American society. Influenced by the belief of American pragmatists in an essentially open and unfinished world that admitted the possibility of innovation, Meyer began the long and arduous process of restoring hope and optimism into psychiatry.

Meyer was well-qualified for his role in terms of both his background and his training. He was born in Switzerland in 1866. Faced with a choice between the ministry and medicine, he chose the latter. He studied under August Forel at the University of Zürich, passing his state examination in 1890. He traveled to England, Scotland, and France, and studied with such eminent figures as John Hughlings Jackson, Thomas Grainger Stewart, Thomas Clouston, and Jean Charcot. Meyer then returned to Zürich to continue neurological research under his old mentor, Forel, and completed a doctoral thesis on the structure of the forebrain of reptiles. Migrating to America, where there appeared to be greater research opportunities, he then accepted a position as pathologist at the Illinois Eastern Hospital for the Insane at Kankakee in

1893, and also taught at the University of Chicago. Although only 27 years of age, Meyer quickly demonstrated those abilities that enabled him to become one of the outstanding and most influential of American psychiatrists. At Kankakee he introduced such changes as competitive examinations for medical internships, a revamped system of examining patients, the keeping of full case histories, and the introduction of regular staff conferences.

Nevertheless, institutional inertia was strong, and Meyer encountered considerable resistance. Furthermore, he disliked the separation of practical routine and scientific work at the hospital, and preferred to combine clinical work with research. Thus when the opportunity arose to go to the Worcester Lunatic Hospital in Massachusetts as pathologist, a position that seemed to hold much wider opportunities, Meyer accepted with eagerness(9).

That Meyer should have been delighted at the opportunity of going to Massachusetts is understandable. Throughout the 19th century Massachusetts had been a pioneer in developing more humane methods of treating the mentally ill. Following the opening of the first state institution at Worcester in 1833, it had founded over the years a comprehensive state hospital system, and had established the first state supervisory board in 1863. Not only was Massachusetts noted for its public hospitals, but its private ones—especially McLean—were among the best in the country. Moreover, Massachusetts possessed a number of institutions of higher learning which were imbued with the new spirit of scientific research. Two such institutions—Harvard and Clark—seemed to offer many opportunities for joint work in the study of mental diseases. Perhaps most important, however, was the existence in the state of a dedicated group of humanitarian reformers with a long tradition of public service. In the 1880's and 1890's these reformers had begun to call attention to the unsatisfactory conditions in the state-supported mental hospital system. In 1893, for example, the Massachusetts State Board of Lunacy and Charity (composed largely of such lay reformers) observed that (10):

Administrative duties . . . are liable to absorb the attention of asylum officers, and a distinctively medical relation to the patients under their care is sometimes lost in the exacting and important demands of executive details. Medical visits, so called, are made at regular intervals, but may, perhaps, amount to little more than a mere "inspection." The vast opportunities for scientific, and therefore useful study, offered by State Institutions, have of late produced but slender results outside of improvements in the housing and classifying of the insane. Laboratories for systematic investigation, even on a small scale, and medical improvement clubs composed of their house officers, are not a part of every Hospital organization, as they well might be if Massachusetts alienists are to keep themselves and their Hospitals in the front rank of similar institutions elsewhere. Training schools for nurses, having a uniform and systematic method, should be conducted in all State Lunatic Hospitals. Their utility has been thoroughly established, and the great gain, both to their teachers, and to those who are taught, and in the resulting care of insane patients, has been amply demonstrated. Although it might require the exercise of a constant ingenuity, the admitted importance of occupation for the insane would seem to justify the expectation of progressing steps toward a solution of that difficult problem. Something more than a long existing routine treatment, into which it is easy to lapse, may properly be looked for in Massachusetts Hospitals.

The following year, heeding Weir Mitchell's criticisms, the Board recommended the appointment of a pathologist at the Worcester or Danvers hospital, whose functions would include research in the nature of mental disease(11).

The proximity of the Worcester hospital to Clark University and President G. Stanley Hall also was an added inducement to Meyer. As a matter of fact, before going to Chicago, Meyer had applied to Hall for a position at the newly-established graduate school. Even at this early date Meyer was seeking a basis for a rapprochement between psychiatry and the new psychology. In the process of concluding all the arrangements with the superintendent of Worcester Lunatic Hospital, Dr. Hosea M. Quinby, Meyer also wrote to Hall of his plans and hopes in December 1895. In this 19-page letter, the original of which is in the Adolf

Meyer Envelope, Registrar's Office, Clark University, Meyer not only drew a graphic picture of the low state of American psychiatry and mental hospitals in the 1890's, but suggested too a series of far-reaching reforms, some of which have yet to be in effect. This letter, which is of considerable historical interest, is reproduced exactly as Dr. Meyer wrote it.

Dec. 7. 95.

President Stanley Hall,
Clark University.

Dear Sir,

In compliance with your note of Dec. 6 [P]. 1895, I beg to submit to you the following notes on the reforms to be suggested at the Worcester Lunatic Hospital, it being understood that this communication is personal.

My aim in coming to Worcester was the organization of a clinic for mental diseases, not primarily for teaching purposes, but as a source of study and investigation. The propositions made to me by Dr. Quinby were, that I should be free of routine duty, "a guide, philosopher and friend" to the assistants and employing my time so as not to feel as if I were frittering it away. He did not suggest a definite plan of work, but left this to me. The encouragement that Dr. [Edward] Cowles had given me and the assurance that you and other members of the University would help me prepare the conditions for work induced me to leave the West and to believe that this hospital offered the first and best chance for my plans.

My first connection with an American institution for the insane taught me the fact that there is a desire for scientific work but that the best friends of scientific work in that Asylum were not trained in its methods and did not know the simplest requirements. I was appointed "pathologist," with the understanding that I should study the nervous system and the changes underlying insanity. Microscope and microtomes I could get; material more than enough for 4 men; with books the difficulty began because back numbers of journals, esp. of foreign journal[s] did not seem to be worth buying on ground of the ultra-wise dictum that in medicine a work is antiquated within 2 years; and also because neither superintendent nor physicians could read them. But the worst and fatal defect was that I was expected to examine brains of people who never had been submitted to an examination; the notes which were available would be full of reports of queer and "interesting" delusions, of logic terms like "disturbed," "noisy," "unable

to get about," "untidy"; but whether there had been delirium or other psycho-pathological symptom-complexes, or a paralysis at the bottom of the "unable to go about," or paralysis of the sphincters-nobody could tell. The information was usually given in that pseudo-medical jargon which a physician may use with lay men in order to make the necessary impression, but which is the death of medical work if carried into medical discussion.

The first task was to try and [sic] interest the physicians in something better. The idea used to be that the autopsy should be made in order to show the cause of death. The clinical diagnosis would be exhaustion and the pathologist had then to find out the rest. The demonstration that in most cases of "exhaustion" the physician should have known of an existing pneumonia or peritonitis, in other words, that the lack of a diagnosis was a carelessness and something unworthy of a physician of ordinary standing, began to call for better reports. I never failed to show that by some method of examination many of the conditions could have been found before death and used as a guide for treatment. A certain plan of record was to be followed in which the methods were indicated and finally the discouraging defense of laziness and ignorance: What is that good for anyhow? began to withdraw from the daily conversation. The lectures on neurology and on mental diseases delivered two evenings a week in winter and in a summer course even one hour every afternoon—roused some interest and finally when I began to examine the new patients myself—always in presence of the staff, after dinner—the desire to follow the methods and the studies became quite general and with it the feeling that the few physicians were not doing the 2100 patients justice. The superintendent who had not gone through all this drilling was not easily convinced of this and used to brag with the fact that in 1875 he had 300 patients to look after and kept his notes well etc. Undoubtedly they were good for the standard of that day in that special hospital; but to-day it is an impossibility to look after more than 100 patients or 150 at the outside and to do all that should be done for the patient and for the profession. Kraepelin has altogether 150 patients and 4 assistants [sic] for them!

The Superintendent and the 3 Trustees (a brewer, a station-agent and a small country banker) could not be moved well enough. But the State Board of Charities, whose president, Dr. Bettman, showed much interest in my efforts, induced Governor Altgeld to ask

the Superintendents to appoint internes who should help the regular assistants. The plan suggested was that of a competitive examination, the only means to undo party-influence and, what is quite as bad, the nepotism of the superintendents and trustees customary in that state. Notwithstanding the most childish stratagems on the side of the Superintendents, who claimed that they could get along without internes and sent articles to the journals intended to scare away applicants and delayed the announcement of the whole matter till about 3 or 4 days before the examination—12 candidates appeared and 5 were chosen.

3 months later, our Superintendent told me, he was sorry that he had not more internes; he never had been so agreeably disappointed. It began to dawn upon him that my policy had been a benefit to the hospital and he entered upon my plans shortly before I left. The chief reasons of my leaving were the fact that I found it impossible to supervise the work of 2100 patients and that the tendency [*sic*] of the Superintendent towards show and bragging display and his position to the physicians did not give the best prospects for quiet patient and honest work. These external developments helped me to formulate the plans for the Worcester Hospital. There are between 900 and 1000 patients and 4 physicians who have never had any special training. They are rooted in the old-fashioned asylum-practice, ready to ask "what is that good for" wherever a new duty is spoken of; They spend an hour in the morning and a small hour in the evening on the wards; for the rest of the time they have to put up their own medicines, write the records (in the office, away from the patients) and write the letters to the patient's friends. There is neither druggist nor stenographer for them. You know the quality of the records; I may say that to me they seem charming illustrations of the "good old" times, if anything, a little worse than those which I found in Kankakee.

Thus I stand again before the task of educating my superiors and associates to the point where they recognize the necessity of all the innovations. They must be: Requiring from the physician to educate himself in order to be able to keep satisfactory observations and records—in return the clerical and drug work must be reduced to a minimum by the appointment of a druggist who would at the same time be able to make chemical analyses and by employing one or two stenographers. There used to be a 5th physician here. His salary should be taken to be divided among 4 internes

or 5, one for each physician; they should receive about \$20 a month (by all means!); otherwise many able men who have to pay for their own clothes etc. would be excluded from the competition. The reorganisation of the work should be carefully prepared, but carried out completely, because half-measures are discouraging and paralysing. The expense of the innovation is small; the salary of the internes would be \$1000 altogether, that of the druggist \$600 and the stenographer \$20 a month. There is evidently perfect willingness to make expenses for laboratory and library, but the question of salaries is always a bugbear in these institutions: the number of employees is always kept below the limit and the "administration" believes that this is economy!

My work here is promising if I get the assurance that I can choose good men. I do not know how Dr. Quinby stands to the question of appointments. So far he would ask the trustees whether he could "go ahead"; then he would pick from his acquaintances or from the acquaintance of his friends and equals a person sufficiently recommended to him—and this settled the appointment. If he appoints men or women who would do under his régime, they would probably not do for what work I want from them. The trouble is that our Superintendents are acquainted among themselves only, but not with the best younger clinicians of this country against whom they have a prejudice and—of whom they are somewhat afraid. Dr. Cowles is free from that because he belongs to one of the best general Hospitals [McLean]; but those who do not, have nothing to do with the rising generation of clinicians, such as Prof. [William] Osler. Recommendations are a dreary thing to go by for appointments. The best plan would be to announce in the best medical schools of the country each medical vacancy and to choose the applicants according to the purpose for which they take up the candidature and their fitness for work as established by a practical examination. Only in exceptional cases recommendations alone should suffice.

As general rules we should put down the following:

1. Every interne or assistant must recognize the necessity of doing the work so that it can be used for clinical investigation; this holds especially for the examinations and records; and he must be able to acquire the training necessary for good work. (Reading knowledge of German and French! at any rate for the assistant-phys.) (At present we are apt to

get men who ask all the time "what is that good for"? etc.; I maintain that there are in this country enough men who have high enough intentions and ideals to accept positions where that question is considered as settled and where the doubt of laziness has made place to the determination for work. Positions in insane Hospitals are despised now because they are known as clerical positions, breeding places for inaccuracy, laziness etc. which would disqualify young men for future work in active competition).

2. Every interne or assistant must enter upon the work with the determination of using every opportunity for self instruction and of contributing to a system of mutual instruction.

3. A man who has not the ability and ambition to contribute some time and energy for the further working out of the medical and pathological observations, is not fit for the position.

(This latter condition is very essential. I avoid the word original research, because it has been misused and does not suggest the right thing).

Dr. Quinby's letter to me contains the remark that I should not have to get acquainted with all the cases, but perhaps follow the more interesting and acute cases. This plan rests on a great fallacy. Frequently those who seem least promising on admission prove to be most important later on; such was at least my experience at the post-mortem Table. Therefore, we cannot decide whether a case is interesting or not without looking at it closely, i.e. without looking at all cases equally well. The best thing to do is to try to get the same examination of each case. History of the family, of the patient (which takes about 1 hour altogether, correspondence included); status praesens (on the average 2 hours, often more), records as often as needed, written on the spot in sight of the patient when the findings are made (the physician dictates to the interne, or for practice the reverse is done). The same holds for post-mortems. Records which are not written to dictation while everything is seen by several people, are not worth the paper and should not be recognised as a basis for further work. We *must* exclude the fallacies of memory and have a certain degree of control given by such cooperation.

These are rules which have made the German Hospitals what they are, although they have and spend so little money. Here positions in insane asylums are nothing but an easy way to become old enough for practice and to save enough money to go abroad or into

practice. This is what the men tell me themselves; and this is why they cannot understand why a position here should be "worth" as much as another better salaried one in a place without a future.—A few words on the work itself: If I have all the help we can arrange systematic courses and mutual instruction in methods of examination, of diagnosis; we must make a study of groups of our cases and compare them with the classical pictures of the literature; find out the differences and the problems suggested by them; the methods of treatment, of psychological and medical observation should always be arranged so that they could be confronted with the present standing of the knowledge in that field and assimilated, or where they show something new we should become conscious of it and recognize the relative value of new observations.

If our expectations of giving trained psychologists a field of work in the hospital shall ever be realized, we must be able to furnish the student all the data of the clinical record; he can not get them himself because it takes much time and practice. If somebody wants to work on heredity, let him go through the histories which wherever possible shall contain a pedigree and a record of signs and causes of degeneration. If someone wants to work on paranoia, let him study the histories of all the cases observed, not only a few "interesting" cases but the whole array—then he will see things in their natural connections.

For this purpose each history must be recorded in an index catalogue for diagnosis, symptoms, causes, treatment etc. This may seem pedantic; but Prof. Osler told me that they carried out this whole system to perfection in old merry England, in Guy's Hospital and that he himself has used it, and undoubtedly owes much of his success to it.

This hasty sketch will, I hope, give an idea of the needs and of the feasibility of the organisation. It is not a question of money but a question of work, and it has the greatest difficulty in the fact that everybody will have to do about twice the amount of work. But then, instead of merely earning a little money each year, the men will be able to carry out something into the community which only Johns Hopkins, McLean and a few other chosen places do now.

Believe me,

Yours respectfully

Adolf Meyer.

DEMENTIA PRAECOX : THE DEVELOPMENT OF THE CONCEPT

PAUL H. WENDER, M.D.¹

Is there anything whereof it may be said, see this is new? It hath been already of old time, which was before us.

Eccl. I : 10.

The twentieth century historian surveying the concept of schizophrenia bears an uncomfortable resemblance to the eighteenth century physician dealing with dropsy. He does not know whether the term comprises one entity² with one etiology, one entity with several etiologies, a group of similar entities with the same etiology, or a group of similar entities with different etiologies. He can trace the historical antecedents of the concept, but he cannot appraise their validity. He cannot at present date the first recognition of its characteristic attributes, its cause or its natural course, because he himself does not know what they are. Such is the plight of the historian who does not wait until an issue is dead before discussing it.

The implications of the term "schizophrenia" are varied and broad, so broad that, as Campbell suggests(5), it is almost a term of negative reference: the category of all functional psychoses which are not manic-depressive. This would be useful—or at least clear—if the meanings of the terms "functional" and "manic-depressive" were certain, but they are not. Despite the fact that the terms "schizophrenia" and "dementia praecox" have been used almost synonymously, the latter is a much clearer term than the former: dementia praecox refers to a putative group of mental disorders defined by 1) prognosis and 2) age of onset.

The concept of a form of insanity, distinct from but often associated with affective alterations, characterized by its pre-

dilection for the young, its impairment of the intellect, and its progressive course, may be recognized quite early in the history of psychiatry. It is the object of this paper to trace the features of the concept through its crystallization and popularization by Emil Kraepelin in 1896.

In modern Western medical literature the three-fold classification of mental disease may be traced back at least as far as Thomas Willis, a physician who is better remembered for the *circulus arteriosus* which bears his name. In his *London Practice of Physick* (24), Willis distinguished "Melancholy" from "Madness," and these, in turn, from "Palsy" and "Apoplexy" (presumably the organic psychoses). He also observed an intimate relation between the affective disorders and so-called "Madness," a relation that has plagued many descriptive psychiatrists who followed him: "After Melancholy, it remains for us to treat Madness, which is so far ally'd to the other that these affects often change turns, and each passes into the other," he wrote. Two further comments in this work are of interest: on factors that affect prognosis he wrote that madness "rais'd on a sudden from some solemn evident cause, as from a vehement passion, is much safer than invading by degrees"; and in discussing etiology he wrote, that "it is a common observation, that men born of parents that are sometimes wont to be mad, will be obnoxious to the same disease: and that often they have lived prudently and soberly above thirty or forty years, yet afterward without any occasion or evident cause will fall mad." These observations, it will be seen, have been made repeatedly since; it is only their interpretation which has occasioned some dispute.

Pinel is generally regarded as the father of modern psychiatry. In his *Treatise on Insanity* (22), which is distinguished for its exposition on the "moral" (as opposed to the medical and pharmacological) treatment of insanity, is found his classification of mental illness. He based the latter not "on the arbitrary distributions of nosologists" which

The author would like to express his gratitude to Dr. Mark D. Altschule, whose assistance has been invaluable in the preparation of this paper.

² The use of the word "entity" is currently in disrepute in some psychiatric circles. The author pleads not guilty to the crime of reification; this term, as well as all other nouns, is used merely for convenience.

were "far from being the result of accurate observation and experience" but rather on "the examination of the different species of derangement analitically." To accomplish his end he adopted "that method of investigation which has invariably succeeded in all the departments of natural history, viz., to notice successively every fact, without any other object than that of collecting materials for future use; and to endeavor, as far as possible, to divest myself of the influence both of my own prepossessions and the authority of others." Having approached his problem in this painstaking way, he divided mental illness into: melancholy—a state characterized by preoccupation or delusion with one idea, accompanied by clearness of thought and *either* elevated or depressed spirits; mania—characterized by excitement with or without incoherence of ideas; dementia—a weakness of the understanding and will; and idiotism—"obliteration of the intellectual faculties and affection." "Dementia" was characterized as a "rapid succession or uninterrupted alternation of insulated ideas, and evanescent and unconnected emotions. Continually repeated acts of extravagance: complete forgetfulness of every previous state: diminished sensibility to external impressions: abolition of the faculty of judgement: perpetual activity." It seems probable that included in this group were persons with manic grandiosity, flight of ideas and senile dementia, as well as those with features of "dementia praecox." As regards the etiology of mental disease, and presumably this syndrome as well, Pinel wrote: "the successful application of moral regimen exclusively, gives weight to the supposition, that, in a majority of instances, there is no organic lesion of the brain nor of the cranium."

It may come as no surprise that then as now, unanimity of opinion did not characterize this field. Pinel's contemporary, George Hill, wrote(13): "Insanity is a disease originating from the combination of various mixed sensations with organic lesion and predisposition, producing in this state a certain effect, which without such combination can never exist."

A particular form of insanity associated with youth is delineated in the English medical literature of the early nineteenth

century. John Haslam, in his *Observations on Madness and Melancholy*(10), after describing mania and melancholia, presents a vivid and recognizable clinical picture:

... There is a form of insanity which occurs in young persons; and, as far as these cases have been the subject of my observation, they have been more frequently noticed in females. Those whom I have seen, have been distinguished by prompt capacity and lively disposition: and in general have become the favourites of parents and tutors, by their facility in acquiring knowledge, and by a prematurity of attainment. This disorder commences, about, or shortly after, the period of menstruation, and in many instances has been unconnected with hereditary taint; as far as could be ascertained by minute enquiry. The attack is almost imperceptible; some months usually elapse, before it becomes the subject of particular notice . . . A degree of apparent thoughtfulness and inactivity precede, together with a diminution of the ordinary curiosity, concerning that which is passing before them. . . . The sensibility appears to be considerably blunted; they do not bear the same affection towards their parents and relations . . . If they read a book, they are unable to give any account of its contents . . . It is very difficult to persuade them to write . . . the orthography becomes puzzling . . . As their apathy increases, they are negligent of their dress, and inattentive to personal cleanliness. Frequently they seem to experience transient impulses of passion, but these have no source in sentiment; the tears, which trickle down at one time, are as unmeaning as the loud laugh which succeeds them; and it often happens that a momentary gust of anger, with its attendant invectives, ceases before the threat can be concluded . . . Thus in the interval between puberty and manhood, I have painfully witnessed this hopeless and degrading change, which in a short time has transformed the most promising and vigorous intellect into a slaving and bloated idiot.

George Man Burrows, in *Commentaries on the Causes, Forms, Symptoms and Treatment, Moral and Medical, of Insanity*(4), described a particular form of intellectual impairment and discussed its relation to the affective disorders (later defined in detail—as we shall see—by the German psychiatrists). On the intellectual alterations he writes: "It is a defect or a hebetude of the understanding, general or partial, confined

to individual faculties of the mind, particularly those concerned in *associating and comparing ideas* [my italics]; whence proceeds great confusion and incapacity of arranging the thoughts." In discussing the relation to the affective disorders he writes: "Demency may alternate with mania or melancholia, or it may, which is more usual, be the sequel of either." The absence of any clear-cut psychological precipitating factor forced the author to propose a constitutional cause. Age of onset and deteriorating course were again advanced, as in Haslam's writings:

Deterioration of the intellectual faculties sometimes arises from a constitutional and inexplicable cause. I have seen instances of youth, in whom more than ordinary abilities have been displayed, and who, up to the period of puberty, have made all due progress in their studies; yet when they have arrived at that epoch at which all their mental faculties are usually developed, have gradually retrograded, til a perfect state of chronic demency, or rather idiocy, has been established.

Historical researches might well stop here: Haslam and Burrows have together stated the Kraepelinian characteristics of endogenous cause, early onset, and deteriorating course, and the Bleulerian stigmata of dissociation of thought and emotion, and withdrawal (autism). However, their contributions have apparently been overlooked by modern psychiatry, if not by their immediate successors. Observed phenomena (as is so often the case in psychiatry) did not long go begging for an explanation. The English psychiatrist Millingen wrote in *Mind and Matter* (21): "Mental disorders generally become manifest after the age of puberty. At this time a revolution of the whole system takes place . . . Instinctive impulses associated with the [gonadal] development now act upon corporeal emotions and mental faculties. At this time of our existence there arises a conflict between the mind and the body."

Until now discussion of the many confusing and complicated nosologies which flourished in nineteenth century psychiatry has been avoided. A good example is the work of Wilhelm Griesinger, a prominent German internist and psychiatrist, whose *Men-*

tal Pathology and Therapeutics (9), first published in 1845, was a standard German textbook of psychiatry until that of Kraepelin. Aside from the nosology, this book is remarkable for its clarity of style and thought.

To begin with, Griesinger distinguished dementia paralytica (no mean accomplishment in 1845), and divided the remaining disorders into the two, by now familiar, categories: 1) disorders of morbid emotional state (with secondary consequences); 2) disorders of false mode of thought and will. (The obviousness of this grouping was acknowledged by an English contemporary, Tuke, who stated (23): "Griesinger has observed that all classification of mental disease must in the end return to the principal forms of insanity, mania (whether acute or chronic), melancholia, and dementia . . . because they are really founded on nature.")

To Griesinger the first group, the affective disorders, represented both a distinct entity, and a commonly occurring stage in the development of the second group. Diseases in the first group, he thought, were usually curable, but after having developed into the second group they were not; he believed that permanent structural alterations of the brain were present in the latter but not the former. It is probable that his beliefs of structural change were related to his observations of prognosis.

Because the nosologic difficulties with which he contended have not yet been satisfactorily resolved, it is of interest to present his solutions; for in psychiatry, as in philosophy, one cannot be sure that the ancients were wrong. The first group, the morbid emotional states, he divided into *melancholia*, *mania*, and *monomania*; the second group, the disorders of false mode of thought, he divided into *chronic mania* and *dementia*. Forms of melancholia were the *hypochondriacal form* in which somatic delusions and hallucinations were prominent; *melancholia in a limited sense* in which depressive mood represented the principal alteration; and *stuporous melancholia*, in which unresponsiveness and mutism were conspicuous. The perspicacious Dr. Griesinger, unwilling to multiply entities, explained that most of the symptoms of melancholia could be regarded as reactions to the primary alteration; he recog-

nized rationalization, and stated that the patients' guilt and self-reproach represented their efforts to explain their mood changes. His case reports of melancholia now seem to include some catatonic and possibly schizophrenic patients. (Before becoming too critical we may reflect on some modern diagnostic schemes which place involutional melancholia, with its frequent hallucinations and delusions, in the same class with pure "manic-depressive psychosis" (1, 19).) Griesinger realized that something might be amiss, for he noted that some stuporous melancholics remembered their state while others did not; and it was this feature which Kraepelin later proposed as the crucial diagnostic difference between depressions and catatonia.

Griesinger's next major subdivision was *states of mental exaltation*, which were defined as persistent states of excitement and exaltation of will, accompanied by increased self-sensation and self-consciousness. These were divided into: *mania*, usually a transient state, in which increased motor activity and excitement were predominant; and *monomania*, which tended to be fixed, and in which the abnormal ideational features of false conceptions and delusions and grandiosity were more conspicuous than the mood change. Griesinger's characterization of "monomania" (which bears a marked resemblance to current "paranoia") as a variant of mood elevation is of some interest; although Kraepelin later separated paranoia and mania, some modern psychiatrists are again noting their dynamic similarities and are considering them to be allied. Griesinger's second major category was that of *states of mental weakness*, which were, as noted, successors to the affective states, and were characterized by weakness of intellect and volition, and which might be accompanied by the suppression or total lack of emotion. His descriptions of these states has a familiar ring.

It may proceed to total abolition of all the mental faculties, with which there is also combined weakness of the emotions and will, want of energy or complete loss of volition, and dullness of the emotions, bluntness of the moral nature arising from the absence or superficiality of reactionary power—or the mental weakness is in a measure concealed by the promi-

nence of certain delirious conceptions, whose obstinate persistence is significant of all the remains of mental power and behind which all is a void.

Griesinger believed that there were two groups: *chronic mania* and *dementia*. He defined chronic mania as the persistence of the delusions and hallucinations seen in monomania after the resumption of normal mood. As previously noted, the latter state was considered to be an intermediate one between "mania" and "paranoia," isolating a frequently seen syndrome.

He characterized dementia by mental weakness with no single delirious idea; individuals in this state, he believed, might be either hyper- or hypo-reactive—*dementia agitée* or *dementia apathétique*. In these states he recognized that emotion is both superficial and inappropriate, and intellection is compromised by concreteness and poor ability to abstract. Griesinger's otherwise fine performance is somewhat spoiled by his inclusion of cases of chronic brain syndrome with intact past and poor recent memory.

According to Griesinger, all those with dementia may either recover (always with permanent intellectual defect—cf., Bleuler) or terminate in an apathetic state of marked deterioration. Although Griesinger's beliefs about prognosis are irrelevant to the main theme of this paper, they should be mentioned, since they are, like his other ideas, surprisingly modern. He stated: 1. In general, the prognosis of melancholia is better than that of mania, which is, in turn, better than that of dementia. 2. Acute onset is more favorable than insidious onset. 3. A good prognostic sign is the possession of insight, or the patient's regarding the symptoms as foreign to *das Ich* (ego). 4. If recovery takes place, it usually does so within one year. The overall outcome figures are 2/3 discharged (half of these cured and half 'socially cured'). To be sure, the composition of the patient population studied by Griesinger is unspecified; although these figures include patients with the affective disorders (and a good prognosis), they presumably also include those with neurosyphilis (and a very poor prognosis). At any rate, the percentage of patients who

require chronic hospitalization has remained startlingly constant in the intervening 100 years: Bleuler's(2) figures in 1911 being 22% to 40% (comprising patients with "medium" and "severe deterioration"—patients in both classes being incapable of self-support); and Freyhan's(8) in 1955 likewise being 22% to 40%. Both Bleuler's and Freyhan's figures refer to the category of schizophrenia.

As may be seen, a mental disorder with a definite symptom complex had been clearly identified by 1850. This complex lacked only one essential—a name. It is well known by primitive peoples that one has considerably more power over a demon when one can name it; this verbal magic is not unfamiliar to the medical profession, which accords more status, or at least more recognition, to named syndromes. The honor of naming dementia praecox fell to B. A. Morel, and this not insignificant contribution may be found in his 1860 textbook, *Traité des Maladies Mentales*(20). The author had the laudable intention of finding a unity of cause, course and outcome of mental disease; his conception of the course is one that is met with frequently: melancholia to mania, to confusion, to either paranoia or dementia. In describing such a case, Morel writes:

My memories carry me back sadly to a case of heredity in a progressive form . . . An unfortunate father consulted me one day about the mental status of his child, age thirteen or fourteen, in whom a violent hatred for the originator of his days had suddenly replaced the most tender feelings . . . He was downhearted at being the smallest in his class, although he was always first in his composition, and this without strain and almost without work. It was, so to speak, by intuition that he understood things, and that everything was arranged in his memory and intelligence. He lost, insensibly, his cheerfulness, became somber, taciturn, and showed a tendency to isolation . . . The state of melancholy depression of the child, his hatred for his father which extended to the idea of killing him, had another cause: his mother was a madwoman, his grandmother eccentric to the last degree. I ordered the interruption of the child's studies and his confinement in a hydro-therapeutic institution . . . He grew considerably, but another phenomenon as disquieting as those mentioned above

came to dominate the situation. The young patient progressively forgot everything he had learned; his intellectual faculties, formerly so brilliant, underwent a very disturbing period of stoppage. A sort of hebetic-like torpor replaced his former activity, and when I revisited him, I judged that the fatal transition to the state of *démence précoce* was in progress. This desperate prognosis is normally far from the minds of parents—as of doctors—who bestow their care on these children. Such is, nevertheless, in most cases, the dire termination of hereditary madness.³

A syndrome had now been named, but how was it fitted into the nosology of so-called "mental disease"? Classificatory schemes abounded in the late nineteenth century, and the unhappy distant spectator is hard put to superimpose coherence. They were constructed on a variety of frameworks, empirical and theoretical. Griesinger's is primarily empirical. On the other hand, Tuke, an English psychiatrist, accepting the ancient division of the mind into the faculties of intellect, emotion and volition, constructs(3) a classification based on aberrations of each faculty. Inspection of his examples reveals that "dementia praecox" falls in all three. A scheme in which the categories are mixed theoretical-empirical, and apparently neither exclusive nor complete, is that of Kahlbaum(15). It is four-fold: 1) *vesania*—total insanity; 2) *vercordia*—manic-depressive states and paranoia; 3) *dysphrenia*—symptomatic psychoses; 4) *paraphrenia*—age-based psychoses, divided into neophrenia, hebephrenia, and presbyphrenia.

At approximately the same time that the above mentioned authors were describing the syndrome, the individual "disease" pictures that Kraepelin was later to synthesize were being described. The *locus classicus* for "paranoia" is uncertain: like "melancholy," it is a term of classical vintage, and it is difficult to ascertain when it was first employed in a sense approximating the modern. Jelliffe(13) attributes its introduc-

³ Morel gives no follow-up of this case. One wonders whether "forgetfulness" refers to a defect of memory or is his interpretation of withdrawal; similarly, one wonders if Morel uses "fatal" in the metaphorical or literal sense. It is ironic that the first case history labeled *dementia praecox* may have been one of congenital neurosyphilis.

tion into psychiatry to Heinroth (*Lehrbuch der Störungen des Seelenlebens*, 1818), who, having divided the mind into intellect, will and feeling, and mental disease into exalted, depressed, and confused functioning of these faculties, applied "paranoia" (with and without a number of qualifiers) to several of his 9 categories. Meyer attributes it to Ellinger in 1845, while Tuke (23) accords the honor to von Gudden, who employed it "in regard to the mental malady under which Leopold II of Bavaria labored."

In 1871 Hecker (11) described an entity which his mentor, Kahlbaum, had called "hebephrenia." Its major features were: 1) onset soon after adolescence; 2) alternation of various states—mania, depression, and confusion; 3) an exaggeration of normal adolescent features so that the spirit became like the body of a clumsy adolescent; instability of mood, varying between flatness and sensitive irritability with sudden seriousness and preoccupation with profound ideas alternating with outbursts of laughter; softening of logic and inability to stay on a subject; 4) the early appearance of some characteristic signs of, and the rapid progression to, the terminal state. The etiology was obscure and the prognosis very poor.

In 1874 Kahlbaum (16) published a paper describing "catatonia," a clinical form of psychic illness, in which he called attention to the common occurrence of particular mental symptoms and muscular signs, resembling in some ways, and differing in others from dementia paralytica. The course and manifestations also bore some resemblance to the affective disorders; hypochondriasis or neurasthenia precedes a mania-like state which might in turn be followed by a depression-like state. The exalted state, he observed, differed from pure mania in that the speech was more obviously disorganized. In the quasi-depressive form the patient was mute, inattentive, expressionless, unresponsive to painful stimuli, and exhibited a unique physical sign: "waxy flexibility." Other motor phenomena of note were manneristic behavior and marked negativism. In general the aberrant thoughts dealt with sexual and religious matters. Kahlbaum regarded the disease as non-hereditary and although he believed or-

ganic pathology was demonstrable he believed the predominant causative agents were psychological: a seclusive, contemplative mode of life, combined with an over-concern with intellectual matters. The prognosis he thought was fair, both for the individual episode, and the eventual outcome, despite the fact that recurrence might occur.

By 1874 the stage was set: the future divergent points of view with regard to etiology (congenital vs. acquired, organic vs. social) had been stated, the symptoms of "dementia praecox" had been characterized, and several symptom groups had been recognized. What remained for Emil Kraepelin was to identify, or perhaps more accurately *create*, the entity "dementia praecox," as it was later almost universally understood.

But before discussing Kraepelin, it is necessary to mention one more figure, whose ideas strikingly anticipated Kraepelin's contributions: In 1886 an English physician, T. S. Clouston, delivered the presidential address (6) at the annual meeting of the Medico-Psychological Association, in which he stated that in attempting to isolate the essential features of insanity, it might be well to pay less attention to the symptoms, which were too diverse, and instead, to categorize by clinical course and prognosis.

We now turn to Emil Kraepelin, who, it seems, has been as frequently belittled as infrequently read. In 1896 the fifth edition of his *Textbook of Psychiatry* was published. Not surprisingly, it included the author's own classification of mental disease. An evaluation of the rest of the scheme is not pertinent in this paper, but in his classification we finally encounter the term "dementia praecox" applied to a *group* of diseases. By now the psychiatric literature abounded in heterogeneous categorizations in which presumably exclusive groups had criterial attributes which might be etiological, descriptive, prognostic, or theoretical. Kraepelin's grouping is comparatively clean-cut, being based predominantly on etiology and symptomatology—except for one "disease." He divided psychoses into the exogenous, which may be curable, and the endogenous, which are not. Mental disease

was divided into (17): 1) infectious psychoses; 2) exhaustion psychoses; 3) intoxication psychoses; 4) thyroidogenous psychoses; 5) dementia praecox; 6) dementia paralytica; 7) organic dementia; 8) involution psychoses; 9) manic-depressive insanity; 10) paranoia; 11) general neuroses; 12) constitutional psychopathic states; 13) defective mental development. Following Clouston, Kraepelin decided to form a subgroup of mental diseases utilizing two infrequently employed indices: age of onset and course. Youthful onset and progressive deterioration were its defining characteristics, and under Morel's term he placed (following, he says, Pick in 1891) Hecker's "hebephrenia," Kahlbaum's "catatonia," and "paranoia."⁴ These disease entities had, he believed, several other major characteristics in common that distinguished them from the other disease entities of unknown etiology. These will be discussed later. Kraepelin's 13 categories yield, with some manipulations, the familiar five-fold classification. By combining the infectious, exhaustion, intoxication, thyroidogenous, and organic psychoses with dementia paralytica and congenital mental deficiency, we arrive at: 1) organic psychoses; 2) neuroses; 3) psychopathy; the psychoses not grossly organic; 4) dementia praecox; and 5) manic-depressive psychoses. The major contribution is reminiscent of Griesenger: separating the affective, periodic, self-limited processes from the predominantly intellectual and volitional chronic progressive ones. What Kraepelin put asunder, many have since attempted to join together (*e.g.*, the "schizo-affective" psychoses). Having grouped together these three putative disease entities (catatonia, hebephrenia, and

paranoia), Kraepelin methodically examined their signs and symptoms; these are listed in scholarly detail in the eighth edition (18). The differentially diagnostic features between the gross brain lesion and "toxic" psychoses on one hand and dementia praecox on the other were carefully detailed. They still are the ones usually employed: the presence in "dementia praecox" of correct orientation, good recent memory, and accurate perception even during periods of apparent confusion (as determined subsequently).

In the sixth edition two areas caused Kraepelin obvious difficulty. The first relates to paranoia. Kraepelin apparently had some qualms about placing it in the category of dementia praecox because it often developed slowly late in life, and failed to terminate in complete "dementia," the person so afflicted often retaining well-systematized thinking, while on other occasions deterioration occurred rapidly. He attempted to resolve this problem by placing patients with the latter characteristics in the category of dementia praecox, paranoid type, and others in the category of "paranoia," which he later called "paraphrenia." The second major difficulty—which is only tacitly stated—is that of distinguishing catatonic excitement from mania; criteria were given, but it is obvious that at times they broke down.

Criticism was directed at a variety of aspects of Kraepelin's work, and in the eighth edition of his textbook we can detect his attempts to deal with two of these points: the age of onset and the universally bad prognosis. In this edition the author admits that the disease may have its onset late in life and that some—to be sure a very few—cases do *seem* to recover.

Now, having abandoned the defining characteristics of age and prognosis, Kraepelin was forced, if he was to keep the entity, to employ other defining criteria. Accordingly the common characteristics of these states were decided to be: "weakening of those emotional activities which permanently form the mainspring of volition"; "a loss of inner unity," the latter being strongly dependent on the first, since, he believed, strong volition gave coherence to thought and action. In addition, he listed

⁴ The last familiar "member" of the family, dementia simplex (simple schizophrenia), was first named and described by Otto Diem in 1903 (7), and is included by Kraepelin as one of the important sub-groups in the 8th edition of his textbook (18). Diem believed that dementia simplex shared the characteristics of the other sub-group, beginning in youth and terminating with the same abnormalities of intellect and emotion. Its defining characteristics were negative: gradual progressive deterioration, without the acute episodes and remissions, or definite mood swings, hallucinations, delusions, *etc.*, which were seen in hebephrenia, catatonia, and paranoia.

the multiple symptoms previously alluded to. Such rearrangement of defining attributes is a perfectly legitimate—and characteristic—step in the development of scientific classification, but what is striking in the eighth edition is the multiplication of sub-categories, many of which were defined largely by their affective qualities. (For example, hebephrenia was divided into dementia simplex, silly dementia, simple depressive dementia, and delusional depressive dementia; the terminal states were divided into simple, hallucinatory, and paranoid weak-mindedness, and drivelling, dull, silly, and manneristic dementia.) One gets the feeling that Kraepelin, trying to break a continuum into discreet intervals, was utilizing smaller and smaller units in an effort to approximate the truth. One must appreciate Kraepelin's honesty in recognizing that the complex data failed to fit a simple theory⁵—a state of affairs which current psychiatry, with its frequent attempts at simple universal formulations, often fails to recognize.

It is usual to conclude an essay with conclusions, but this author, somewhat unwillingly, is unable to do so. Perhaps the most appropriate conclusion can be found in the work of an American author, Alexander Bryant Johnson, whose inclusion in this essay is fitting as a forgotten man (he virtually created the science of semantics in the early nineteenth century, many years before it was rediscovered). In his *Treatise on Language* (14), he attempted to demonstrate that men are as often used by, as they are users of, language, and that mistaking words for things, men are often led astray. His statement of one of the difficulties which misleads physicians is pertinent to present day psychiatry and the problem of dementia praecox.

The identity which language implies is responded to by nature very nearly, or we could possess no medical science; but the most skillful physician is often defeated by the individualities of nature. Physicians have long noted these individualities, and deemed them anomalous.

lies of nature. The anomaly is, however, in language, which unites under one name, as identities, what is only partially identical. Individuality is no anomaly of nature. It is nature's regular production, and boundless richness.

THEORIES OF PSYCHOPROPHYLAXIS IN OBSTETRICS (PROPHYLAXIS OR THERAPY)

L. CHERTOK, M.D.¹

At the present time, by far the most widely used method of drugless analgesia in childbirth is the psychoprophylactic method (PPM), as described in 1949 by the Soviet psychiatrist Velvovski and applied in the Soviet Union and Eastern Europe. Introduced into France by Lamaze(12) in 1952, it was actively supported by the Catholic Church(19) and it spread rapidly through the "Latin countries" of Europe and the American continent.

The method comprises instruction in relevant anatomy and physiology, training in techniques of relaxing, breathing and taking an active part in labour, and the establishment of a good emotional atmosphere (the elements of "mental hygiene" or "verbal asepsis," in the Russian terminology). The main purpose of the method has been to do away with pain during labour. There is no device for measuring pain. The only criteria are the observed behaviour of the woman and what she herself says, both restricted by subjectivity. Nevertheless, it does seem that psychoprophylactic preparation lessens pain, even to the extent of abolishing it altogether in some women. But in addition to the analgesic effect, it has been claimed that it offers other benefits on the psychological level, those of conscious and active experience of childbirth, beneficial and maturing for the mother. Moreover, psychotherapeutic effects may include purely obstetric benefits at the physiological level (facilitating labour). Finally, the reduction or discontinuance of toxic drugs should be of benefit to both mother and infant.

All these advantages have not yet re-

ceived absolute objective, experimental verification but one can certainly say that the psychoprophylactic method has greatly modified the patient's surroundings in the labour ward, and the attitude of doctors and hospital staff towards her.

Although the practical effectiveness of the method is scarcely questioned, its theoretical interpretation is very much in dispute. Its proponents have called it "psychoprophylactic," and not "psychotherapeutic," i.e., have assigned it the task of *preventing* pain.

All the theoretical discussion centers around this problem: prophylaxis or therapy. In order to attempt an answer to this question, it may be useful to trace briefly the origins of the method.

Origin of the Psychoprophylactic Method. Like some other modern psychological treatments, the method is an offshoot of hypnosis. For 25 years, following the work of the French school of the 19th century and the German school of the period 1920-1923, Soviet writers had been putting to experimental test a *psychotherapeutic* method of achieving pain-free labour, the hypnosuggestive method (HSM)² and came to the following conclusions(20, 23): 1. Pain is not an inevitable accompaniment of labour. 2. Verbal suggestion may have an immediate or delayed effect. 3. Certain variants of suggestion may be used, especially indirect suggestion. 4. Fear is a very important factor in pain during labour.

The Soviet writers for some time thought of using the HSM on a large scale. But when this proved to be impossible, Velvovski described a new method which he called the "psychoprophylactic method" or "system of psychoprophylaxis." In this method, *hypnosis* and *suggestion* were gradually replaced by *persuasion*. The aims of this procedure were to *convince* the expectant mother that pain during labour is not unavoidable and to remove fear. This was

² For a detailed account of the history of drugless methods of analgesia, see (5).

¹ Principal investigator, research on psychological analgesia in obstetrics, Maternity Department, Hospital Rothschild, Paris (Head of Department, P. Walter). Research sponsored by the Ligue Française d'Hygiène Mentale and supported by a grant from the Foundation Fund for Research in Psychiatry (FFRP 57-158).

This article was translated by D. Graham and revised by the author.

achieved by teaching the anatomy and physiology of childbirth and by talks aimed at reassuring the expectant mother. To this verbal instruction was added training in pain-preventing "exercises" or "procedures" (rhythmic breathing, stroking of the abdomen, etc.) to be applied during contractions of the uterus.³

Velvovski interpreted the new method, developed in response to practical requirements, in theoretical terms which contrasted it with the HSM (23). While the aim of the latter is supposed to be to *abolish* or to reduce pain, Velvovski considers that his method *prevents* pain.

Velvovski's basic assumption is that labour is normally painless. If it is nevertheless most frequently painful, this is because of psychological and socio-cultural forces of a "conditioned" nature. The mechanisms by which the two methods work are likewise contrasted. For Velvovski, the PPM makes use of the physiological processes of cortical excitation or activation, i.e., *activity*, the HSM or cortical inhibition, i.e., *passivity*.

The "translation" of these psychological realities into physiological terms is a continual source of ambiguity. This kind of outlook can be attributed to the general orientation proposed in 1950 at the joint meeting of the two Soviet Academies (Science and Medicine), in which it was recommended that psychological concepts should be expressed in terms of Pavlovian physiology. Since 1956, there has been a tendency to let psychology have its autonomy back again.⁴ But this new point of view is not

found in publications on the PPM since then.

Theoretical Controversies in the Soviet Union. The PPM has been the subject of many controversies within the Soviet Union itself. The most important of these took place at the Leningrad Congress of 1951 (7) and the Kiev Congress of 1956 (8). We have reported on these elsewhere (5). The theoretical explanations have been challenged, in particular on the following points: 1. It has not been proved that labour is normally painless (3, 16). 2. The use of the term "conditioned" to apply to pain during labour is a misuse of the term. Davidenkov (9) gives an example of "conditioned" pain. If a pin-prick is associated with the light of a lamp which is switched on, the light itself can later induce pain. But he asks why, if pain during labour is associated with the whole environment in which labour takes place, it disappears after delivery. 3. The element of suggestion is not absent from the method (11, 22).

It is clear from the above criticisms that the contrast which Velvovski makes between a *psychotherapeutic method* and a *psychoprophylactic method* is by no means generally accepted. It lacks an experimental basis, and it is also worth noticing that few physiologists had any part in the development of the PPM. This is, indeed, constantly deplored by Nicolaiev, one of its proponents (17). Nicolaiev has proposed a change in the name of the method (18). In fact the development of the name itself also reflects a certain theoretical fluidity. The first name given (1949) was "system of psychoprophylaxis of the pain of childbirth." At the Kiev Congress (1956) the name was changed to "the psychoprophylactic method of preparation of expectant mothers for childbirth."

To emphasise the importance of physical preparation, which he himself introduced, Nicolaiev suggests that the method should now be called "psycho-physio-prophylactic preparation for labour" (18). For him, the "physio-prophylactic" aspect includes, in addition to gymnastic exercises (physical culture), such physical methods as ultra-violet rays, heat, cold, showers, etc. This raises the physical resistance of the organism

³ For detailed technique see (5, 12, 23).

⁴ This was indicated by the appearance in *Kommunist*, 4: 87, 1956, of an editorial article entitled "On closing the gap between theory and practice in psychology."

An important meeting was held May 8-12, 1962, the All-Union Conference on the Philosophical Problems of the Physiology of the Higher Nervous Activity and of Psychology (summary in Korsakov J. *Neurol. Psychiat.*, 62: 1578, 1962; also echoed in *Am. J. Psychiat.*, 119: 586, 1962). At this conference, decisions against certain dogmatic interpretations of the decisions of the 1950 meeting were taken, and psychology was officially re-established and raised to the status of an independent science.

and reinforces the use of suggestion in the method.⁵

There appears to be a tendency among Soviet obstetricians at the present time to emphasise gymnastic exercises and other physical procedures. For example, a recent article by Rechetova(21) describes a technique, in which two aspects are added to the classical psychoprophylaxis, namely, diet and physio-prophylaxis, the latter including both gymnastic exercises and other physical procedures.⁶

Views of French Writers. These controversies have not had much place in theoretical writings by French followers(1, 24) of the PPM. For long they used the terminology of Pavlovian physiology, adopting in the main the ideas of Velvovski who contrasts

suggestion and persuasion, and attributes mutually opposed physiological processes to them.

A change began to appear in 1957. It was agreed that the first theoretical treatments of the method were, in the words actually used by one of them, "rough and narrow"(15). New points of view were expressed. Vermorel(25) abandons the use of Pavlovian terminology to "translate" psychological phenomena, and resorts to a language which uses a number of concepts in their psychoanalytic sense—*anxiety, unconscious motives, fantasies, orality, transference, etc.* He makes frequent reference to authors such as Helen Deutsch and Gressot. For him, the PPM is first and foremost a form of instruction (pedagogy). But he explicitly states, "It is its psychotherapeutic effects which are being studied." This refers, of course, to a superficial specific kind of psychotherapy, limited to pregnancy and labour.

Angelergues(2) favours "the perfectly legitimate rejection of Pavlovian ideas in psychology and psychopathology." He does not, however, turn to the concepts of interpersonal dynamic psychology to replace them. He admits that Pavlovian ideas are still valuable in relation to *training* (learning), which is for him the basis of the PPM. He believes that there is some "accidental and fortuitous" psychotherapy in all training, but considers that it is negligible, holding that true psychotherapy is that which effects structural changes in the personality. Training, he says, "has as its aim adjustment of the woman to a specific situation, and can attain this end only in so far as this situation is experienced as an event relatively isolated from the drama of the self. In preparing the woman, we work to provide her with a weapon against herself, by using the processes of conditioning."

Another French writer, Muldworf, is one of those who seem most attached to the explanatory value of Pavlovian physiology for the method.

He agrees that we must "transcend the physiological narrowness of misinterpreted Pavlovism," but immediately adds that "Pavlovian experimentation is still the basis on which the theory of psychoprophylaxis is erected"(14). Since the physiology of

⁵ Nicolaiev is inaccurate when, to emphasise the importance of gymnastic exercise, he cites the case of Lamaze's technique in which 6 lessons of 10 are given by physiotherapists. The physiotherapists certainly do not give gymnastic exercise a dominant role in preparation. Nicolaiev clearly confuses relaxation and physical culture. Note that in the Soviet Union, the former is thought of as a procedure dependent wholly on suggestion (production of hypnoidal states which "reinforce" the theoretical instruction and the training in the "pain-preventing procedures"). Hypnoidal relaxation exercises were eliminated from current preparation about 1954, and reserved for difficult cases. They were still in use at the time of Lamaze's visit to the Soviet Union in 1951. Lamaze interpreted them as muscular exercise and introduced them under this heading into the technique which he was to develop on his return to France (from which there has arisen much confusion over the interpretation of relaxation, cf. (6)).

⁶ In this way, one of the differences between the PPM and Read's method, which has often been emphasised, would disappear, i.e., thinking of the former as "mental" and the latter as "physical." Some proponents of the PPM have actually taken the view that gymnastic exercise is quite useless, since pain is a cortical and not a muscular problem.

There were acrimonious disputes on theoretical and practical aspects for several years between the proponents of the two methods(5). Those who practised the PPM reproached the others for the inefficiency of their method. The First World Congress on Psychosomatic Medicine and Childbirth (July 8-12, 1962) brought both parties together in Paris, and a discussion of both points of view resulted in peaceful coexistence. Nicolaiev, one of the proponents of the PPM in the Soviet Union, wrote after the Congress, "In spite of having a different ideological and theoretical basis, both methods, when properly used, give satisfactory results" (Akush. Ginek., 1 : 149, 1963).

conditioning is "a very complex experimental entity," "beyond our scope," Muldwarf abandons any attempt to explain pain during labour and psychological analgesia on the basis of the formation or extinction of conditioned reflexes. "This," he says, "would be an illegitimate and anti-scientific transposition from one field—physiology—to another, psychology" (15).

He also wants to see psychoprophylaxis above all as a form of instruction, this term including both education and training. He considers that there is at present no psychological theory which takes due account of instruction, and he criticises psychoanalysis in particular. There remains "empirical," rational psychology, which persuades and informs, helps the woman to resolve her present conflicts, guides her towards the solution of her difficulties, reduces her negative emotions and so on.

On the problem of the nature of pain during labour, Muldwarf (13) takes a position close to that of Velvovski. He considers that childbirth is normally painless, and that pain is the result of psychological and socio-cultural factors. Thus the effects of the method would be at a *prophylactic* level.

Critical View. The controversies among Soviet writers, and the various points of view among French writers, confirm that the PPM has not yet acquired any solid theoretical basis. The relations between psychoprophylaxis and psychotherapy are not made clear.

The problem of the analgesic effect of instruction, education and training remains controversial. The French writers mentioned above recognise the psychotherapeutic value of instruction (learning), but do not indicate the respective parts played by the intellectual aspects, the affective aspects and the motor aspects of which it is made up. If mere knowledge by itself does not appear to have any direct analgesic effect, the affective aspect, introducing an interpersonal element, opens the way to experimentally demonstrated analgesia. At a different level, a degree of analgesia can be achieved by using pain-preventing "procedures" based on "cortical activity" or distraction of attention, previously also known as indirect suggestion.

We may now wonder whether all instruction, all training, every acquisition or enrichment of the ego (whether it involves learning a foreign language or learning to ski) does not modify the deeper layers of the personality of the person concerned, with eventual repercussions on sensibility to pain. But this is only a hypothesis for which it would be difficult to find experimental support, given the numerous links of the chain between cause and supposed effect.

The point of view of Angelergues, who would enclose the pregnant woman in her own particular state, an abstraction from her personal drama, by representing childbirth to her as a job of work, a particular task to accomplish, requiring an active, conscious mental attitude, inspires a few remarks. First of all, is such an attitude sufficient to effect analgesia, in view of the fact that the pain in childbirth is influenced by deeper levels? Second, if analgesia is achieved, is it not in large part due to suggestion, to the "exhortations" of the person who is doing the preparing? Finally, if it is desirable for the woman to be active and cooperate, it is also necessary to ensure that her activity is not pushed too far, and does not encourage masculine protest reaction. For then the very activity which according to Angelergues should keep the woman away from neuroticism would paradoxically end by leading her there.

Is the psychotherapy in psychoprophylactic instruction genuine psychotherapy? The answers given by the writers considered are reserved and ambiguous. Vermorel agrees that in the PPM, as in all psychotherapy, there are affective changes. "The doctor or midwife" he says, "plays a role analogous to that of the parents for the young child." But he equally asserts that "the psychoprophylactic method is not, properly speaking, psychotherapy in the strict sense of the term; it is rather a kind of instruction, with secondary psychotherapeutic effects" (25).

For Muldwarf, "psychoprophylaxis is a kind of training, not of psychotherapy. It is a form of instruction with psychotherapeutic aims and effects, but it is not a form of psychotherapy in the proper sense of the term" (15). Angelergues, as we have seen, refuses to place psychoprophylaxis among

the psychotherapies. Our own view is that the woman who receives instruction, theoretical and practical, with a view to painless childbirth at once puts herself in a psychotherapeutic situation. It is true that this does not mean *deep* psychotherapy, as Angelergues emphasises, but this is not sufficient reason for refusing, like Angelergues, to allow it the very name of psychotherapy. With the PPM, if we do not have to do with psychotherapy which includes introspection, interpretation, *etc.*, nevertheless the woman finds herself in a net of relationships, and psychodynamic forces are aroused. This might be viewed as a kind of short psychotherapy, superficial, gratifying, invigorating and so on. It often yields speedy positive results, for pregnant women are particularly receptive. In fact, pregnancy provokes an affective "crisis" (4, 10) in all women, for they appear more neurotic than they really are; and a brief and superficial psychotherapy may then be effective. But it seems to us that this can be effectively given by the obstetrician, who thus remains "the central and directing person" as Angelergues requires (2). It is true that it is desirable for him to take an interest in the psychological aspects of his relations with the future mother, but this is something to be found in every act of medical practice. In this, he will find an adviser in the person of the psychiatrist attached to his unit. The role of the psychiatrist will be more important in cases with clear psychopathology requiring specialised psychotherapeutic care.

An Attempt at Formulation. We shall now return to the question with which we started—analgesia by psychotherapy or by psychoprophylaxis? In order to answer this question, we should have to know precisely the physiological mechanism of analgesia in each of the methods concerned. But the criticisms which we have just made are sufficient proof that we know no such thing. We only know, in an empirical way, the analgesic power of suggestion, direct or indirect. This does not exclude the possibility of other more complex analgesic mechanisms at other levels, the effects of which are less apparent. The psychological interpretation of these various mechanisms of analgesia offers a vast field for research. But

from our own experience of this research, we are aware of the great methodological difficulties it runs into. The integration of the psychological and the physiological requires extreme care, and Velvovskii's theoretical accounts are full of ambiguity precisely because in them he has systematically translated the former into the latter. As things are at the present time, the psychological frame of reference still seems to us the better fitted for handling clinical reality.

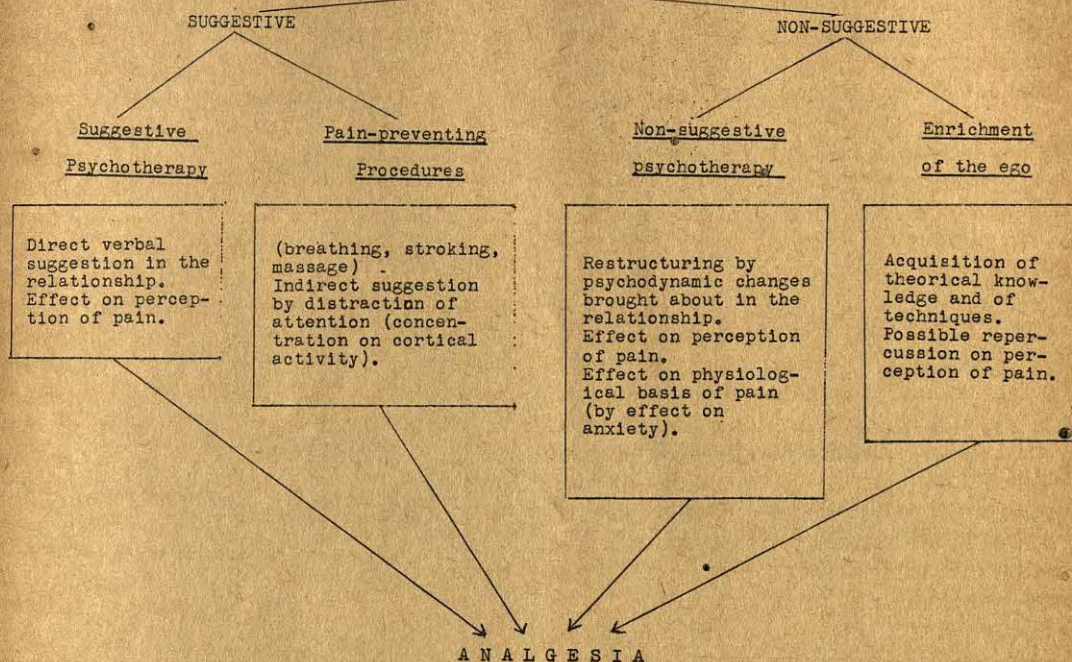

Now, we may give a schematic interpretation of the mechanisms of analgesia. In the HSM, the property of reducing pain consists of a force which is *psychotherapeutic, suggestive, verbal* (or *interpersonal*), *massive* and *direct*, at the level of central perception of pain. This force may be applied during the confinement, or during preparation with deferred effect.

In the PPM as well, part of the power to prevent pain comes in a form which is *psychotherapeutic, of the nature of suggestion, verbal* (or *interpersonal*) and *direct* but *not massive*. It is diluted in a network of relationships. Its power may be exerted during the confinement, or during preparation with deferred effect.

The PPM in addition includes analgesia achieved by *non-suggestive, verbal* (*interpersonal*), *indirect* means. The suppression of fear by instruction, by reassuring surroundings, by the replacement of fantasy by reality, by the creation of a set of cordial relationships, results in a "normalising" of the confinement, and the disappearance of somatic causes of pain (spasms). Note that this involves a typically psychosomatic mode of action. It is perhaps at this level that the adjective "prophylactic" is most justifiable. But again, in the same method, the power of preventing pain is also presented in a *non-verbal* (*non-interpersonal*) way—breathing exercises, active relaxation and other "pain-preventing procedures" (procedures amounting to distraction of attention, also known as "indirect suggestion"). Finally, as we have seen, another kind of non-interpersonal analgesia might be linked with the enrichment of the ego by instruction or training. This, however, is only a hypothesis.

It must be added that certain constituent parts of the method may work in several

FIGURE 1
METHODS OF ANALGESIA

ways. Thus relaxation may serve as groundwork for interpersonal experience. It may sometimes represent a pain-preventing procedure by the concentration of attention on the bodily sensations which it produces (a mechanism similar to that which is involved

in breathing "procedures"). Finally, it may act at the muscular level. The use of one or several of these modes of action will depend, as we have said elsewhere(6), on the personality of the woman and her relations with the person who is preparing her

FIGURE 2
METHODS OF ANALGESIA

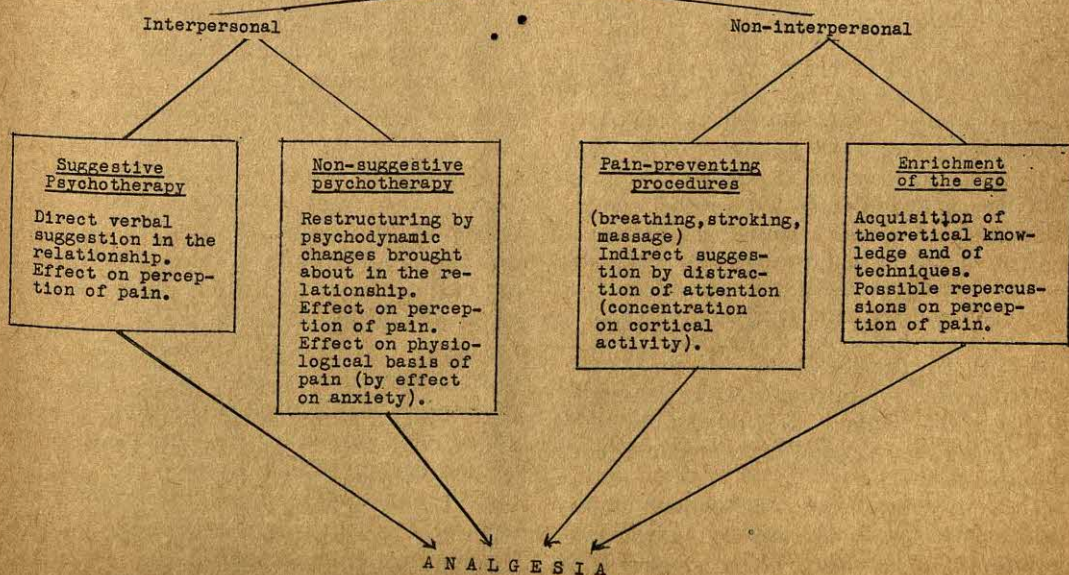

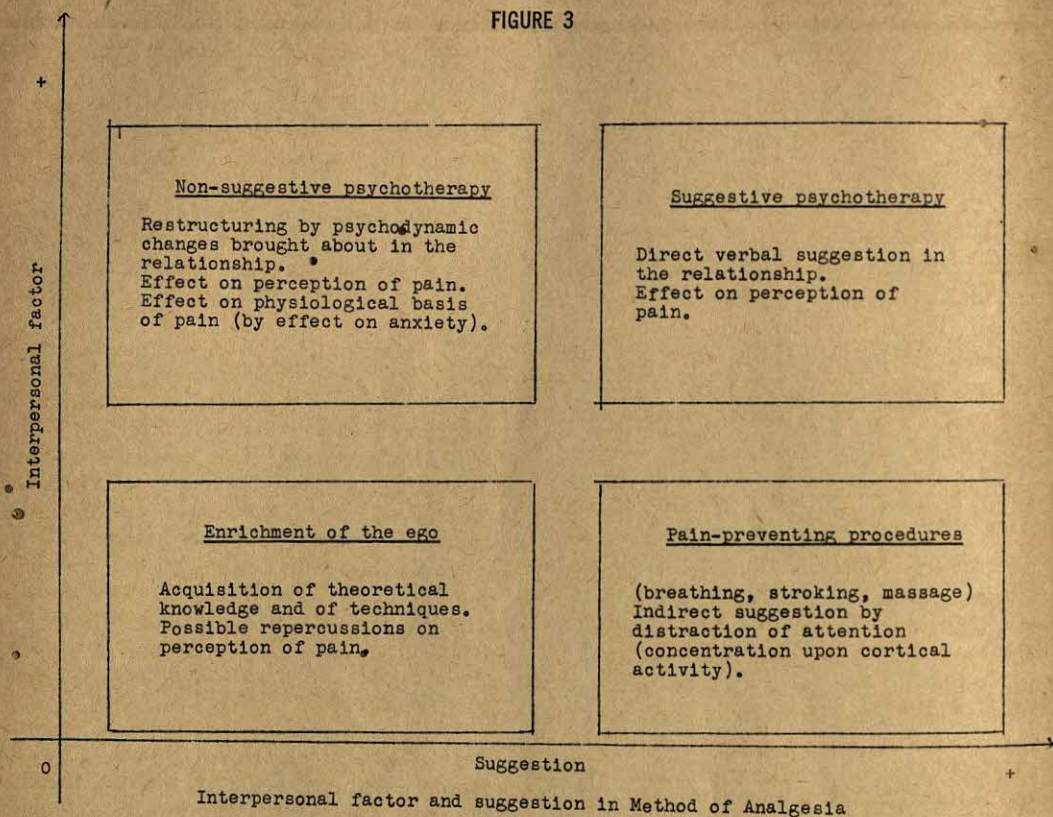

FIGURE 3

and the group of which she is a member.

The 3 diagrams illustrate the operation of the different factors in the various methods of analgesia. In the first diagram, the methods of analgesia are classified according to the importance of suggestion in their modes of action. In the second, the same methods are classified according to the importance of the interpersonal factor in their modes of action.

These distinctions are introduced to clarify theorising and should be viewed in a purely operational way. It is not implied that the opposition between "suggestive" and "non-suggestive" on the one hand, and between "interpersonal" and "non-interpersonal" on the other hand, should be regarded as absolute. It is clear that there is an interpersonal variable in the "pain-preventing procedures" and in the "enrichment of the ego"; but here, it is not the basic factor in effecting analgesia, as it is in the "psychotherapeutic" methods.

The third diagram combines the other two. It places the methods of analgesia in terms of both the interpersonal factor and the factor of suggestion.

These two factors are represented by two orthogonal axes. Each method of analgesia depends to a greater extent on each of the

two factors, the further it lies from the origin (towards the top of the diagram for the interpersonal factor, towards the right for the factor of suggestion). Thus, "suggestive" psychotherapy is of all the methods of analgesia the one which depends most upon *both* the interpersonal factor and the factor of suggestion.

SUMMARY AND CONCLUSIONS

The most widely used drugless method of obstetrical analgesia is the psychoprophylactic method (PPM) described by Velvovskii. It is an offshoot of the hypnosuggestive method (HSM). Hypnosis has been abandoned. The new method is based upon instruction in anatomy and physiology, and training in techniques of relaxation, breathing and active participation during labour, all in a good emotional climate.

The two methods have been contrasted thus. The HSM is said to be based on *suggestion*, the PPM on *persuasion*, with the appropriate physiological corollaries, namely cortical *inhibition* in the case of the former, hence *therapy*, and *excitation* in the case of the latter, hence *prophylaxis*. But this contrast is challenged in the absence of

physiological proof. The two methods do differ, but in another way. In HSM, the pain-preventing effect consists principally in *verbal, massive, direct* action. In the PPM, too, part of the pain-preventing effect appears as *verbal* and *direct* but *not massive*. It is diluted in a network of relationships. But it also appears in a *verbal* and *indirect* form; the suppression of fear has beneficial effects on contractions of the uterus. There is finally the *non-verbal form* represented by breathing exercises, active relaxation and other pain-preventing "procedures." The psychotherapeutic element remains of importance in the PPM. The HSM requires a particular skill from those who apply it, and what is more, hypnosis, surrounded as it is by a mystical halo, meets with much conscious and unconscious resistance, both among the public and in the medical world. In eliminating hypnosis, Velvovski has shown his sense of realities; no doubt he has been unable to interpret in a wholly satisfactory way the physiological and psychological realities on which the method rests, but we should not find this surprising when we realize the difficulty in this field. The field offers a vast and exciting prospect of research to all concerned to understand the nature of pain and to find the means of relieving it. In taking the discussion into the realm of science, Velvovski has already himself achieved considerable progress. Moreover, his rationalization has reassured both public and doctors and thus permitted the application of the method on a large scale.

STUDIES ON THE PSYCHOPATHOLOGY OF SLEEP AND DREAMS ¹

CHARLES FISHER, M.D., AND WILLIAM C. DEMENT, M.D.²

In these days, when important new discoveries are being made on molecular, cellular, biochemical and neurophysiological levels, there has arisen a tendency to de-emphasize the psychological. Kety(1) has suggested that a total explanation of behavior, strictly in terms of physics and chemistry, is not likely, and that it is extremely pretentious to believe that the tools of the biological disciplines alone can unravel the mysteries of behavior. He makes the profound comment, "There will, no doubt, some day be a biochemistry or a biophysics of memory—but not of memories." He remarks that psychoanalysis, whatever its defects, may represent the closest approximation "to the rich and almost inexhaustible fund of information which reposes in the individual human brain, and, to a significant extent, determines individual behavior." He concludes with a plea for the study of the nervous system and behavior in a variety of disciplines and techniques, each with its own virtues and its own peculiar limitations.

The purpose of this paper will be to suggest that psychoanalysis, as the most comprehensive of current psychological theories, has great value for investigations on the behavioral level(2). It will not be concerned with research using the psychoanalytic method or specifically designed to validate psychoanalytic propositions or theory, but with research using the experimental method designed in the light of psychoanalytic theory, or the data of which are understood and interpreted through the theory. This type of research is not primarily concerned with validation but with new discovery. To the extent, however, that a psychoanalytic consideration of experimental work leads to the discovery of valid new relationships

among phenomena, an indirect but definite contribution to the validation of psychoanalytic theory may be made. At the same time, new discoveries leading to additional testable hypotheses have a feed-back function on the theory itself, and modify it. One of the purposes of this type of research is to establish a theoretical model of personality functioning encompassing the interrelationships among the simultaneous processes which take place on different levels of integration, the molecular, cellular, biochemical, neurophysiological, as well as unconscious and conscious psychological levels.

We will attempt to illustrate the above point of view through a discussion of recent experimental work on the psychophysiology of sleep and dreams. At the present time, important multidisciplinary work on the part of physiologists, psychologists, psychiatrists and psychoanalysts is being done in this area. This constitutes a genuine breakthrough making possible the investigation of heretofore inaccessible problems of sleep, dreaming, and other forms of nocturnal psychic activity.

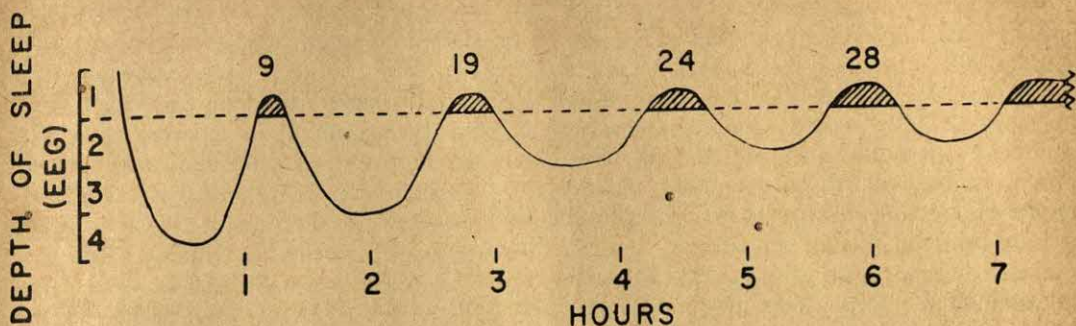

It has been found by Dement, Kleitman, and their co-workers(3-9) that dreaming is associated with bursts of rapid vertical and horizontal eye movements (REMs), and that these occur only during periods of Stage 1 EEG, characterized by a low voltage, relatively fast pattern and an absolute lack of sleep spindles. When the EEG and eye movements are recorded continuously throughout an entire night of sleep, a more or less cyclic pattern of change is observed, as shown in Figure 1. In an average 7- or 8-hour night, there are usually 5 such dream periods, as indicated by the shaded areas in the figure, the numbers above the shaded areas indicating the average length of the dream periods in minutes. Each dream period is preceded and followed by intervals (Stages 2, 3 and 4), during which no REMs are recorded, and the EEG patterns are distinctly different, containing sleep

¹ Read at the 118th annual meeting of The American Psychiatric Association, Toronto, Canada, May 7-11, 1962.

FIGURE 1

spindles and slow delta waves. The most striking finding has been that dreaming occurs in a cyclic fashion and the rhythmic pattern seems to be relatively fixed and stable. This cyclic variation has been recorded every night in hundreds of subjects who have been observed in our laboratory and elsewhere. The mean percentage dream time of individuals within a particular age group appears to be fairly constant. In the age range from 20 to 30 years, it is almost always within a few percentage points of 20% of the total sleep time, *i.e.*, about 1½ hours of dreaming during a 7- or 8-hour period of sleep.

A considerable body of evidence(10) indicates that dreaming is a continuous sensory experience, especially in the visual modality, occurring throughout the entire period of Stage 1 EEG, even though the actual REMs are discontinuous and the amount of time taken up by them constitutes less than 25% Stage 1. Specific patterns of eye movement have been shown by Roffwarg, *et al.*,(11) to be correlated with the movement of objects and events in the dream; *i.e.*, the dreamer moves his eyes while looking at and participating in the hallucinatory events of the dream, just as a waking person would while watching similar events in real life. The intervals of ocular quiescence between bursts of movement are equally important in this relationship, since they are associated with portions of the dream in which the dreamer is staring fixedly at distant activity or a nearby stationary object. The dreamer appears to be completely involved in his experience and to participate in the dream with both emotional and physiological responses. When he is under emotional stress

or physically active in the manifest dream, his pulse may quicken, his respirations may become irregular and he gazes sharply about, his eye movements closely coordinated to the hallucinated visual imagery. The dream has a dimension in time and does not occur instantaneously. A quasi-waking level of physiological activity is attained which does not occur in any of the other sleep stages. We have concluded, therefore, that the duration of the Stage 1 EEG periods can legitimately be taken as a measure of the length of the dream periods. This conclusion is important because we have mostly concerned ourselves not with individual dreams but with the establishment of *nightly total dream time*, *i.e.*, with the dreaming process as a whole.

There are two other points which should be discussed briefly. First is the problem of psychic activity during non-dreaming stages of sleep. Recent work(12) suggests that psychic activity goes on all during the night and that such activity during non-dreaming periods (Stages 2, 3 and 4) differs from that occurring during Stage 1 dreaming sleep in that it consists of much more secondary process thought, more related to recent memory and current daily preoccupations. Other studies(10, 13, 14) indicate that rather complex, discriminatory forms of cognitive activity can occur during Stages 2, 3 and 4, but not during dreaming sleep. The second problem is concerned with the "depth" of various stages of sleep. Recent evidence(10) indicates that Stage 1 dreaming sleep may not represent "light sleep" as previously supposed, but from many points of view, including that of arousal thresholds, may be as "deep" as Stages 3 and 4. As a matter of fact, it now appears

that dreaming sleep cannot be placed on the ordinary sleep-wakefulness continuum, that it represents a qualitatively different form of sleep from a psychophysiological point of view, with its own characteristics. Furthermore, it has recently been shown by Jouv \acute{e} t(15), as will be discussed later, that dreaming sleep is a different form of sleep, triggered off and regulated by a special neurophysiological mechanism.

We have been interested in investigating the nature, meaning and function of the dream-sleep cycle which appears to be relatively fixed and stable, and universally present, and in throwing light on whether dreaming is a necessary psychobiological function. We approached this problem in two different ways: One has been to experimentally manipulate the cycle in the direction of suppressing it, and to investigate the behavioral and other consequences of such suppression(16-18). We wondered whether individuals deprived of the large amount of dreaming found to be universally present in normal subjects, would develop mental disturbances. We have been able to suppress dreaming by forced awakenings, by total sleep deprivation and certain drugs. A second approach has been to study the natural and spontaneous fluctuations in the cycle in psychoses and other psychopathological states(19, 20).

Dement(16) developed the simple but somewhat drastic method of forced awakenings. Subjects were awakened immediately, within a minute or so, after the onset of dreaming, as indicated by the appearance of Stage 1 EEG and REMs, and were kept awake for several minutes before they were allowed to go back to sleep. With this method, continued over a period of consecutive nights, it was possible to reduce the normal amount of dreaming by 65-75%. The forced awakening method has now been applied to 20 adult subjects, mostly in the age range from 20 to 30, for periods ranging from 1 to 16 nights. It was found that a progressively increasing number of awakenings was necessary to suppress dreaming. With each succeeding night, the subjects increasingly attempted to dream, and, in effect, would get in a minute or two of dreaming each time before they were awakened. In a typical experiment, the number of awaken-

ings might be 7 on the first night, gradually increasing to as many as 30 by the fifth night. Following the period of dream deprivation, the subjects were allowed to sleep undisturbed for a number of nights. During these so-called "recovery nights," marked increases in the amount of dreaming, as compared to the subjects' normal baseline levels, were recorded. For the group as a whole, the increase on the first recovery night averaged 50% and in some instances the rise was as high as 80%. Thus, the dream suppression procedure appeared to bring about a dream deficit—an increase in the pressure or need to dream, manifested by increasing and compulsory attempts to dream during the nights of forced awakenings, and a large compensatory increase in total dream time during the recovery nights.

Extensive control experiments were carried out in which an equivalent number of awakenings were done during the non-dreaming phases of sleep. The dream deprivation effect did not develop, indicating quite conclusively that it is not the awakenings themselves nor the concomitant moderate sleep loss that is responsible for the effect.³ Furthermore, we have found that total sleep deprivation brings about dream suppression, the building up of a dream deficit and compensatory increases in dreaming during subsequent recovery periods. We have also been able to confirm the discovery made by Maron and Rechtschaffen(20a), that the administration of a combination of dexedrine and nembutal produces the same effects. With these two latter types of procedures, the complicating factor of the forced awakenings is eliminated and is clearly ruled out as the cause of the dream deprivation effect. The dream deprivation experiments strongly suggest

³ Subsequent re-analysis of the results of the control experiments has shown that a moderate but much less drastic dream suppression effect takes place followed by moderate compensatory increases in dreaming during subsequent recovery periods. This is associated not with increasing attempts to dream but with an actual reduction of the number of dreaming periods due to the repeated intrusions into the non-dreaming stages of sleep. The repeated awakenings bring about a "spreading effect," that is, mechanically lengthen the interval between the REM periods and reduce the number of the latter.

that dreaming is a necessary psychobiological function and that more or less complete suppression of it might have serious psychic consequences.

At this point, we would like to examine the phenomena thus far described in terms of the psychoanalytic theory of dreaming and the theory of instinctual drives. The psychoanalytic theory of instinctual drives was developed(2) in order to explain certain pathological phenomena, irrational ideas and behavior which are not necessarily pathological, the origins of behaviors and thoughts that man experiences as beyond his control, that are *peremptory*, in contrast to those which he experiences as subject to his will; in short, to account for the origins of behavior and ideas which emerge "spontaneously," and are not obvious responses to an external stimulus or a somatic condition. Dreaming is the type of psychic phenomenon *par excellence* showing these characteristics.

Freud's theory of dreaming has a dual aspect: He believed that the principal function of dreaming was to provide a *safety valve* for the partial discharge of instinctual drives during sleep, especially those repressed, infantile ones that he thought of as indestructible, and, at the same time, by virtue of the distorting and disguising function of the dream work, to preserve sleep. The theory assumes that during sleep there is a relative decathexis of the mental apparatus with a consequent quiescence of its functions. However, certain energies of the mind remain active, e.g., according to the older topographic theory, the repressed wishes in the System Ucs., and, according to the later structural theory, instinctual drives in the id. In addition, preconscious mental processes and their energies in the ego, referred to as day residues, also remain active. These active id and ego energies strive for discharge, and the dream work consists of a complicated interplay among id, ego and superego, the final result of which is the series of hallucinatory sensory images which we call the manifest dream.

Recent work has made it possible to link dreaming as a behavioral event with the underlying physiological and neurophysiological events that accompany it. We would

suggest that the initiation and activation of the Stage 1 REM phase of sleep is concomitant with instinctual drive discharge processes in the id and those energy shifts between ego and id leading to the hallucinatory dream. The spontaneous, peremptory and obligatory nature of dreaming has been demonstrated in the most vivid fashion in the dream deprivation experiments, and it may be suggested that these characteristics are connected with the safety valve, instinctual drive discharge function of dreaming. Similarly, from the somatic side, the dream-sleep cycle is built into the organism from birth and appears to be associated with a spontaneous, cyclic, peremptory activation of the Stage 1 REM phase. We are dealing with the same phenomenon from two points of view, the physiological and the psychological, and can observe common characteristics.

If we accept the above assumptions, suppression of the Stage 1-REM phase, from the somatic side, and of dreaming, from the psychological side, would lead one to predict the occurrence of an inhibition of instinctual drive discharge associated with a probable intensification of pressure toward discharge. That increased, compensatory dreaming occurs following the development of a dream deficit is evidence supporting this assumption. According to psychoanalytic theory, instinctual drive cathexis prevented from consummatory action may find substitute forms of discharge in fantasy, symptoms, etc. This is the phenomenon of displacement, one of the chief characteristics of the primary process. Further evidence for the occurrence of an inhibitory process is to be found in the behavioral observations made on our dream deprived subjects. We assumed that instinctual drives and their derivatives prevented from discharge in nocturnal dreaming would make themselves manifest in the daytime in various kinds of disturbed behavior. During dream deprivation, but not during the period of control awakenings, our subjects showed disturbances in a number of ego functions: they developed greater or lesser degrees of tension and anxiety, difficulty in concentration, irritability, motor incoordination, disturbance in time sense and in memory. One subject developed a

severe anxiety attack and another a period of depersonalization. Two subjects showed evidence of intrusion of primary process thought into waking consciousness when tested by Holt's modification of the Rorschach (21). Three subjects manifested a latent hallucinatory tendency, *e.g.*, they developed formed hallucinations when exposed to flickering light at the height of dream deprivation, though they did not do so during the control period. Five subjects developed a peculiar, intense feeling of hunger and emptiness and increased eating. Our tentative explanation of this is that certain subjects, especially those with pre-existing oral conflicts, show a regressive displacement to the hunger originally associated with repressed libidinal oral drive tensions, when these are prevented from taking their normal path of discharge in nocturnal dreaming.

We have suggested that dream deprivation, carried out intensively enough and for a prolonged period of time, might bring about a very large dream deficit, a great intensification of the pressure of instinctual drives toward discharge, eventual eruption of the dream cycle into the waking state and the development of hallucinations, delusions and other psychotic symptoms. Although we have not yet produced psychotic symptoms but only the above described tendencies in that direction by forced awakenings psychotic outbreaks have been shown to occur following 100 hours or more of total sleep deprivation (22). We have shown that with prolonged sleep deprivation there is an accompanying dream deprivation and the occurrence of compensatory dreaming during subsequent recovery periods. In view of this, it is likely that dream deprivation plays a role in the development of psychotic symptoms during prolonged total sleep deprivation. Total sleep loss probably has a greater disruptive effect on ego functions, defenses and controls than does dream deprivation where the autonomy of the ego is much better preserved. Morris and his co-workers (23) have recently investigated the course of development of hallucinations in sleep deprived subjects. Their work also suggests that with increasing sleep loss the dream cycle finally erupts into the waking ego. We believe, however, that prolonged

dream deprivation alone might produce this effect.

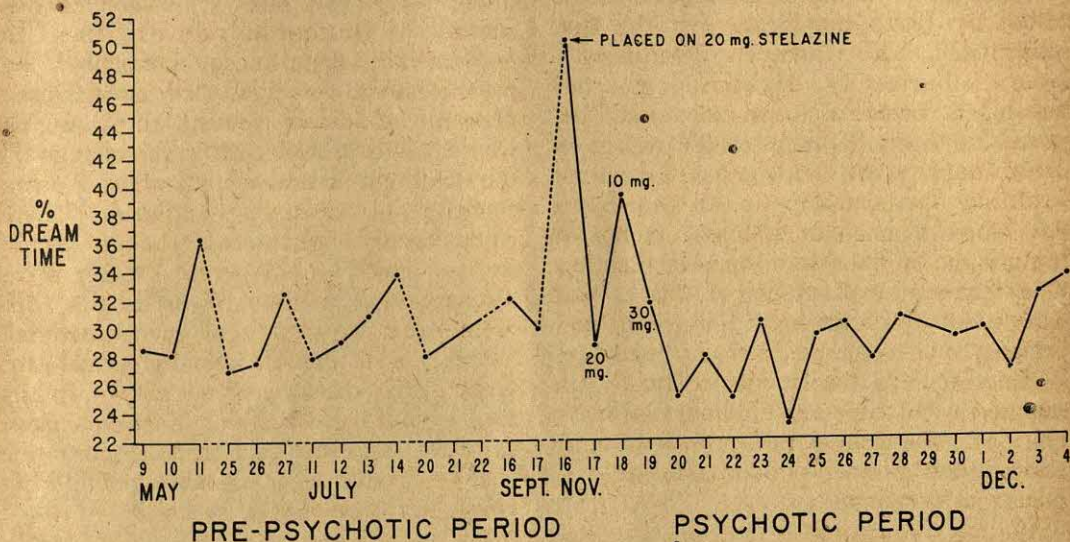

If it is true, as Freud proposed, that the dream serves as a safety valve for the discharge of instinctual drives, then in any mental disturbance, postulated by psychoanalytic theory to show an increased pressure of drives toward discharge, it would be expected that some change in the dreaming process would occur. We can conceive of several possibilities. There could occur a qualitative change in the dreams which would permit greater drive discharge, *e.g.*, nightmares or dreams with more overt expression of drive material. Whether such dreams actually provide for greater drive discharge is not known. In any case, even if there were qualitative changes, as drive pressure increased, quantitative changes would occur, namely, *a simple increase in the amount of dreaming.*

For example, it is generally assumed that in an acute schizophrenic psychosis, there is increased conflict with an intensification of the pressure of drives toward discharge in the presence of an ego defect or defects, *e.g.*, weakened defenses, a failure of repression due, in Hartmann's formulation, to a deficiency in the neutralization of aggressive energy so that insufficient counter-cathexis is provided. Similarly, in a pre-psychotic or borderline character, one might postulate the occurrence of increased drive pressure and weakened ego defenses and controls. Is it possible that in such individuals total dream time is increased? We have now made observations bearing on this question on 5 borderline patients, 1 of whom became psychotic (19, 20).

A 25-year-old white male was diagnosed as a pre-psychotic character, potentially a paranoid schizophrenic. He showed disturbances in a number of areas of ego functioning especially in perception and alterations of consciousness in the form of prolonged sleeping spells. He was taken into treatment with the idea of following fluctuations in his dream-sleep cycle during the course of therapy. Over a 5-month period, on 4 occasions, he slept in the laboratory for 3 or 4 nights at a time while his EEG and REMS were recorded. His total dream time was found to be markedly elevated, varying between 27% and 36%, and averaging about 30%, in contrast to the 20% average for

FIGURE 2

TOTAL DREAM TIME PERCENT DURING COURSE OF PSYCHOSIS

normal individuals in his age range (Figure 2). At the end of 5 months, he rather precipitously developed an acute paranoid psychosis. He first became delusional and then began to hallucinate in both the visual and auditory spheres. He was in a severe panic, would run through the streets and over roof tops fleeing from imaginary pursuers. Within several days after the onset of hallucinations, he was placed on massive doses of Stelazine and we were able to obtain EEG and REM recordings over a period of 18 nights. On the first night in the laboratory he showed a total dream time of 50.1%, by far the largest we have ever seen. By the second day, dream time percent fell to its pre-psychotic level, but when the dose of Stelazine was decreased, it again rose to 39.4%. There was also a marked disruption of the cycle, the first dream period beginning at the very onset of sleep instead of the usual 1 hour or 1½ hours after onset, and lasting for 2½ hours.

We have never seen this kind of early dream onset, except in patients with narcolepsy, an illness which was clearly ruled out in our patient. On the second night, there was a brief period of dreaming at sleep onset lasting 23 minutes, but on subsequent nights this phenomenon disappeared. The initial 2½-hour period of dreaming also differed from normal dream periods in that there was a considerable amount of alpha activity alternating with stretches of Stage 1 EEG. During the alpha periods, the eye movements, for the most part, disappeared and

then re-emerged when the low voltage Stage 1 activity supervened. The patient appeared to be asleep, from a behavioral point of view, and when aroused shortly after REMs appeared, he reported a dream. In view of the abnormal amount of alpha present, however, we cannot consider this sleep onset dreaming as entirely equivalent to a normal dream period, but rather as intermediate between dreaming and waking, or perhaps between dreaming and waking hallucination. On the third night, the dream-sleep cycle appeared quite normal, but the dream time remained at a very high level, 39.4%, even though the patient had had a considerable amount of Stelazine. He was kept on 20 to 30 mgm. of this drug for 6 months. His hallucinations disappeared within several days after the initial administration of the drug, delusional activity gradually diminished and he became more amenable to psychotherapy. After the drug was discontinued, his dream time percent remained at its pre-psychotic level of 28-30% and has persisted at this level for a period of 1½ years. At the present, he is free of psychotic symptoms but remains vulnerable.

We suggest that this patient showed a high percentage dream time in his pre-psychotic period because of intensified drive pressure in the presence of a weak ego organization. As drive pressure mounted and defenses became weaker, his dream time percent rose to an even higher level, and at

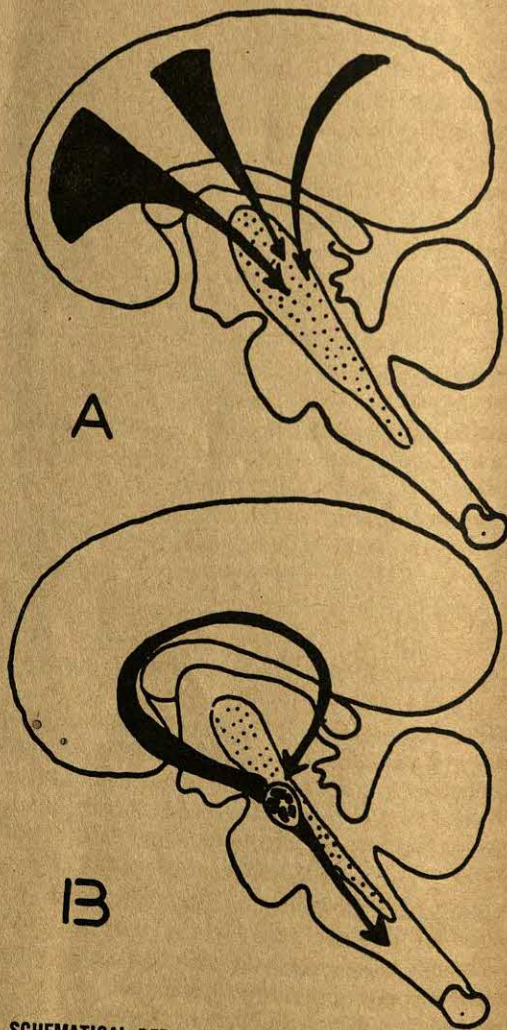

the point where he became acutely psychotic, delusional and hallucinating, it had attained a level of 50.1%. It seems likely that the quick remission of his acute psychotic symptoms was due to the action of Stelazine, either its effect on reducing instinctual drive pressure or some effect on ego defenses and controls, or both. As an accompaniment of these hypothesized effects, total dream time rather quickly returned to its pre-psychotic level. We do not wish to imply that there is a causal connection between increased dream time and the type of paranoid psychosis that our patient had, but only that the psychotic symptoms were temporally associated with increased dream time. That the findings of high total dream time in this patient during his pre-psychotic and psychotic phases were not fortuitous is indicated by the following additional data. We investigated the dream-sleep cycle in 5 borderline, potentially schizophrenic patients, including the one presented above. The mean percentage dream time for this group, all in the age range between 22 and 26, was 26.5% as compared to 19.8% for a group of 11 normal control subjects in the same age group. The difference between the mean values is significant at the .001 level.

We would like to propose that the total dream time level in any given patient on any given night is *the outcome of the balance between the pressure of instinctual drives towards discharge and the adequacy of the defensive and controlling functions of the ego*. In the paranoid patient described, we assume that drive pressure was markedly increased in the presence of pathologically weakened defenses, resulting in a breakthrough of the dream cycle into the waking ego with the development of delusions and hallucinations.

Finally, we would like to call attention to some recent neurophysiological work. As pointed out earlier Stage 1 REM phase of dreaming sleep has characteristics making it difficult to place on a continuum with Stages 2, 3 and 4. Both from a psychological and physiological point of view, it seems to be a *different* form of sleep. This idea has recently received confirmation through a brilliant and important neurophysiological investigation by Juvet and his co-workers

(15, 25). A sleep cycle bearing striking analogies to that of the human has been found in such lower forms as the cat, dog, and monkey, and it now seems probable that these forms dream. On the basis of work on the cat and on humans with brain lesions, Juvet concluded that sleep is controlled by a dual mechanism and that two different neurophysiological systems are involved (Figure 3). The first system appears

FIGURE 3

SCHEMATICAL REPRESENTATION OF THE TWO PHASES OF SLEEP

- A) Telencephalic sleep, descending inhibitory activity from the cortex upon the ascending reticular system.
- B) Rhombencephalic sleep (R.P.S.). The triggering inhibitory rhombencephalic center is connected with ascending fibers to the limbic system (Limbic Midbrain circuit) and with descending fibers to the pontobulbar inhibitory reticular formation. Dreaming occurs during this phase.

By permission of the author(29).

to intervene during Stage 2, 3 and 4 spindle and slow wave sleep and requires the presence of the neocortex. The neocortex is responsible for the slow activity which is brought about by a cortico-fugal inhibitory action on the reticular activating system. Jouvett designates this phase as telencephalic or "neo-sleep." He believes that it may represent a stage which is acquired during telencephalization. On the other hand, the second type of sleep is designated by Jouvett as rhombencephalic or "archisleep." This corresponds to the Stage 1 REM phase in the human. It is an active phenomenon and is triggered off by a mechanism localized in the caudal pontile nucleus of the pontile reticular formation. If the caudal pontile nucleus is destroyed, either in the cat or human, the rhombencephalic phase of sleep disappears. Jouvett points out that the pontile reticular formation is probably connected with the limbic system through the so-called limbic mid-brain circuit, since lesions at various levels along this pathway interfere with certain aspects of "archisleep." He proposes that dreaming occurs when the pontile limbic system, shown in Figure 3B, triggers the rhombencephalic phase of sleep. Although we do not wish to indulge in facile neurologizing, Jouvett's findings are of great interest because the activation of the pontile limbic system may be thought of as part of the neurophysiological substrate of what, in psychoanalytic terms, we designate as drive discharge. It may be of some significance that the center in the pons which appears to activate the rhombencephalic phase of sleep and dreaming is also connected with the limbic system, which includes the hypothalamus, *i.e.*, with those phylogenetically old parts of the brain alleged to be associated with emotions and drives. These are the very parts of the brain which one might expect on *a priori* grounds to be linked with the instinctual drives conceived in psychoanalytic theory. In this connection, it is of interest that Lilly(24) has suggested that the reward and punishment centers, discovered by Olds(25), through self-stimulation experiments in the limbic and hypothalamic areas, may be correlated with the aggressive and sexual drives in the psycho-

analytic sense. Margules and Olds(27), and Hoebel and Teitelbaum(28) have shown that the reward and feeding systems in the hypothalamus are identical; *i.e.*, the points in the hypothalamus which are related to self-stimulation are also connected with drive activity.

In conclusion, it has been our purpose to point out the value of psychoanalytic theory in organizing and interpreting experimental data and in providing testable hypotheses for further experiments. In addition, we have attempted to correlate the psychological with the physiological and neurophysiological levels of integration by interpreting recent findings on the psychophysiology of sleep and dreams in the light of psychoanalytic drive and dream theory. A physiological and neurophysiological dimension has been added to our understanding of dreaming, and soon we may also have a biochemistry of dreaming, since Jouvett believes that his pontile center is triggered off by a neurohumoral mechanism. But, to paraphrase Kety, although there may someday be a biochemistry of dreaming, there will never be a biochemistry of dreams, the understanding of which will always require psychological interpretation.

CONCURRENT TREATMENT GROUPS OF MOTHERS AND CHILDREN

MARJORIE LE VAY, M.B., AND N. H. RATHOD, M.B.¹

A child's behaviour is largely reactive to the attitude of his parents. Kanner(5) suggests that future textbooks of child psychiatry might be organized on the basis of parental attitudes and their effects on children. Of the parents the mother has often the greater influence as it is through his relationship with her that a child learns his basic patterns of behaviour. In Slavson's(8) words "the chief, and often the sole, source of difficulties in the child is his mother, who, for constitutional or psychological reasons is unable to function properly as a mother and a wife." He considers that environmental factors are an integral part of the treatment of the prepubertal child, and the mother's attitude the most important factor in that environment. Kahn(4), when discussing the therapeutic process with children, has said: "Treatment of the child alone, except when adolescence is reached, is usually inadequate and often unjustifiable." Treatment aimed at the modification of the maternal attitude may be through guidance, designed to enlarge the understanding of the child's needs, or by psychotherapy, designed to deal with the unconscious conflicts of the mother in her relationship with the child. Based on Slavson's hypothesis, this study aims at testing whether the relief of behaviour disorders in children can be obtained by the modification of maternal attitudes. We used group treatment to do this.

Group treatment for parents started in 1937 at the Brooklyn Child Guidance Clinic and flourished under Slavson. There are many reports of such child-centred groups, mostly of mothers (2, 3, 6). Amster(1) found many advantages in group work with mothers: "The individual becomes the concern of the group, emotional release and human relationships are stimulated quickly, tolerance of specific behaviour as such is achieved, and the children are compared

with real, not ideal, standards. The individual learns and adapts to the new standards." Child-centred group treatment of parents is often more practical than individual treatment. To quote Slavson(9) again: "Our experience has convinced us that group guidance of parents, with lesser interpersonal disturbances, is in every respect more effective and more efficient than individual guidance." He advocates group treatment in most cases, except when the mother is suffering from severe psychiatric disorder or deep-seated conflicts, or when the family are well-known in the community and the mother therefore finds communication difficult.

Method. The setting for the study was the Croydon Child Guidance Clinic. In sources of referral, staffing and facilities it is essentially similar to the average clinic in this country. Individual treatment of the child by the psychiatrist, with casework with the mother by the psychiatric social worker, is the usual practice. We chose children suffering from what may be classified, according to Slavson(8), as primary or reactive behaviour disorders. He describes this as deviant behaviour, not the result of or secondary to constitutional or psychological defect or illness, but as a direct outcome of experience. The population we studied were children of this kind and their mothers. Selection was made after a diagnostic interview of both mother and child, intellectual assessment and a school report being available. The children were all of school age, but prepubertal, and living at home with their parents. They had symptoms of at least a year's duration. The only other condition for selection was that the mothers agreed to come for group discussion and the children to play together. Twenty-two children were selected, 9 girls and 13 boys, aged between 7 and 13 years and with I.Q. ranges between 92 and 135 on the W.I.S.C., the mean being 110. One of us handled the mothers' groups and the other the children's.

¹ Respectively, Senior Registrar, Senior Hospital Medical Officer, Warlingham Park Hospital, Surrey, England.

The children's groups each consisted of 4 or 5 children of both sexes, and of similar age. The psychiatrist introduced the children at the first meeting as regards names, reason for their being brought to the Clinic, other members of the family, and the children's likes and dislikes. After this the therapist did not take part in the group activities unless invited to do so. He refrained from making any interpretations of the children's behaviour, and none of them was seen individually. Group games were encouraged, but not insisted on. Younger siblings were included in the play to relieve the adult group of their presence. Mostly they played games with balls or hide-and-seek in the clinic garden, occasionally they chose to paint or talk to each other.

The mothers' groups were held by the other psychiatrist at the same time as the children's. There were 5 separate groups, with sessions lasting an hour and held weekly except when interrupted for holidays. At each first meeting the 4 or 5 mothers were introduced by the psychiatrist and then invited to describe their children's problems. Commiseration and advice were exchanged, habitual attitudes were compared and attempts made to define normal behaviour at the relevant age. Although the aim was mainly at child-centred groups, when problems needing dynamic interpretation arose these were not withheld. For instance, comparisons were often made by the mothers with their own experience of love and discipline as children, and then the relevance of present attitudes was discussed. The groups were also concerned with the mothers' own current problems, such as their emergence from the social isolation due to the prolonged dependence of their young children.

Improvement in the children's behaviour was reported early, and termination of treatment was discussed as soon as improvement was substantial. Where there were symptoms at school, progress was then checked by a school report. The transfer of one of the authors from the Clinic, for administrative reasons, prevented extension of this work with more children.

Controls. We compared our results with those of the most closely matched cases taken on for treatment in the previous year.

These children were treated individually by the psychiatrist, and the mothers were in casework with the psychiatric social worker, though in 3 cases some of the children's sessions were with the psychologist and 3 mothers did not have regular casework; but they may be said to have all had traditional child guidance treatment. They were all cases of behaviour disorder, living at home with their parents, and were the best matches for age, sex, level of intelligence and symptoms; when there was sufficient choice family groups were taken into account in matching.

Results. Of the 22 children in the trial group, 15 were discharged symptom-free, 3 were improved and 4 unchanged. This was achieved in 4 to 11 sessions spread over 2 to 5 months, the average being 6 to 7 sessions in 3 months.

Of the control group, 1 became symptom-free while on the treatment waiting-list, 3 were discharged symptom-free and 2 improved after treatment. These last 5 attended an average of 19 sessions over 10 months. In 7 cases treatment had to be discontinued because of refusal to attend the clinic further before any substantial improvement was reported. In 9 cases symptoms were unchanged after a year or more in treatment, these having an average of 26 treatment sessions.

Follow-up. The mothers of the experimental group were interviewed a year later and 14 of the 18 cases that had been discharged symptom-free or improved had remained free of complaints without any further treatment.

DISCUSSION

The results of the study are encouraging. Treatment of the mother, rather than of the child, in these reactive disorders, appears to be better in results and less time-consuming. The 4 failures in the study were as follows: one case was excluded from the group because a severely immature personality disorder became apparent; in one the mother reported after 2 sessions that treatment was no longer necessary as there was no longer a problem (this "flight into normality" not being maintained); the other 2 failures only attended half the sessions, as one mother was admitted to hos-

pital and the other was from a locally well-known family of the type Slavson describes as being unsuitable for this treatment. Attendance on the whole, however, compared favourably with that for individual treatment, and there was no difficulty in persuading the mothers to join initially. Our aim was merely at symptomatic relief, but using what we consider the basic pathology, the disturbed mother-child relationship, to obtain that relief. If our findings are confirmed this method could result in a great saving of therapeutic time, and also free the psychiatric social worker from her long hours with the mother to tackle more serious social problems. It could reduce the inconvenience to mother and child in attending the clinic for months on end, and save many half-days of schooling.

SUMMARY

Behaviour problems in 22 children were approached by group treatment of the

mothers aimed at the modification of their attitude to the children. Results are better than for a matched number of children treated by orthodox play-therapy for the child and case-work for the mother.

CLINICAL NOTES

(The Clinical Notes report the findings of the authors and do not necessarily represent the opinion of the Journal.)

COMPARISON OF A PSYCHOACTIVE DRUG AND AN ANABOLIC STEROID IN CHRONICALLY ILL MENTAL PATIENTS

A. BARRON, M.D., L. H. RUDY, M.D., AND J. A. SMITH, M.D.¹

Perhaps the greatest problem in psychiatry continues to be the lack of an effective treatment for those patients already chronically ill and those who are becoming so. In spite of the increased concern over the possible undesirable side effects of new products, the most encouraging new therapies which are available for trial, rather than discussion, are drugs.

Carphenazine was compared with oxymetholone, an anabolic steroid, and a placebo in a group of chronically ill patients. Oxymetholone was included because of a reported euphoria in some patients taking this compound. In addition it had been reported as being a desirable adjunct in the treatment of schizophrenia.

The group treated consisted of 30 chronic female patients residing on the same ward in a state hospital. Their ages ranged from 24 to 61 years, and the average length of hospitalization was 10.9 years. The diagnoses were schizophrenic reaction, 29, and chronic brain syndrome with psychotic reaction, 1. The study was carried out as a "double blind with a cross over."

The 30 patients were randomly divided into 3 groups of 10. Each group received an active preparation and a placebo for one month. A 7- to 10-day drug free interval was allowed after each change of medication.

Standardized forms were used for recording behavior change. These forms have been previously described(2). The usual behavior of the participating patients was

known to the nurse observer who made the recordings. A control evaluation was made before and at the finish of each period of drug administration. In addition weekly standardized progress notes were kept. The nurse worked directly with a psychiatrist who examined any patient in whom side effects were reported.

Complete blood counts, alkaline phosphatase and thymol turbidity studies were done prior to the beginning of the study and at weekly intervals, during the course of the evaluation.

The dosage of each compound was increased at 10-day intervals. The amount of each product given daily, orally, was as follows: carphenazine, 75 mgm, 100 mgm and 150 mgm; oxymetholone 5 mgm, 7.5 mgm and 10 mgm.

The patients' clinical responses during the study were tabulated as worse, no change, slightly improved, moderately improved and markedly improved.

The results with carphenazine: 2 worse, 18 no change, 8 slightly improved, 1 moderately and 1 markedly improved. Oxymetholone showed the following: 9 worse, 18 no change and 3 slightly improved. During the interval of placebo administration, 18 of the patients were worse and 12 showed no change.

A gain in weight previously observed during the administration of carphenazine did not occur in this study. No serious side effects occurred during the length of the study. Two patients who were receiving carphenazine showed a slight decrease in leukocytes; this was a minimal change and was not attributed to the drug being given. The side effects from carphenazine were controlled by reducing the dosage or by

¹ Illinois State Psychiatric Institute, Chicago, Ill. Appreciation is expressed to the Wyeth Labs. for supplies of carphenazine (Proketazine) and to Syntex Lab. Inc. for supplies of oxymetholone (Anadrol).

the use of antiparkinsonian medication. The undesirable changes occurring with oxymetholone and the placebo were primarily an increase in agitation.

DISCUSSION

The use of a "cross over" technique and the giving of the different active preparations, and a placebo, in identical capsules allows one to attribute more validly whatever changes are observed to the preparations being evaluated.

The results obtained can only be considered in the light of the severity and chronicity of the illness in the patients being treated. The changes which occurred with carphenazine are comparable to those previously observed.

It was felt the 3 patients who responded to oxymetholone may have common characteristics not shared by other members of the group; and they are being studied separately. Since patients presently diagnosed as schizophrenic may represent several different etiological entities, there may well be a sub-group for whom an anabolic steroid is indicated although it is not possible at the moment to identify them—except by clinical trial.

PHENELZINE IN THE TREATMENT OF DEPRESSION

HENRY V. AGIN, M.D.¹

Recurrent depressions of various types constitute the most frequent psychiatric symptom complexes seen at the adult psychiatric clinic of the Beth El Hospital. Since the advent of the monoamine oxidase inhibitors approximately 4 years ago, several of them have been found to produce serious toxic effects and no longer are used. Others, however, have been employed continuously since their introduction and, in addition to being effective, have been found safe in most respects. One of these latter agents, phenelzine sulfate,² has maintained an exceptional record of safety in our experience, as the following report reflects.

Method. Approximately 300 patients with various types of depression were treated with phenelzine during the past 2 years; 77 (56 women and 21 men, ranging in age from 19 to 72 years) were selected for this report as being representative of the types of depression treated. The diagnoses were: psychoneurotic depression in 49 patients, psychotic depression in 27, and postpartum depression in 1. All had undergone physical and laboratory examination and had re-

ceived one or more forms of treatment prior to receiving phenelzine, including tranquilizers, ECT, and other antidepressants.

Physical and laboratory examinations were performed before, during, and at the completion of the study. All previous therapy except for geriatric vitamins was discontinued. The dosage of phenelzine sulfate was based on the severity of depression, with the majority of patients receiving initial and maintenance doses of one tablet (15 mg.) t.i.d. The efficacy of phenelzine therapy was considered *satisfactory* or *unsatisfactory* on the basis of symptomatic improvement and ability of the patient to resume activity at a normal level of efficiency.

Results. Approximately 82% of the patients responded to therapy with phenelzine; 70.1% obtained satisfactory results. The response was excellent in 69.4% of the patients with psychoneurotic depression, in 70.4% of those with psychotic depression, and in 1 patient with postpartum depression. The response to phenelzine was evident within 5 to 15 days. Patients in the older age groups were particularly responsive. There was no evidence of toxicity. Side effects (headache, insomnia, and con-

¹ Chief, Child Guidance Clinic and Adult Psychiatric Clinic, Beth El Hospital, Brooklyn, N. Y.

² Nardil®—Warner-Chilcott.

stipation) were mild and easily controlled. Significant lowering of blood pressure did not occur in any of the normotensive patients; however mild orthostatic hypotension did occur in hypertensive patients, but was readily overcome by the use of methylphenidate.*

A comparison of the results obtained with phenelzine and those with other MAO inhibitors (1, 2) showed that the percentage of satisfactory results was approximately the same. The major clinical differences were the severity and frequency of side effects associated with the other drugs that were not observed with the use of phenelzine.

CONCLUSION

Phenelzine provides effective therapy for the treatment of depressed patients, and is especially effective in patients in the older age groups. Because of its safety and lack of severe side effects, it should be used in preference to ECT, except when the threat of suicide is acute or an immediate improvement is required, without regard to other factors.

THE FALLACY OF THE "DOUBLE BLIND"

JOSEPH A. BARS, M.D.¹

In the early years of psychotropic drug therapy, clinical research reports on the same drug by different investigators often gave contradictory results. This led to considerable confusion and to the conviction that the difference in results was due to the bias of the investigators and the suggestibility of the patients. An effort was made to rectify this and bring as much objectivity as possible to the research project. For this purpose the "double blind" study was initiated.

In the "double blind" neither the investigator nor the patient were aware of the nature of the medication. The drug under study was given at a predetermined dose to a random sampling of patients, and a placebo under the same appearance as the drug and in the same number of tablets was given to a comparable sampling of patients. At the end of a predetermined period the patients were evaluated as to degree of improvement. Then a cross-over often occurred, the patients on the active drug receiving the placebo, and those on placebo receiving the drug. After another period the patients were again evaluated. It was not till then that the "double blind" was broken, and the investigator was told who was re-

ceiving the active drug and who the placebo. In this way it was hoped that the results of the investigations would have objective and scientific validity.

Unfortunately the "double blind" was based on some false premises. For example, it did not take into consideration the fact that tranquilizers have two separate and distinct actions, a sedative or calming action, which can be seen and measured relatively soon after administration of the drug, and an anti-psychotic (*i.e.*, anti-delusional and anti-hallucinatory) action, which may not be detected for several months. However, in most "double blind" studies the patients were kept on the drug for only a few weeks. Thus, although these studies could measure solely the sedative action of the drug, they purported to measure its entire effectiveness. The result was that false conclusions were reached; in fact, several "double blind" studies concluded that tranquilizers had no advantage over phenobarbital.

Another false premise of the "double blind" was the assumption that patients with the same symptom would respond in the same way to the same amount of the drug. It was like saying that all diabetics with the same fasting blood sugar would require the same amount of insulin. How-

¹ Rockland State Hospital, Orangeburg, N. Y.

ever, we know from clinical experience that dosage is a very important factor in determining the success or failure of drug therapy, and that patients with apparently the same symptom will differ greatly in their dosage requirements. Therefore, the "double blind" study in disregarding the individual dosage needs of the patient cannot give a valid picture of the effectiveness of a drug.

There is also a self-deception which is being practised in many "double blind" studies. In order to take into consideration the varying dosage needs of the individual patients, some recent studies have been designed so that a fixed dose is given for only 1 to 3 months; and thereafter the physician may change the dosage in accordance with his clinical judgment, although presumably he does not know which is the active drug and which is the placebo. In this way, it is believed that the "double blind" remains intact while the drug dose is being varied. However, we know from experience that all tranquilizers with anti-psychotic activity will produce extra-pyramidal side effects, either parkinsonism, dystonia or akathisia, if the dose of the drug is raised sufficiently. Therefore, if the investigator keeps raising the dose in an

effort to obtain better therapeutic results he will eventually produce side-effects which will betray the nature of the drug he is using. Is this not a bit of self-deception to continue calling such a study "double blind"?

It is not possible to gain a valid evaluation of a drug, and eliminate the clinical skill and judgment of the investigator, just as it is not possible to obtain a valid picture of the effectiveness of psychoanalysis without considering the clinical skill of the analyst. It is erroneous to believe that treatment with a certain drug will have the same result, no matter who the therapist is, (and I am excluding any concomitant psychotherapy). To treat effectively with drugs requires experience, training and clinical acumen.

Yet, despite all these deficiencies of the "double blind," it is still proposed as the method of choice in the investigation of psychotropic drugs; and the results of the "double blind" study are automatically considered to be scientifically valid. However, instead of bringing clarity, the "double blind" has only succeeded in adding to the confusion by many half-truths and unwarranted conclusions.

CASE REPORTS

PERIODIC PSYCHOSIS OF PUBERTY

MARK D. ALTSCHULE, M.D., AND JACOB BREM, M.D.¹

Most of the recent discussions of syndromes currently called "schizophrenic" relate exacerbations and remissions to environmental factors. However, the literature contains scattered reports of patients with similar psychoses that are characterized by such periodicity as to suggest the action of internal factors. The cases reported fall into two categories: (a) periodic psychoses in women postpartum, and (b) periodic psychoses in puberty (called in the German literature "periodische Umdämmerungen in der Pubertät," or periodic "twilight," i.e., confusional, states in puberty). An instance of the second type of syndrome forms the basis of the present report. Recognition of this syndrome is important both for practical reasons (it has a good prognosis) and for theoretical reasons (it emphasizes that what is called schizophrenia consists of a heterogeneous group of conditions).

The patient, aged 13 when the present illness began, had her first psychotic symptoms on October 18, 1959. On that day, during one of her menstrual periods, she began to have visual and auditory hallucinations, to be confused and frightened, and to become markedly overtalkative. According to her mother, the patient's speech was rambling and contained many references to imaginary persons in other rooms or outside the house who criticized or threatened her. She did not recognize that she had hallucinations and delusions.

The family history was not remarkable. The patient was a first child, born at full term; delivery uneventful. Her mother had had extreme anorexia and some vomiting during the first 3 months of pregnancy. The patient started to walk and talk normally and grew normally except that she had always had a small head. She had had mumps and measles of average severity. She was retarded in intelligence but not markedly so; she had always attended ungraded classes at school. The patient often became nervous when she encountered

unfamiliar situations. Her periods began at age 11 and always lasted for 7 to 9 days. Profuse protracted flow, and the passage of many clots, characterized the first period. The patient was seen by a physician who gave an injection of 40 mg. of proluton, which terminated the hemorrhage.

The psychotic episode that ushered in the patient's illness led to her being hospitalized for a few days at St. Vincent's Hospital in Worcester, Mass. where skull roentgenograms, lumbar puncture, and serologic tests gave an normal. A slight anemia was found, for which iron was prescribed.

The evidences of psychosis disappeared quickly, and the patient was discharged. Her next period was uneventful except for nervousness and irritability. However, during the following period, which began Dec. 30, 1959, the patient again became hallucinated, deluded, confused, and frightened. She was readmitted to St. Vincent's Hospital on Jan. 3, 1960, after 3 days of illness. She was seen to be responding to auditory hallucinations and was in poor contact with her environment. The patient was given Compazine, 5 mg. t.i.d., and varying amounts of Sparine; her mental symptoms cleared rapidly on the ninth hospital day. She also received a urinary antiseptic drug for a 2-month period, because of albuminuria and slight pyuria. She was discharged with orders to take Compazine 5 mg. t.i.d. before and during her menstrual periods.

The patient had an attack of herpes zoster late in February, 1960, but otherwise she did well until April, when she once more began to have mental symptoms with her periods, despite the use of Compazine. On Aug. 31, 1960, these symptoms were so severe as to require hospitalization once more; she was menstruating at this time. She was confused and fearful and had auditory hallucinations.

The patient first came to the Laboratory of Clinical Physiology at McLean Hospital Oct. 7, 1960, at which time she appeared to be a pleasant but slightly retarded girl who seemed nervous, but not inappropriately so. The next day her period started; she rapidly became confused and apprehensive, and responded to visual and auditory hallucinations. Readmis-

¹ Respectively, Waverley, Worcester, Mass.

sion to St. Vincent's Hospital was followed by recovery in about a week. The patient's next period started Nov. 20, 1960; she became restless and irritable, but had no other mental changes. Three periods subsequently were uneventful. Her course remained unchanged until Mar. 29, 1961, when she became irritable again; 2 months later her psychosis recurred. During the next year several recurrences in association with menstrual periods required hospitalization again.

Physical examination at the McLean Hospital showed a large girl whose head was small for her age and size. The blood pressure was 110 mm. of mercury systolic and 70 mm. diastolic. The finding of a mild normochromic normocytic anemia was confirmed (the hematocrit reading was 37% cells).

DISCUSSION

The clinical syndrome described here seems to be rare. The disorder does not appear to be related to one commonly seen in schizophrenic and manic-depressive women, *i.e.*, exacerbation of the symptoms starting 5 to 10 days before the period and lasting until a day or two after the onset of flow. In such instances the patients remain mentally abnormal after the end of the exacerbation.

The syndrome here discussed resembles to some degree the "hyperestrogenic cyclic psychosis" described in a patient by Lingjaerde and Bredland(1); their patient had a postpartum manic psychosis and the episodes of psychotic illness occurred before nearly every period. It is interesting that other clinical instances of periodic psychoses also have been reported in postpartum patients(2, 3).

Williams and Weeks(4) reported on 16 cases of premenstrual tension accompanied by psychotic manifestations; however, their paper is difficult to evaluate thoroughly because of the paucity of data. Of their 16 patients 4 were under 14 years of age. The time of onset of severe mental symptoms was given as 1 day before the period in 5 cases. This does not differ significantly from the findings in our patient, whose psychosis sometimes began on the first day, although it often began a few days later.

Grosch(5) and Wenzel(6) each reported a patient with a syndrome that they called "periodic confusional state in puberty." The

patients were girls, one of whom—like our patient—was mentally retarded; the illness consisted in cyclic episodes that began a few days to a week before each period. The symptoms were apathy, lack of initiative, depression, hypochondriasis, anxiety, confusion, and, in Grosch's(5) case, hallucinations. These patients, together with some of those of Williams and Weeks(4) and the one described here, seem to constitute a clinically-homogeneous group with a syndrome of cyclic severe mental change related to menses and starting at puberty. Except for the time of onset, the syndrome resembles one that occurs in postpartum psychosis, as noted above(1-3). These considerations suggest that some disturbance of female sex-hormone production or metabolism is the cause of the syndrome, no matter at what age it occurs. However, this conclusion is negated by the fact that Beringer(7), Pipkin(8), and Grahmann(9) each reported severe cyclic mental changes beginning at puberty in boys; the cycles in some of the cases also were 4 weeks apart. Accordingly, relating the syndrome directly to the menstrual cycle appears to be invalid. On the other hand, the occurrence of the syndrome in boys and girls at puberty and in women in the postpartum period suggests that some disturbance in anterior-pituitary gonadotropic function is the cause of the syndrome.

However, no conclusion can be reached about the classification of the syndrome, either on the basis of its etiology or on the basis of its clinical manifestations. For the present the patient is best regarded as having a periodic psychotic syndrome of unknown origin and mechanism. The findings in the case here described and in the similar ones reported in the literature emphasize the inadequacy of any currently-popular description of the pathogenesis or even the nature of what is now called schizophrenia. In fact, the validity of the diagnosis of schizophrenia may be seriously questioned in any case. The criteria used in its diagnosis vary to such a degree from physician to physician and even in the same physician from time to time as to limit seriously the usefulness of the term (10-12). The findings in patients with periodic pubertal psychosis suggests that

in at least some patients the cause of the so-called schizophrenic psychosis is metabolic and not sociologic, unless one wishes to adhere to the hypothesis that sociologic phenomena are affected by the phases of the moon and by sunspots, and are therefore also cyclic.

SUMMARY

The clinical course of an instance of periodic psychosis in puberty is described. The findings in this and similar patients discussed in the literature indicate the existence of a psychotic syndrome in boys and girls that begins at puberty. The partial similarity to another periodic cyclic syndrome, that which occurs postpartum, is pointed out. The findings in cases such as the one reported show the inadequacy of hypotheses concerning the sociologic etiology of so-called schizophrenia and also indicate that the diagnosis of schizophrenia does not apply to a homogeneous group of patients.

GALACTORRHEA, HEADACHE AND WEIGHT-GAIN DURING TREATMENT WITH THIORIDAZINE

PIETRO CASTELNUOVO-TEDESCO, M.D., PETER E. TANGUAY, M.D.,
BOYD M. KROUT, M.D., AND EARL C. BURGESS, M.D.¹

Galactorrhea(1, 5-7) and weight-gain(4) have been recognized as occasional side effects of phenothiazine drugs, but the occurrence of severe, disabling frontal headache during treatment with a phenothiazine compound has not received adequate attention(2). Two cases with these manifestations during treatment with thioridazine (Mellaril) are described.

Case 1. A 21-year-old emotionally unstable woman was hospitalized on 8/25/61 because of anxiety, aggressive outbursts and dissociative episodes. There was no history of galactorrhea, frequent headache or other CNS symptoms. Physical and neurological examinations, routine laboratory studies, EEG, spinal fluid, and skull x-rays were within normal limits. Be-

ginning 9/12/61 she was given thioridazine 300 mgm., and later, 450 mgm. per day. She improved noticeably but on 9/17/61 began to report severe frontal headaches which thereafter occurred almost daily and required analgesics. On 10/5/61 her breasts were noticeably enlarged, secreting copious amounts of fluid. She reported also a ravenous appetite and a rapid gain in weight from 130 lbs. on admission to 149 lbs. on 10/9/61.

On 10/9/61 thioridazine was discontinued; headaches stopped on 10/12/61. A gradual loss of weight to 141 lbs. and decrease in the size of the breasts followed. Thioridazine was begun again on 11/7/61 and the daily dose was gradually increased from 200 mgm. to 800 mgm. On 11/20/61 she reported that headaches had returned and on 11/25/61 that her breasts were again enlarging and secreting fluid. Her weight then was 147.5 lbs. Normal menses occurred during her hospitalization. Flow of colostrum and headaches did not recur after 11/27/61 despite continued

¹ Psychiatric Service, Harbor General Hospital, Torrance, Calif., and the Dept. of Psychiatry, Univ. of California School of Medicine, Los Angeles.

use of thioridazine for one month after discharge on 11/29/61.

Case 2. A 29-year-old chronically schizophrenic woman was hospitalized on 9/26/61 because of overwhelming fears of impending death and of harming others. Prior to this, while being treated as an outpatient with prochlorperazine (Compazine) she had noted intermittent galactorrhea and recurrent severe frontal headaches which had raised concern about a possible brain tumor. It is interesting that during this period prochlorperazine was repeatedly started and stopped on the advice of various physicians who saw her. With this exception, headaches were not prominent in her past history. Physical and neurological examinations, routine laboratory studies, spinal fluid, EEG and skull x-rays were within normal limits. Beginning 10/6/61 she was given thioridazine, 600 mgm. and later 1000 mgm. per day. Soon she improved markedly. On 10/20/61 she complained that "milk" was flowing from her breasts which were firm and enlarged. Severe, prolonged, frontal headache, occasionally associated with nausea and vomiting, occurred almost daily between 10/22/61 and 12/17/61 when it finally disappeared. Enlargement of the breasts persisted, but colostrum no longer drained spontaneously. Her weight rose from 190 to 194 lbs. then slowly returned to 190 lbs. Normal menses occurred during the hospitalization.

Because of the patient's still tentative improvement, thioridazine was not discontinued. The patient was discharged, improved, on 12/21/61. Four months later while still on thioridazine she showed some persistent enlargement of her breasts, but headaches and weight-gain had not recurred.

The occurrence of galactorrhea and weight-gain in certain patients receiving phenothiazine drugs has been attributed to activation of the hypothalamic-pituitary mechanisms. Presumably a temporary, partial, hypothalamic inhibition is followed by pituitary release (6, 8). The phenothiazine-

induced headache has not received attention in the literature. We wonder if it also may not be of pituitary origin, akin to the headache of acromegaly, and due to engorgement and stimulation of the gland. In any case, one notes that a certain "escape effect" seems to occur and that breast changes, headache, and weight-gain tend to subside, even though administration of the drug in high dosage is continued. Certain practical diagnostic considerations need to be kept in mind in connection with these phenomena. Severe, persistent frontal headache occurring alone or together with galactorrhea, may raise concern about a possible brain tumor. Headache that is somewhat less severe and insistent and occurs alone may be ascribed erroneously to emotional factors and prompt the physician to increase the dose of the ataraxic. Breast enlargement, weight-gain, and amenorrhea (sometimes seen together with a positive pregnancy test (3, 4)) may falsely indicate an early pregnancy.

A TOXIC REACTION TO COMBINED ELAVIL—LIBRIUM THERAPY

FRANCIS J. KANE, JR., M.D., AND TERRY W. TAYLOR, M.D.¹

It is now known that fatal toxic reactions can occur with combined drug therapy of

depression, particularly involving the use of Tofranil and MAO inhibitors together (1). No previous cases of toxicity have been reported with the combined use of

¹ University of North Carolina, Dept. of Psychiatry, Chapel Hill, N. C.

Librium and MAO inhibitors(2).

A 48-year-old married man was admitted to the psychiatric inpatient service of the North Carolina Memorial Hospital on 11/6/62, because of persistent depression and inability to function as formerly. He had been hospitalized in Sept. 1962, at his local hospital because of this depression, was put on Elavil, 75 mg. daily and Librium, 30 mg. daily, had improved and been discharged. At home he worsened, increased his medication to 40 mg. Librium and 150 mg. Elavil daily, and was noted thereafter to become forgetful, confused, speak with slurred speech, and seem incoordinated. He was accused of being drunk on several occasions. On admission the patient was cooperative, oriented, and showed no serious affect depression. He abstracted in a concrete fashion, and made serious errors on serial subtraction. He also complained of diplopia while playing ping-pong. Physical examination revealed slowed speech, hand tremor, coarse 60/minute tremor of both hands, worse on attempted performance of task, adiadochokinesia on the left, dysmetria bilaterally on finger-nose testing. He needed two hands to put his cigarette in his mouth. EEG was within normal limits, x-rays of the skull showed slight pineal shift of no significance clinically. Neurological examination on 11/16/62, showed clearing of most of the physical signs except for the slight incoordination that was generalized. Psychological testing revealed definite impairment of fine motor and visual motor coordination and some cortical impairment shown by impaired ability to abstract, as well as some difficulty with memory. Depression was not prominent. He was dis-

charged on 12/18/62, much improved with no residual symptoms, mental or physical.

This patient showed a moderate acute brain syndrome associated with considerable impairment of motor coordination suggestive of cerebellar disfunction. Since Librium has been known to cause ataxia, it seems possible that this may be an exaggeration of this known side effect. The concomitant use of Elavil in large doses may be related casually to this exaggerated response. It is of interest that a case similar in many respects has been reported with Reserpine therapy(3).

SUMMARY

The occurrence of an acute brain syndrome with evidence of cerebellar dysfunction following the ingestion of Librium and Elavil concomitantly would seem to indicate an enhancement of the toxic effect of these drugs and would indicate extreme caution in their use together. The occurrence of similar incompatibilities among drugs used and the treatment of depression is well known and fatalities have been reported.

TOXIC PSYCHOSIS DUE TO IODOFORM

ALAN L. MORGENSTERN, M.D.¹

Psychiatric symptoms due to iodoform toxicity were better known to surgeons of previous generations than they are to psychiatrists of today. Iodoform was more widely used several decades ago and the best descriptions of its toxic effects are found in textbooks of that era. There are no references to the mental symptoms of

iodoform toxicity in the current psychiatric literature.

Psychotic depression was suspected in a 68-year-old woman on a general surgery ward and psychiatric consultation was requested. The patient had come to the hospital 4 months previously for removal of a malignant melanoma of the right sole; there were no signs of metastasis. She returned 2 months later for perfusion of the right lower extremity, right groin dissection, and skin grafting. To stimulate healing of the sites of surgery daily packing

¹ Medical Center, University of Colorado, Denver, Colo.

1963]

with iodoform gauze was begun. In the next several days the patient's pleasant and alert state of mind changed drastically. She appeared depressed and soon was so uncommunicative and confused that the possibility of a functional psychosis was considered. Her previously good appetite disappeared and she refused all nourishment. The patient wandered around the ward and had to be led back to her bed; she was more confused at night and slept poorly. During this time her pulse varied from 80 to 120 and temperature from 36.0 to 37.5; respiratory rate and blood pressure remained normal. Repeated physical and laboratory examinations failed to reveal the cause of her worsened condition.

When the patient was seen in consultation she was delirious. She thought the year was 1898 and that she was in her home town; she had no understanding that she was sick and in hospital. A daughter was the only family member she recognized. Recent and remote memory were severely impaired and other measures of intellectual functioning were similarly compromised. It was possible to learn from the patient that she did not feel guilty and that she was neither hallucinating nor delusional.

It was suggested that the patient's delirium might be caused by iodoform and accordingly vaseline dressings were substituted. Within 4 days she was normally alert and all evidence of delirium had disappeared. During these 4 days she was helped to eat and drink and no medications were given. The patient later underwent more surgery without unusual mental symptoms.

Iodoform (triiodomethane) was discovered in 1828 and first used as a remedy several years later. It was introduced into the U.S.P. in 1870 and by that time was being used mainly as an antiseptic. Therapeutics textbooks of the end of the 19th century discuss in detail the delirious re-

actions of iodoform sensitivity². Older patients are most susceptible. The early symptoms are anxiety and depression which are followed by restlessness and insomnia. Mania occasionally occurs. Delirium follows the early symptoms and may be accompanied by visual hallucinations and persecutory delusions. The delirious patient usually has a small and rapid pulse despite normal temperature and respiratory rate. If the cause of the delirium is not discovered coma and death may result.

Most cases of iodoform delirium occur in patients who have large abraded or ulcerated surfaces painted with the drug or have abscess and other cavities packed with iodoform gauze. The symptoms are thought to be due mainly to hypersensitivity to the iodoform absorbed. In addition the alkaline and protein fluids of the body hasten the drug's decomposition into iodine and iodides which may exert toxic effects, including action on the thyroid.³

The treatment of an iodoform delirium rests on the discovery of its cause and prompt removal of the drug. No really practical laboratory test is available to help in diagnosis. While the patient is recovering only general supportive measures are required.

SUMMARY

Toxic psychosis due to iodoform hypersensitivity is uncommon and is rarely recognized. It generally occurs when the drug is painted on large surfaces which allow its absorption or when iodoform gauze is used as a packing in cavities. This case showed the typical mental symptoms of depression followed by delirium. The treatment is removal of the drug and general supportive measures until recovery is effected.

COMMENTS

THE RELATION BETWEEN MONEY AND SERVICES

"Action for Mental Health" has had excellent effect in furthering popular knowledge of the needs and opportunities for development in the mental health field. In program, its primary stress was on treatment beginning closer to the home of the patient and, whenever possible, on its being completed within the range of the home community. This aim was assumed to be within the possibility of accomplishment to such an extent that the familiar large mental hospital with its load of custodial cases would have to be turned over for other use; a projected history something like that of tuberculosis hospitals was formulated. The change from present systems of treatment to the one envisioned was expected to cost triple current expenditures. And for the most part, "Action" left the matter there. Little or nothing was said about the administrative structure of the services to be built for the recommended local development, nor of the way the various sorts of personnel were to be organized to furnish service to the public.

The President's remarkable address to Congress on mental illness and mental retardation of February 5, 1963, helps to fill the gap "Action" left unfilled by proposing mental health centers as the primary unit to furnish local services. The message contemplates two possible loci for these centers, the general hospital (since it is mentioned first it may be assumed to be preferred) and a separate institution offering multiple services. But the administrative structure for the local service remains unclear. Citizens of communities could rightly have taken umbrage if the President or any other federal governmental authority had been explicit as to what the local organization should be. The fact remains, however, that the political authority suggested a more specific way of filling the gap between the money and the services than did the professional report, "Action."

It still appears to be a popular fad in psychiatry that administration is of a lower

order of practice than therapeutics; this notion probably accounts for the failure of "Action" to have tackled the problems of the gap between money and service in any telling fashion. Administration did get more than the usual amount of attention in December's Conference on Psychiatric Education; perhaps this is evidence of a changing point of view that will give more respect to the way things can get done. Advance in knowledge demands that some men protect themselves from the real world of pressures of service and devote themselves to research, but sometimes it appears that not love for basic research but unwillingness to accept the profession's responsibility for service has been the controlling interest.

Many administrators have pointed out that it is often quite impossible to distinguish between the psychological principles used in administration and those used in therapy, particularly if one includes group therapy. In both instances, the ultimate object is to obtain action, behavior, that will lead to relief of a problem. The difference is not so much in principles as in the selection of who is to get the attention. According to the popular stereotype of individual therapy, the selection of the patient he will accept is made by the therapist. Even outside this group, the patient will be seeking treatment or others will be seeking it for him; a direct need for service is recognized. In administration, the people to be worked with are selected by others, the electorate, the group of directors of a private agency, the elected legislature or board of county commissioners. The administrator works for the most part with people selected primarily for reasons other than promoting community mental health. Too frequently, he works with people quite unmotivated to accept his aims for mental health services for the community.

The skills and methods of administration are designed first to enable the administra-

tor to improve the motivation of these sorts of persons to consider the problems of the community in the area of responsibility he represents. When he has their attention, he has the opportunity to present his suggestions for the needed change, improved and extended services. He is working with a tenuous motivation which might be considered as something like an ambivalent transference. In this situation, his proposals must be actionable, specific. If, for example, a mental health center is desirable, its mode of operation and cooperation must be specifically spelled out, its financing clear and its capacity for helping defined in terms of needs to be met in the place where it is to be. The lesson of the Fountain Committee must be learned,

namely, that the "common man" does not expect the scientist to be any more pure and high-minded than he, the "common man," is. Just as the ordinary citizen is expected to budget, so the scientist is expected to plan so that ends meet. The challenge to administration is to fill the gap between the need for money and the need for services with a workable administrative structure in the realm of the "art of the possible." Psychiatry cannot abhor the administrative vacuum, nor ignore its challenge; it must fill it or be displaced by someone or some group which does see the function of administration as the challenge to skill in human organization it presents.

Paul V. Lemkau, M.D.

RULES OF CONDUCT

The end of society is peace and mutual protection so that the individual may reach the fullest and highest life attainable by man. The rules of conduct by which this end is to be attained are discoverable—like the other so-called laws of Nature—by observation and experiment, and only in that way.

—THOMAS HUXLEY

NEWS AND NOTES

SIXTH EUROPEAN CONFERENCE ON PSYCHOSOMATIC RESEARCH.—This conference will take place in Athens, Greece, May 6-8, 1964. The main topics will be: (1) Psychosomatic Aspects of Heart Diseases; (2) Gynecological Problems (Frigidity-Sterility-Painless Childbirth) and their Psychosomatic Aspects; and (3) Skin Diseases from the Psychosomatic Standpoint.

A section of free papers will also be arranged. The official language of the Conference will be English, but a speaker may use French or German if his paper, translated into English, is available for all the congress members.

Address all correspondence to: George S. Philippopoulos, M.D., 4 Monis Petraki St., Athens (140), Greece.

THE ACADEMY OF PSYCHOSOMATIC MEDICINE.—The Academy is meeting in San Francisco, Oct. 17-20. Arrangements are being made for a pre- and post-convention tour, with a seminar in Chicago on Oct. 15, and a seminar cruise aboard the S.S. *Lurline* from San Francisco, leaving the night of Oct. 19, and a seminar in Honolulu, Oct. 25. The party will fly back to the mainland on the 27th. Any persons interested in taking part in this cruise should contact Dr. James L. McCartney, 520 Franklin Avenue, Garden City, N. Y. for details.

DR. OVERHOLSER HONOURED BY THE AMVETS.—This organization, made up of veterans of World War II and the Korean War, at their recent national convention presented their Silver Helmet, an award in the field of rehabilitation, to Dr. Winfred Overholser, long-time superintendent of St. Elizabeths Hospital, "in recognition of his unsurpassed dedication and superb contributions to man's eternal struggle against man's greatest enemy—mental illness."

THE AMERICAN NEUROLOGICAL ASSOCIATION.—The 88th annual meeting of the Association will be held at the Claridge Hotel, Atlantic City, N. J. June 10-12, 1963 under the Presidency of Dr. Charles

Aring. Programs may be purchased at the time of the meeting or mailed from the Secretary's Office after May 15th at a cost of \$2.00. Information may be obtained from the Secretary, Dr. Melvin D. Yahr, Neurological Institute, 710 West 168th Street, New York 32, New York.

The Fulton Society will hold its first annual meeting on Sunday, June 9th at 2 P.M. at the Claridge Hotel.

The meeting of the American Association of Neuropathologists will be held June 8-9 at the Hotel Dennis, Atlantic City. Inquiries regarding this meeting should be directed to Dr. Irwin Feigin, Secretary, 550 First Avenue, New York 16, New York.

STANFORD UNIVERSITY SCHOOL OF MEDICINE, PSYCHIATRIC FACULTY.—Four senior appointments to the Department of Psychiatry have recently been made: 1) Dr. Seymour Levine from the Institute of Psychiatry, Maudsley Hospital, London, whose special interest is the biological analysis of behavior development; 2) Dr. William C. Dement from the Department of Psychiatry, Mt. Sinai Hospital, New York who is interested in the biology of sleep and wakefulness; 3) Dr. P. Herbert Leiderman from the Department of Psychiatry, Harvard University, who will soon join the staff, is mainly interested in the effect of social environment on individual behavior and physiologic processes; and 4) Dr. Raymond B. Clayton, Department of Chemistry, Harvard University, to arrive in the summer, who will work on biochemical studies in brain function and behavior.

AUTHOR'S REQUEST RE DR. JUNG LETTERS.—Dr. Gerhard Adler has been entrusted by the heirs of the late Dr. C. G. Jung with the editing of his correspondence, and would be most appreciative if anyone possessing letters would communicate them to him at the Bollingen Foundation, 140 E. 62nd St., New York 21, N. Y.; either originals (which will be returned immediately upon being copied), or photocopies (any expense incurred in making copies will be

refunded). It is not intended to publish material of a strictly personal nature, and correspondents may indicate whether any parts of the letters should for the present be withheld from publication.

THE AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY, INC.—The following are new Diplomates who successfully completed the Board examinations given in New Orleans, La., Mar. 30, Apr. 1-2, 1963:

BOOK REVIEWS

SARTON ON THE HISTORY OF SCIENCE. Edited by *Dorothy Stimson*. (Cambridge: Harvard Univ. Press, 1962, pp. 383. \$10.00.)

George Sarton (1884-1956)^a was the founder of the modern study of the history of science. The journal he founded, and maintained at his own expense for the greater part of his association with it, *Isis*, is the most famous international journal on the history of science. Almost every issue of that journal was preceded by a preface written by Sarton. In the whole files of the history of science there was and is nothing comparable to those prefaces. Many a subscriber to the journal was led to become one by the accidental reading of one of those prefaces. Like nothing else that Sarton so ably wrote, they gave the character of the man: a combination of charm, idealism, poetry, and a rigorous addiction to truth and the methodology of science as applied to the study of the history of science.

Before his death Sarton drew up a list of his contributions to *Isis* which he thought might be worthy of reprinting. It is from that list that the present volume is made up. Articles on the scientific basis of the history of science, Avicenna, Maimonides, Leonardo Da Vinci, Simon Stevin, Montucla, Quetelet, Bonpland, Moseley, on the reviewing of learned books, iconographic honesty, remarks concerning the history of 20th century science, and much else, go to make up this highly readable sampling of a great man's work. It makes for the best kind of reading.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

THE ROLE OF SCHOOLS IN MENTAL HEALTH. By *Wesley Allin Smith*, and *George W. Goethals*. (New York: Basic Books, 1962, pp. 337. \$7.50.)

This volume is the seventh in the series of reports by the Joint Commission on Mental Illness and Health. It represents a vast amount of work in surveying the literature on education and mental health, over 5,000 books and articles being reviewed for this project. Two audiences were kept in mind by the authors—professionals in the fields of education and of mental health and citizens without special training who are interested in the topic. Nevertheless, it is of vital interest to any psy-

chiatrist who is concerned with the prevention of mental illness through improvement of conditions in society which predispose people to crippling emotional conflict.

The authors seek to answer the question, what if anything ought schools to do about mental health? Their discussion of the issues is sensitive and perceptive. Objections to school mental health programs are discussed with clarity and sympathy. For example, some people fear that the academic function of education may be jeopardized when teachers pay attention to emotional aspects of personality and character development. Others fear that attention to mental health promotes conformist ideas, or will cause people to "adjust" to conditions in society which should be criticized and improved.

The authors handle these and other such questions with great skill. They consider the goals of education and mental health promotion as quite compatible or even synonymous. They make a careful distinction between mental health concepts involved in teaching and the processes employed in psychotherapy. A teacher's understanding of human behavior is ideally used as a lever to enhance students' learning in every aspect of the curriculum.

In the ideal form of training for teachers, first preference should go to grounding in the subject that is taught, followed by familiarity with methods of teaching, a grasp of psychological principles concerning intellectual development and individual differences and aptitudes, understanding normal personality development and individual differences in motivation, acquaintance with mental hygiene and psychopathology of childhood and adolescence, and, finally, personal maturity in a teacher. It would be desirable if many teachers could teach subjects related to mental health, particularly sex education, courtship and marriage, child rearing practices, human relations, and some aspects of elementary psychology. The point of view in this book is not that teachers use mental health material as a primary focus in teaching but that they be familiar with these principles in order that they may do a better job than otherwise of promoting intellectual capacity and skill in their students.

DANA L. FARNSWORTH, M.D.,
Cambridge, Mass.

CLINICAL RESEARCH DESIGN AND ANALYSIS.

By *Eugene E. Levitt* (Springfield, Ill. : C. C Thomas, 1961, pp. 199. (8.50.)

This book has been written chiefly for clinicians who need to understand research methods and the necessary statistical devices for the analysis and evaluation of research data. Beginning with a philosophy for the behavioral scientist, the author presents in order, discussions of methodological concepts, types of investigations, the designing of an experiment, the validity of construct definitions, the experimental sample, statistical analysis of results, the drawing of inferences and conclusions, and suggestions on writing a research report.

The author's comments on the philosophy of science, methodology and fundamental statistical techniques apply generally as well to several divisions of biological science outside the strictly clinical field. In any research situation the objective of the project is of first importance. The more exactly and specifically the question can be formulated, the more clearly is the field of the investigator defined. It clarifies the issue and should reveal what the worker is really trying to find out. It constitutes the essential prerequisite of reliable research work.

The science of the experimenter must be systematic, mechanistic, materialistic, objective, verifiable and communicable and, therefore, the design of the experiment should not resemble a mixed grill of viands. Research data may be far more valuable for use in fields for which they were not intended, therefore they should be presented in a form that the conclusions can be checked by any qualified person. Statistical analysis is a necessary "tool" in most investigations, but it is all too frequently not handled efficiently.

The book is pragmatically oriented. The information is extensive, accurate and clearly presented. It should be very useful for beginners in research and for many others among the hordes entering the now popular field of experimental testing of neuro-psychopharmacologic drugs. It represents an effort to create an attitude of more rigid definition of research problems, the formulation and conducting of experiments, the nature of the conclusions drawn and the ways of reporting the results. In places the sophisticated researchers will find it rather elemental and over-simplified, but if the principles were followed by all concerned it should cut down a great deal of the sterile, dragnet "fox hunting" or "Easter egg hunting" types of approach.

Charles W. Eliot of Harvard said, "The human race has more and greater benefits to expect from the successful cultivation of the sciences which deal with living things than from all the other sciences put together." Reliable research intelligence and long term thinking are needed now (1962), perhaps, as never before.

NOLAN D. C. LEWIS, M.D.,
Frederick, Md.

MALPRACTICE LAW DISSECTED FOR QUICK GRASPING. By *Charles L. Cusumano*. (New York : Medicine-Law Press, 1962, pp. 130. \$10.00.)

In view particularly of the growing number of malpractice suits being brought against physicians (and psychiatrists are *not* immune ^f), a book of this sort is welcome. The pages are letter size (8 x 10½ inches), and printed in double columns, so that a truly impressive mass of material is presented. The author, a veteran lawyer of 30 years' trial experience, marshals his information succinctly, in readily comprehensible language, and under clear and concise headings.

There are 28 chapters, dealing for example with the relationship of physician and patient, the duties of the physician toward the patient, common and other malpractice grounds, physicians' defenses, consent to treatment, abortions, liability of the physician for restraint or commitment of the mentally ill, and (most important) protective suggestions for physicians. There are also chapters on the liability of dentists, nurses and hospitals. The index is thorough, and a bibliography is added for further reference to various aspects of the law of malpractice.

The book does not purport to be compendious, but it is an extremely useful general treatment by an expert of a subject which is of vital interest to every physician in practice, regardless of specialty.

WINFRED OVERHOLSER, M.D.,
Washington, D. C.

DIE PSYCHOTHERAPIE IN DER PRAXIS. By *Viktor E. Frankl*. (Wien : Franz Deuticke, 1961, pp. 256. OS 148.)

Viktor Frankl's writings dispel a lot of doubt about the feasibility of the new, existential approach in psychiatry. This approach has been accepted in many psychiatric centres of Western Europe and it is spreading, slowly and cautiously, to North America. Here, it seems to be more criticised than studied. Existentialism is misunderstood as an intrusion of an alien

philosophy into our field of clinical psychiatry. This suspicion is not justified. Existentialism is not opposed to any other system, dynamic or organic. It only emphasizes the need for a truly holistic concept of man.

Frankl is a clinician, and he demonstrates how existential attitudes may be applied in psychiatric practice. He does not leave the secure ground of empirical observation. He sees and treats the whole person. For him the human being is not only his body and his mind but something more which is called the spiritual dimension. As psychiatrists we are inclined to shrink away from whatever is called spiritual, because this word has a religious connotation. To avoid this confusion, Frankl ingeniously uses a neologism. He speaks of noëtic phenomena and noödynamics.

Frankl teaches that man is motivated not only by Freud's will to pleasure and Adler's will to power but also by a will to meaning. Man has to find the meaning, the unique sense, of his living. The loss of a sense of being causes an existential vacuum which may produce a noögenic neurosis. These patients can be helped by the special type of psychotherapy which Frankl calls logotherapy (logos—meaning).

The second, revised and supplemented edition of his *Psychotherapie in der Praxis* gives a clear presentation of logotherapeutic concepts and procedures. The reader who abhors any noödynamic involvement will find very interesting descriptions of Frankl's easily applicable, special psychotherapeutic techniques such as paradoxical intention and de-reflection.

G. KACZANOWSKI, M.D.,
Whitby, Ont.

RECOGNIZING THE DEPRESSED PATIENT. By Frank J. Ayd, Jr., M.D. (New York: Grune & Stratton, 1961, pp. 138.)

This is a well-written, informative book of mixed blessings. Addressed to the general practitioner it fulfills its promise for diagnostic cues in the symptoms that bring a depressed patient to the physician, and in its compendium of statistics on suicide and recurrence of post-partum depression gives convenient information well worth the psychiatrist's interest. But the critique of etiology and treatment is biased and the predepressive personality profile is misleadingly oversimplified.

The book's excellences are numerous. It gives a good phenomenologic description of some of the depressed states and recommendations on how to cope with the potential suicide. Dr. Ayd reminds us of the possibility,

rarely thought of, that some patients are homicidal. We are also given a rationale for hospitalization and suggestions for handling the patient's reality situations. A very nice point made is that the physician should not accept the patient's explanation for his sense of guilt, thereby not re-enforcing it.

However, a number of significant exceptions must be taken. Clinically, the distinction drawn between the manic-depressive and the neurotic or reactive depressive is ambiguous and even ambivalent. (Incidentally neurotic and reactive are used as being synonymous.) The distinction is based on neatly drawn personality pictures that actually predispose to erroneous application: "The manic-depressive subject to depression basically is a considerate, affable, humble, tolerant, generous, easy-going, shy and sensitive individual . . . The psychoneurotic, by contrast, is egocentric, selfish, intolerant, inconsiderate, critical, aggressive, and exhibitionistic" (p. 92).

The eye of the beholder! In the paper by Cohen, *et al.*, "An Intensive Study of Twelve Cases of Manic-Depressive Psychosis" (*Psychiatry*, 17: 103, 1954) the patient profile before and during therapy is presented as of a demanding, reproachful individual, not perceptive of subtleties, with difficulty in establishing rapport and given to stereotyped and restricted speech.

Anyway Dr. Ayd is prone to claim the so-called neurotic or reactive depressive for the organic camp. Furthermore, we are pressed to the inference that a depression which responds to antidepressant drugs is organic, one that does not is neurotic—an inference with the danger of *post hoc* reasoning.

Dr. Ayd describes only depression with rhythmic recurrence. However, it is a common clinical experience that we encounter patients with a depleting, persisting, moderate depression. By this oversimplification, he is enabled to use the rhythmic recurrence as though it is evidence of an exclusively organic etiology.

Further oversimplification: Mention of the fact that the obsessive personality occurs both in the pre-schizophrenic and in those with never a psychosis is omitted. The practitioner left with a sense of a one-to-one correlation that may help him detect the depressive may make him argue himself out of recognizing the ambulatory schizophrenic.

The troubling question of the etiologic factors in the depressive states is met by a dogmatic, straight, organic answer. The work of psychotherapists toward the psychogenesis, psychodynamics and therapeutic effectiveness in depressions is dismissed with less than faint

praise. Though Dr. Ayd states, "No definite pathology has been established for affective disorders, but the clinical observations of recent years, have given substance to the hypothesis that there is a neurophysiologic basis for this illness" (p. 6), and again "The importance and influence of altered cerebral physiology in determining the emotional symptoms of a depression cannot be stressed too much" (p. 49).

However, it is not disproved that the psychogenic may be the prior condition for disturbing the diencephalic mechanism, since we are psychosomatic beings and not disembodied abstractions.

Strained interpersonal relationships are presented only as the result of a physiologic illness. The familial incidence of depressive reaction cited is accounted for as hereditary and the contrary hypothesis, about emotional interaction within a family as subculture affecting the personalities of all its members, is not even mentioned.

Dr. Ayd engages in the paradox of attacking psychotherapy of depressives when practiced by psychotherapists, but sanctioning it by the general physician, at least as a supportive reassuring variety. "There is no valid evidence . . . that any type of psychotherapy will prevent or reduce the risk of recurrence (p. 19). Without critical analysis of cases, this position must remain simply the author's slanted assertion. This writer has contrary experience of the swift alleviation of fairly severe depressives in long range psychotherapy without drug therapy and well within the 6 months mentioned by Dr. Ayd as the spontaneous course of the disorder.

In short, this book excels in helpful practical pointers for the general physician but the oversimplification and the dogmatic position taken can be misleading and discourage an open mind about inquiry into depression.

ROSE SPIEGEL, M.D.,

THE CRY FOR HELP. Edited by Norman L. Farberow, Ph.D., and Edwin S. Schneidman, Ph.D. (New York, Toronto, London: McGraw-Hill, 1961, pp. 398, incl. bibliography, indices. \$11.75.)

This is a book about suicide. It is based on the work of the Suicide Prevention Center in Los Angeles. Including the editors, 14 contributors account for the text. The discussions include statistical studies, suicides in schizophrenia, medicolegal questions, equivocal suicide deaths, survey of suicide prevention agen-

cies in general and the one in Los Angeles in particular.

There has been no agreement around the world, either in past times or now, in social attitudes toward the suicidal act, social consequences that are on record, religious attitudes, if any, and notably legal and medical judgments as to the mental state of the suicide. And the specialist who tries to look into the mind of the suicidal person, or to guess, after the fatal event, what was in there, is not likely to be very successful.

For example, there is no reconciliation between the position of the rigid clinician who insists that the suicidal act is in itself and always a symptom of mental illness and the broader view of those, whether psychiatrists or not, who are persuaded that in the absence of other evidence pointing to an unscand mind, the self-determined end of one's life may not be simply an act of clear reason. Perhaps the not least unintelligent of coroners' reports was one that stated: The deceased came to his death by his own hand for reasons best known to himself.

The authors estimate that each year some 6000 persons in Los Angeles County make serious suicidal attempts. It is with those who are hospitalized that the staff of the Suicide Prevention Center (SPC) is mainly concerned. The work of SPC they describe in this book. The description is comprehensive with endless details—all interesting, and many important.

The well recognized numerical discrepancy in attempted and successful suicide between males and females is shown by these figures for L. A. County, 1957: attempted suicide—males 828, females 1824; committed suicide—males 540, females 228. These figures represent documented cases, not the total number known to have occurred.

A schedule is presented containing the questions one must try to answer in evaluating the suicidal risk in any given case in order to determine appropriate measures to be taken.

The authors emphasize the need for more information about prodromal symptoms that so many suicidal persons show in advance of the suicidal act. For obvious reasons these manifestations are difficult to come by. Those who have observed them are prone to minimize their importance and recall them too late.

Knowledge that the SPC exists in the community prompts telephone calls from friends or relatives of suicidally inclined persons and often the patient can be brought in for consultation and any necessary action can be taken. The SPC has established working relations with more than 50 health and welfare agencies

and resources in Los Angeles with gratifying results. At the time of writing the SPC hoped but was not yet financially able to establish a 24-hour psychiatric service for suicidal persons.

One function of the SPC is to clear up myths and gross misconceptions about the act of suicide and suicidal talk or threats.

Beside the Los Angeles Center, established in 1958, several others are described in this book, those at Boston, London, New York, Vienna, West Berlin; and in addition there are published telephone numbers in a number of large cities which persons needing help can call.

The text portion of this book is in two parts. Part I, *The Community Response to the Cry for Help* (pp. 149), contains the solid social and medical work the SPC is doing in Los Angeles, only a few salient features of which are here mentioned. Part II, *The Psychotherapeutic Response to the Cry for Help* (pp. 169), is a very curious section. Here psychiatry becomes splintered. Beginning with Freud and his defectors, also two psychologists—eight in all—theoretical material is presented by disciples of these several systems. The authors placed before these selected commentators a specimen case history which had been compiled by asking the patient questions and then interviewing his mother. Both of these answered after their own fashion. The history thus obtained, although of ample length, was quite superficial. On the basis of this information the respondents were asked to interpret the case of this patient whom they had never seen, and to make psychotherapeutic applications according to their several theoretical systems. What purpose this great mass of speculative material could serve in relation to the essential work of the SPC is difficult to discern. This section simply presents condensed statements of eight varieties of psychotherapy currently in practice.

The patient who was unwittingly the basis of this voluminous esoteric exegesis was discharged from the general hospital three days after the SPC psychiatrist had finished interviewing him and before he could be subjected to any or all of the specialized regimes described in Part II. Follow-up was thorough but in vain. Neither the patient nor his parents could be reached. Letters remained unanswered, "he and his parents simply seemed to have disappeared from Los Angeles . . . At least he has not appeared on the suicide lists of the Los Angeles County Coroner to date."

A bibliography classified under the headings: Psychological — General, Sociological,

Medico-Legal, Religions-Philosophical, and filling 60 pages closes the book.

C. B. F.

AN INTRODUCTION TO PSYCHIATRY. 2nd Ed. By *Max Valentine*. (Baltimore: Williams & Wilkins, 1962, pp. 316. \$5.00.)

This admirable small manual in a soft leatherette binding covers with great clarity the major problems of the clinician and private practitioner. The author starts with the milestones in the progress of mental healing, from the beginning of recorded history (3000 B.C.) to date. Throughout the 20th century only seven names are mentioned in the neurology column: Sherrington, Alzheimer, Cushing, von Economo, Dandy, Cannon and Penfield. For the same period 17 names are recorded in the progress of psychiatry, including Adler, Jung and the therapists Sakel, Cerletti and Moniz, of lobotomy fame. Valentine begins modern psychiatry with Galton (1879) and Freud is pushed back to the 19th century (1893).

He discusses mind and body, instinct and emotion, the innate release mechanism and perception, including gestalt. Perceptual recognition is influenced by inner drives. He accepts Ashby's theory that the knowledge of a person's awareness is prior to all other forms of knowledge. Emotional correlates affect the body systems. The phylogenic development of emotional response has an adaptive value. He distinguishes in the etiologies the genogenic, thermogenic, histogenic and emotogenic.

The chapter on case-taking and symptomatology is given in greater detail. In personality development the psychoanalytical approach is evident. In child psychiatry he finds two major problems, the developmental and behavioral. In the psychiatric syndromes of the adult, he elaborates anxiety, depression and obsession.

For mild depressions he advises the amphetamines and ritalin. He discourages the use of the iproniazids. He favors a return to the use of ECT in depressions. Hysteria and sexual abnormalities are prominently presented. The author has not given up, evidently, the inclusion of "anorexia nervosa" as a psychiatric entity in the existence of which we, in America, do not believe.

In the further chapters the author discusses schizophrenia and other psychoses together with psychopathy, while the chapters on treatment are rather condensed. The last chapters treat mental tests, mental subnormality and forensic problems.

Every chapter is accompanied by an ample

bibliography ("references" and "further reading"): The small, convenient pocket-sized book covers the same field as the larger texts, but with more clarity and practicality.

HIRSCH L. GORDON, M.D.,
New York, N. Y.

VALUES IN PSYCHOTHERAPY. By Charlotte Böhler, Preface by Edward J. Stainbrook. (New York: Crowell-Collier, 1962, pp. 251, \$6.95.)

Psychotherapy, as the contact of two or more people, has the purpose of restoring the patient(s). Restoration to what? Here is the problem to which Charlotte Böhler has devoted her present book.

In first approximation, one may speak of values, of guideposts necessary for navigation in the storms of life. We all have a basic experience of the righteous and the wrong way of life. Without this, the question for the special forms of ethics and ethical values would be senseless. Even if we cannot theoretically understand or practically orient our actions on the values we recognize, we could not discuss any form of absolute or subjective or relativist or sceptical ethics, unless we advert to the primary experience of the righteous. Granting that without values psychotherapy is impossible, the next question is, what should be the role of the psychotherapist? Böhler has given us a valuable survey of the various attitudes from the older psychoanalytic activism, the belief in the automatic reorientation of the patient on new behavior patterns, up to more recent tenets of Freud himself and many of his modern followers together with glimpses at the beliefs held by existentialists. Of late we have come to acknowledge that sooner or later one has to "push." The "mechanisms" that may be used by the psychotherapist, such as identification, transference, creating a new initial neurosis, on top of the old one, are discussed. This reviewer wants to mention Rudolph Eckstein's lucid reflections on parallels between the therapeutic and the social processes. Eckstein bases his ideas mainly on the analogies developed by Freud in the first edition of his *Traumdeutung (Interpretation of the Dreams)*. Eckstein finally asks, what is the structure of the external world to which the organism has to adapt? However, adaptation is only one of the values.

The survey of the theories on: When is a patient to be considered cured? shows that at present we have no more of a system of values or the patient's valuations than we are possessed of a generally accepted definition of mental health (see Marie Jahoda: *Current*

Concepts of Positive Mental Health, 1959).

Böhler winds up with the modest statement "in enumerating five frequent and typical situations (between therapists and patient) . . . I do not claim to have answers, I merely raise questions." The book, in fact, contains most interestingly described cases and a survey of the ideas, rife among psychotherapists, for both of which we must be grateful.

W. G. ELIASBERG, M.D.
New York, N. Y.

A STUDY OF PSYCHOPHYSICAL METHODS FOR RELIEF OF CHILDBIRTH PAIN. By C. L. Buxton. (Philadelphia: W. B. Saunders, 1962, pp. 116.)

It is fortunate that a writer of Dr. C. L. Buxton's experience and qualifications has undertaken such a study. As Professor of Obstetrics and Gynaecology at Yale University School of Medicine, he is eminently fitted both by the experience in their own obstetrical unit and his opportunity to compare various methods for relief of pain in childbirth. As a result of a year's study in various centres in Europe, Britain, and the United States, he objectively approaches the comparison and analysis of the various methods employed. Consideration is given to the programme of "Natural Childbirth" outlined by Grantly Dick Read and Helen Heardman emphasizing psychological education and physical preparation for this event. The original Russian method of psychoprophylaxis involving a sublimation of pain at the cerebral level is compared with autogene training which is characterized by psychic and somatic relaxation to the point of self hypnosis. Hypnosis itself is considered as well.

Specific programmes at individual institutions rely more or less on one of these techniques or combinations of features from several being adapted to the local needs. It is almost impossible to objectively assess the result of such programmes, but there must be general agreement that psychological education and physical preparation is fine training for any event in life whether it be childbirth or the tests and problems confronting us daily. Perhaps the most important value of such an assessment is to emphasize the variation in individuals and the consequent variation in meeting their needs. No single programme can be adapted to all patients and the selection of what is best for each individual presents a real challenge to the attending medical and nursing staff. As Dr. Buxton concludes "It [psychophysical training] will merge almost imperceptibly into the over all concept of good prenatal and intrapartum obstetrical care so

and controversial identity and still retain all that it will lose its present possibly militant of its essential advantages." Everyone interested in good obstetric care will find this volume extremely thought provoking and helpful in placing both psychophysical and pharmacological methods for relief of pain in childbirth in a rational perspective.

W. H. ALLEMANG, M.D.,
Toronto, Ont.

ELECTRODIAGNOSIS AND ELECTROMYOGRAPHY. Second Edition. Edited by *Sidney Licht*. (New Haven, Conn.: Elizabeth Licht, 1961, pp. 470. \$12.00.)

The second edition of this book dealing with the application of physiological techniques in the diagnosis of neuromuscular disorders has been considerably revised. The list of contributors has been expanded and chapters dealing with equipment and several new techniques have been added.

The first part of the book includes an excellent chapter on apparatus and basic electrical theory necessary for the understanding and proper application of the electronic equipment used in the various procedures. Concise accounts of the physiology and histology of skeletal muscle and nerve are presented. A new addition is a well illustrated description of the normal histology and pathology of motor endplates and small intramuscular nerves. While one cannot agree with the author that this technique will replace a routine muscle biopsy, the changes found will be of interest to those unfamiliar with the recent reports in the literature.

In the second part of the book, methods for the determination of chronaxy and strength duration curves are presented fully. Two chapters are devoted to electromyography. There is considerable redundancy, and precise accounts of all the varied aspects of muscle function recorded and measured by electromyography are not clearly stated. Another section covers motor and sensory nerve conduction and provides a complete account of this new and valuable method and the author's wide experience. Short introductory descriptions of electroencephalography and electroretinography complete the volume.

This book will be of interest to those physicians and surgeons undertaking the investigation and treatment of patients with injuries and disorders of peripheral nerve and diseases of muscle. It is a comprehensive account of all the current electrical techniques and contains much useful information.

Toronto, Ont.

DISEASE AND DESTINY. A Bibliography of Medical References to the Famous. By *Judson Bennett Gilbert*. With Additions and Introduction by *Gordon E. Mestler*. (London: Dawson's of Pall Mall, 1962, pp. 535. £6.10.0.)

Dr. Judson Bennett Gilbert (1898-1950) was a urologist and scholar who spent many years in the vast bibliographic labor of collecting references to the diseases, disorders, and illnesses of the famous. The posthumously published volume contains some 12,000 references of this kind. The entries are arranged alphabetically under the names of the individuals who form the subject of interest. This is something to be grateful for, and although it is the obvious method of classification, one can imagine a classification by disease, which would have played havoc with the bibliographer's intention and the researcher's time. All students of the historiography of the afflictions of the famous will be eternally indebted to the late Dr. Gilbert for his admirable work, and to his coadjutor and editor Dr. Gordon E. Mestler for bringing this work to publication.

ASHLEY MONTAGU, PH.D.,
Princeton, N. J.

THE SCIENCE OF DREAMS. By *Edwin Diamond*. (Garden City, N. Y.: Doubleday, 1962, pp. 263. \$4.50.)

Psychiatrists usually think of dreams as expressions of unconscious hopes or fears; that is, as psychologically powered. Many other physicians prefer an essentially physiological hypothesis; or they assume that dreams are due to indigestion. In this book, Mr. Diamond, science editor of *Newsweek*, presents the case for the physiologic explanation. He summarizes the experimental work at several universities and hospitals which suggests that EEG changes are produced during dreams. It thus becomes theoretically possible to find out just when a sleeper starts and stops dreaming. On the basis of this and similar evidence, Mr. Diamond says that everyone dreams every night, that everyone has more than a thousand dreams a year, and that dreams are so hard to remember because during sleep, "the higher brain centers are taking it easy."

He notes that dreams rarely concern business affairs or world events or newspaper stories. Unpleasant dreams, he finds, are more numerous than pleasant ones, in spite of the traditional semantic implications of the word "dream." He quotes Calvin Hall as saying that "dreaming, on the whole, is not a pleasant pastime."

Why do we dream? Mr. Diamond offers an ingenious and somewhat involved teleologic explanation. It goes like this. When the hungry infant is not fed on time, he bemuses himself with a hallucinatory memory of earlier feedings. This discharges the mouth-centered tension and conditions him so that dreams become a common way of relieving all tensions. If dreams were not available, then "this would dam the pressure to the breaking point. Pressure would then burst into waking life, and inundate the conscious mind with distorted images. The senses would be befuddled and perceptions blunted. The dream cycle, on the other hand, regularly drains off these pressures before they build up dangerously. In Fisher's words, the dream 'by permitting each of us to go quietly insane every night, helps preserve the mind and ensure daytime sanity.'"

The normal operation of the brain, he suggests, requires an unbroken flow of arousal signals from the reticular formation. To provide the necessary and varied sensory bombardment is one of the functions of the dream. The visceral brain and memory constitute the storehouse from which comes "the stimulation needed to keep the rest of the brain in working order."

In reading this coldly physiologic explanation one is impressed with the author's lack of interest in possible meaning patterns. The whole interpretation, indeed, displays a kind of blunting of affect. It is this non-emotional, uncommitted, objectively measurable feature which gives it the boastful title, *Science of Dreams*. You cannot prove by similarly objective technics (EEG, for instance) that there is any meaning in dream content; but you can feel, if you cannot prove, that there is more to it than this sterile and mechanical physiologic explanation.

HENRY A. DAVIDSON, M.D.,
Cedar Grove, N. J.

PSYCHOLOGY FROM THE BIOLOGICAL VIEWPOINT. (PSYCHOLOGIE IN BIOLOGISCHER SICHT.) By W. R. Hess. (Stuttgart: Georg Thieme Verlag, 1962, pp. 120, DM 20.00.)

In this book Hess discusses in his cautious and circumspect way, whether and to what extent brain physiology can contribute to our understanding of psychological phenomena. Until recently physiology had very little to offer the future psychiatrist and neurologist. One had to be satisfied with the data supplied by morphological methods. Students, however, are interested in the processes which take place in the living brain and which are connected with the psychological events. In the course

of his extensive experimental studies on animals Hess had frequently observed that electrical stimulation as well as cauterization of circumscribed brain stem areas, particularly in the diencephalon and the hypothalamus, would produce symptoms and syndromes which showed a remarkable resemblance to behaviour patterns usually connected with certain contents of consciousness. These observations led to a systematic search for the available data on the effect of stimulation and/or destruction of cerebral structures on the one hand and psychological phenomena on the other hand. An account of these findings based on Hess' own experiments as well as on the experimental work of other workers using identical or comparable techniques is given in this book. Neurosurgical observations, mainly by Penfield, are frequently referred to. So are some observations recently made in psychopharmacology, particularly with LSD.

The book is divided into three parts. The first deals with the fundamental behaviour patterns and mental capacities of man (and certain higher organized animal species), which are defined and described in some detail as to their biological significance. The second part forms the main content of the book. It deals in great detail with the relationships between mental functions and cerebral organization as evidenced by animal experiments and clinical experience. The third part elucidates the principles which govern the relationship between mental processes and cerebral innervation patterns. The fundamental principle is the fact that the brain is endowed with the capacity to form contents of consciousness.

In the opinion of this reviewer Hess' book should be interesting not only to medical students, but to everybody seriously interested in the mind-body problem. It is a thought-provoking book.

V. A. KRAL, M.D.,
Montreal, Canada.

DIE PFLEGE DER GEMÜTS-UND GEISTESKRANKEN. By Walter Morgenthaler. 7., völlig neu bearbeitete Auflage unter Mitarbeit von Dr. F. Singeisen. (Bern und Stuttgart: Medizinischer Verlag Hans Huber, 1962, pp. 360.)

Dr. Morgenthaler was a junior staff member of the University Mental Hospital Waldau in Bern when, in 1908, he had the idea of organizing a course for the hospital's staff of psychiatric nurses and attendants. The Personnel Association of Swiss Mental Hospital Attendants launched a campaign to have a similar course made obligatory in all Swiss mental hos-

pitals. Dr. Morgenthaler was almost the only psychiatrist to promote this, and in spite of much professional and political opposition the program was started in 1925 and Dr. Morgenthaler published the official textbook in 1928.

Dr. Morgenthaler was a pioneer in many fields. He was one of the first to systematically study the artistic achievement of psychotics and to collect their paintings. A schizophrenic patient in Waldau, Adolf Wölffli, had become famous for his paintings even in artistic circles. Morgenthaler wrote about him a well-known illustrated monograph "Ein Geisteskranker als Künstler" (1921). He also organized a psychiatric museum in Waldau Hospital where he collected paintings by psychotic patients as well as a unique collection of authentic old restraining and "shock therapy" devices.

Morgenthaler was the first to recognize the merits of Hermann Rorschach's ink-blot test. Without his help, Rorschach would never have been able to publish his book. (Incidentally, it was Morgenthaler who suggested the word "Psychodiagnostik" to Rorschach who adopted it.) After Rorschach's death, Morgenthaler was for several years almost alone in his fight for recognition of Rorschach's test. It was Morgenthaler who organized the first International Rorschach Congress in 1949, and who founded the International Rorschach Society and later the International Rorschach Archive. He also founded the Swiss Society of Psychology and became chief editor of its journal. Among his other publications is "Geschlecht-Liebe-Ehe," a book on marriage counselling (a field in which Morgenthaler also pioneered), and a study on the last letters of 47 persons who had committed suicide (1945).

This 7th edition of Morgenthaler's textbook of psychiatric nursing has been revised by Dr. Singeisen, but does not differ essentially from the previous editions. Every page of the book shows that it is built on practical experiences. There is hardly a difficulty to be expected to arise between nurse and patient which has not been anticipated and discussed in the book. It is also in the true sense a *textbook* to be used in courses, read and discussed line by line. It strives to give precise definitions of every psychological and psychiatric term; no word is used, of which the meaning is vague or am-

biguous. Very little psychoanalytic terminology is included. The text is concise and of a crystalline clarity. The description of mental diseases follows a classification derived from Kraepelin. The illustrations are abundant and excellent.

The book is obviously written for Swiss psychiatric nurses, although French, Italian and Spanish translations do exist. But it could hardly be applied outside of Switzerland without some modifications.

We take the opportunity in this review to express our congratulations to Dr. Walter Morgenthaler who recently celebrated his 80th birthday.

H. ELLENBERGER, M.D.,
Montreal, Canada.

MENSCHENFUEHRUNG IM BLICKFELD DER PÄDAGOGIK UND PSYCHOHYGIENE. (Leading People in the Focus of Pedagogy and Mental Hygiene.) By Haensel, Dienelt, and Stransky. (Oesterreichischer Bundesverlag-Wien, 1960, pp. 140. \$8.50 and \$10.50 hard cover.)

Three Viennese, the sociologist Ludwig Haensel (meantime deceased), the pedagogue Karl Dienelt, and the psychiatrist Erwin Stransky, presented this book "to the World Federation for Mental Health in World Mental Health Year (1960)."

Haensel discusses the sociological problems, especially the still increasing difficulties grown-ups and adolescents are faced with in their mutual relationships. Dienelt emphasizes the importance of the personality of the pedagogue (Erzieher) who needs self-discipline if he wants to develop it in his pupils. Stransky presents the significance of the I-Thou-relationship and the subordination-authority-relationship about which he published a monograph "Subordination, Authority, Psychotherapy" as early as 1928. Stransky explains that many psychopathological phenomena may occur in the evolution of and adjustment to figures of authority. Stransky is anxious to bring home that the physician-patient-relationship makes it particularly obvious that the leading persons concerned are closely inter-related and that treatment must be adapted accordingly.

EVALYN KAHN, PH.D.,
Houston, Tex.

IN MEMORIAM

ISRAEL SPANIER WECHSLER, M.D. (1886-1962)

To write a memorial of Dr. Wechsler is truly an interdisciplinary task. He was outstanding not only as a neurologist, psychiatrist and medical educator, but as a historian, philosopher and literary man.

He was born in Roumania and came to this country at the age of 14. He was educated in New York City public schools and graduated from the Medical College of New York University in 1907. After a short period in general practise, he began his training at the Neurological Institute under Dr. Frederick Tilney. He became chief of the Vanderbilt Clinic in 1919 and professor of clinical neurology at Columbia University in 1931. He was attending neurologist at the Montefiore Hospital from 1920 to 1938 and chief of the Department of Neurology of The Mount Sinai Hospital from 1938 to 1951. His offices included the Chairmanship of the Section of Neurology and Psychiatry of the New York Academy of Medicine, the Presidency of the New York Neurological Society and the Presidency of the American Neurological Association.

Dr. Wechsler participated in the development of Montefiore Hospital into a great neurological center. This was the era of classical descriptive neurology, of nosology and the correlation of clinical and neuropathological data. With his colleagues, Keschner, Goodhart, Savitsky, Brock and Davison, he elucidated the hitherto confused area of the extrapyramidal diseases and other disorders of movement. His coming to Mount Sinai paralleled the growth of his interest in neurophysiology and neurochemistry. His introduction of vitamins into the treatment of peripheral neuropathies provided a basis for much further research. He was particularly stimulated by the work of Fulton and Ranson, and the subsequent work on the role of the hypothalamus and limbic system in emotional behavior. It is fitting that the Israel Wechsler Memorial Lectures, begun during his lifetime, should have included such

speakers as Fulton, Magoun and Kety.

Although his *Textbook of Clinical Neurology*, now in its ninth English edition, is his most widely read work, he wrote extensively on psychiatric subjects. His book, *The Neuroses*, is a compact summary and guide to treatment. Dr. Wechsler was fond of recalling his service at the Vanderbilt Clinic where a physician was expected to be as adept in the treatment of tabes dorsalis as in the handling of a phobic reaction. He himself was an excellent psychotherapist. Wechsler's pursuit of problems of the mind included not only the area of brain function and pathology, but psychological, social and cultural aspects. He drew attention early to the changing manifestations of the neuroses with cultural change. He was interested in psychoanalysis and traveled to Vienna to visit Freud on two occasions. His formulation of the neuroses involved a number of psychoanalytic concepts. Yet he was highly critical of the unscientific attitude of some analysts and believed firmly that there could be no ultimate understanding of mental processes without fundamental knowledge of the structure and function of the brain. While Dr. Wechsler would gently chide those of his neurological residents who had been "seduced" by psychoanalysis, he recognized the need of each discipline to develop independently with new methods of study before a correlation could be made. Actually, Dr. Wechsler gave a neuropsychiatric baptism to more of today's outstanding psychoanalysts than probably any teacher of his generation.

Dr. Wechsler's outstanding quality was his humanity. He was attentive to and considerate of the youngest interne on his staff at a time when the hierarchical organization of other hospital services resembled a pecking order. He was respectful of patients whom others regarded as "frontal lobe syndromes." He was not dogmatic and liked to say that he learned from each member of

his staff, particularly those whose training in modern medical schools had been in some areas superior to his own. The sudden death of his only son, Robert, a medical student, was a tragic loss. Yet Israel Wechsler had many sons. He furthered the careers of many young men, obtaining grants and fellowships and giving generously of his personal funds.

Wechsler read and wrote extensively of the history of medicine. His *Introduction to History of Neurology* was a regular feature of his textbook and is a fascinating account of the development of our ideas of brain and mind. His biographical accounts of Maimonides, the physician, and S. Weir Mitchell also reflect his scholarly and literary interests. His style was lucid and he had a particular gift for epigram and apt metaphor. He was as likely to criticize a member of his staff for a dangling participle as he was for the omission of a pendular knee jerk. He was a charming, witty speaker. His reminiscences of his friendships with Einstein, Freud, Sinclair Lewis and the philosopher Morris Raphael Cohen indicate the breadth of his enthusiasms.

Dr. Wechsler was a vigorous Zionist, and he selected the Hebrew University in

Jerusalem as the special object of his devotion. He furthered its growth by raising large sums of money, by arranging the exchange of students and faculty with American centers, and by assisting personally in the training of men in this country and Israel. In 1949 he went to Jerusalem to take part in the inauguration of the Hebrew University—Hadassah Medical School. He was a member and Deputy Chairman of the Board of Governors and for several years was the President of the American Friends of the Hebrew University.

In 1947 the Maimonides Citation was conferred upon him by the Jewish Theological Seminary of America in recognition of his contributions to medicine and for his work in the cause of the Hebrew University and Medical School.

Dr. Wechsler is survived by his wife, Minnie, his daughter, Miriam, his son-in-law, Dr. Louis Linn, and his two grandchildren, Judy and Robert. His brother, Dr. David Wechsler, is the noted psychologist.

Israel Wechsler loved wisdom and he loved people. They miss him as I do.

Edwin A. Weinstein, M.D.,
Bethesda, Md.

ANNUAL INDEX

This periodical is indexed alphabetically under both Subject and Author entries.

In searching for a specific article, the Author entry should be consulted if the name of the author is known, since the complete bibliographical reference is to be found only after the author's name. When there are two or more authors for an article, the complete entry appears only under the name of the first author. Under the name of each of the joint authors a cross reference is made to the original author entry.

The same applies to book reviews, the complete title of the book being listed under the author's name in the list entitled Book Reviews in the Subject Index.

Titles under the Subject Index are often inverted or shortened, and when there are two or more authors, the name of only the first is shown. For the complete author reference, the Author Index should be consulted. The Subject Index covers original articles, biographical and historical materials, editorial comments, correspondence, book reviews and in memoriams.

Ab. indicates an abstract; C.N. a clinical note; Corr. correspondence; C.R. a case report; Ed. an editorial comment; H.N. a historical note; O.N. an official notice; and S.R. a special report.

Constitution and By-Laws ; I, Dec. '62.

Report of Coordinating Chairman : Committees on Community Aspects of Psychiatry ; xi, Sept. '62.

Report of Coordinating Chairman : Committees on Professional Standards ; xiii, Sept. '62.

Report of Coordinating Chairman : Committees on Technical Aspects of Psychiatry ; ix, Sept. '62.

Report of Treasurer ; viii, Sept. '62.

Summary of Meetings of Council and Executive Committee ; i, Sept. '62.

Toronto Meeting Highlights (Ed.) ; 81, July '62.

American Psychiatry : Adolf Meyer on, in 1895 : G. N. Grob, 1135, June '63.

Amnesia : Clinical Study of 98 Cases ; T. A. Kiersch, 57, July '62.

Anorexia Nervosa : And Gonadal Dysgenesis (Turner's Syndrome) (C.R.) ; F. N. Pitts, Jr., 1110, May '63.

Antarctic : Navy Psychiatric Assessment Program in the ; J. E. Nardini, 97, Aug. '62.

Anxious Neurotic Outpatients : Evaluations of Tranquilizing Agents in (C.N.) ; K. Rickels, 1093, May '63.

Aphasia : A Review ; M. H. Chaiton ; 872, Mar. '63.

Aphonia : Hysterical (H.N.) ; M. S. Wilson, 80, July '62.

Appointments : Failure to Keep, with the Army Psychiatrist : An Indicator of Conflict ; L. J. Grolld, 446, Nov. '62.

Armenia : Psychiatry in (Corr.) ; 796, Feb. '63.

ARMY :

• General Hospital : Psychiatry in (Ab.) ; J. F. Tuttle, 978, Apr. '63.

Psychiatrist : Failure to Keep Appointments with, An Indicator of Conflict ; L. J. Grolld, 446, Nov. '62.

• Soldier and Psychiatrist ; J. T. Ungerleider, 875, Mar. '63.

Assessment Program : Navy Psychiatric, in the Antarctic ; J. E. Nardini, 97, Aug. '62.

Auditory Studies : In Schizophrenia ; A. M. Ludwig, 122, Aug. '62.

Autism : John Haslam on Early Infantile (H.N.) ; G. E. Vaillant, 376, Oct. '62.

Automata : Communication Amongst (Corr.) ; 84, July '62.

Automobile Accidents : Suicide and Unconscious Motivation ; M. L. Selzer, 237, Sept. '62.

B

Barton, Walter E., Biographical Sketch ; Leo Alexander, 16, July '62.

BEHAVIOR :

Comparative View of Aggressive ; L. D. Clark, 336, Oct. '62.

Disorder : Relation of Housing to (C.N.) ; E. A. Grootenboer, 469, Nov. '62.

Therapeutic Process and, as Observed in Physical Rehabilitation ; M. D. Zane, 246, Sept. '62.

Therapy : Spontaneous Remission and Transference in Neurotics ; H. J. Eysenck, 867, Mar. '63.

Use of AHR 437 in Behavioral Problems (C.N.) ; I. A. Kraft, 472, Nov. '62.

BIOCHEMISTRY :

Genetics, and the Nature-Nurture Problem ; B. T. Eiduson, 342, Oct. '62.

Histamine-Induced Vanil-Mandelic-Aciduria : in the Schizophrenic and Non-schizophrenic Psychiatric Patient (C.N.) ; P. Koch, 464, Nov. '62.

Neurophysiology, and Endocrinology (Review of Progress) ; O. R. Langworthy, 604, Jan. '63.

Psychological and Biochemical Syntheses During Recovery from Psychosis ; S. Bogoch, 128, Aug. '62.

Psychotomimetic Drugs and Brain Biogenic Amines ; D. X. Freedman, 843, Mar. '63.

Relationship Between Serotonin Antagonism and Tranquilizing Activity (Ab.) ; D. M. Gallant, 882, Mar. '63.

Serum Glutamic-Oxalacetic Transaminase And Cephalin-Cholesterol Flocculation Tests in Acute Psychiatric Illnesses (C.N.) ; F. N. Pitts, Jr., 472, Nov. '62.

Blindness, Space-Form : Cytogenetic and Psychosexual Incongruities with a Note on ; J. Money, 820, Mar. '63.

Bone-Marrow Aplasia : Fatal, Complicating Prochlorperazine Therapy (C.R.) ; K. Bhaskaran, 373, Oct. '62.

Amitriptyline :

Perphenazine : In Treatment of Schizophrenia (C.N.) ; R. E. Kennedy, 1092, May '63.

Preliminary Study of, in Treatment of Depression (C.N.) ; T. Fahy, 171, Aug. '62.

Treatment ; ECG Changes During (C.N.) ; E. B. Rasmussen, 781, Feb. '63.

Trifluoperazine Combined with, in Paranoid Psychosis (C.N.) ; S. F. Cheng, 780, Feb. '63.

Benzquinamide : Preliminary Report (C.N.) ; A. Sainz, 777, Feb. '63.

Benztropine Methanesulfonate : Procyclidine and, Compared in Drug Induced Extrapyramidal Reactions (C.N.) ; R. T. Childers, Jr., 462, Nov. '62.

Butyrylperazine :

Comparative Analysis of, at Manhattan State Hospital and the University Psychiatric Clinic at Erlangen ; H. C. B. Denber, 203, Sept. '62.

- Comparison of, and Trifluoperazine in Chronic Schizophrenic Subjects (C.N.) ; W. Mandel, 70, July '62.
- Carphenazine :
Evaluation of, and Piperacetazine in Previously Placebo-Treated Chronic Schizophrenics (C.N.) ; B. Claffey, 75, July '62.
In the Treatment of Chronic Schizophrenics (C.N.) ; J. A. Barsa, 169, Aug. '62.
- Chlordiazepoxide :
As Adjunctive Therapy in Convulsive Disorders (C.N.) ; S. Merlis, 575, Dec. '62.
Effective Adjunct to Psychotherapy of Neurotic States (C.N.) ; S. G. Brown, 774, Feb. '63.
- Chlorpromazine :
Effects of, on Brain Tissue Respiration (C.N.) ; J. Wortis, 363, Oct. '62.
Four Deaths Associated with (C.R.) ; R. T. Childers, Jr., 374, Oct. '62.
Mother's Milk and (C.R.) ; K. H. Blacker, 178, Aug. '62.
New Topical Spray Agent to Protect Patients on, from Sunlight (C.N.) ; I. W. Sletten, 991, Apr. '63.
Therapy : Severe Oral Moniliasis Complicating (C.R.) ; F. J. Kane, Jr., 890, Mar. '63.
- Chlorprothixene :
Effects of, in Well-Established Schizophrenic Reactions (C.R.) ; I. K. Gayus, 180, Aug. '62.
Experience with, in a State Hospital (C.N.) ; P. B. Hagopian, 466, Nov. '62.
In Treatment of Psychotic Patients (C.N.) ; J. A. Barsa, 468, Nov. '62.
- Clopenithiol : Effect of, on Chronic Psychiatric Patients (C.N.) ; T. A. Ban, 984, Apr. '63.
- Cocaine : And I.N.H. ; Mania Associated with (C.R.) ; F. J. Kane, Jr., 1098, May '63.
- Compazine Suppositories : Re : (Corr.) ; 84, July '62.
- Deprol : Use of High Dosage, in Alcoholic and Narcotic Withdrawal (C.R.) ; L. Snow, 475, Nov. '62.
- Desmethylinipramine : Preliminary Investigation of (C.N.) ; J. E. Oltman, 370, Oct. '62.
- Diazepam : A New Tranquilizer (C.N.) ; A. DiFrancesco, 989, Apr. '63.
- Elavil : Re : Experiences with (Corr.) ; 85, July '62.
- Elavil-Librium : Toxic Reaction to Combined, Therapy (C.R.) ; F. J. Kane, Jr., 1179, June '63.
- Fluphenazine :
Dosage : Development of Parkinsonism after Gradual Reduction of (C.R.) ; W. Kruse, 995, Apr. '63.
- In Chronic Refractory Schizophrenics (C.N.) ; N. E. Stratas, 72, July '62.
- In Treatment of Hospitalized Mental Patients (C.N.) ; L. E. Moore, 987, Apr. '63.
- G-33040 : Effects of, in Depressive States (C.N.) ; H. Azima, 465, Nov. '62.
- Glutethimide : Addictive and Possible Toxic Properties of (C.N.) ; C. F. Essig, 993, Apr. '63.
- Haloperidol :
Drug-Induced EEG Abnormalities as Predictors of Clinical Response to Thiopropazate and (C.N.) ; L. E. Hollister, 887, Mar. '63.
Third Evaluation of (C.N.) ; H. C. B. Denber, 172, Aug. '62.
- Hydroxyphenamate : Impressions of Possible Effects of a New Tranquilizer (C.N.) ; J. Meyer, 463, Nov. '62.
- Imipramine :
Control of Enuresis with (C.R.) ; L. H. Margolis, 269, Sept. '62.
Enuresis and (C.R.) ; N. Destounis, 893, Mar. '63.
In Depression ; N. Roulet, 427, Nov. '62.
In Treatment of Adult Enuretics (C.N.) ; E. E. Dorison, 474, Nov. '62.
Psychiatric Reaction Patterns to ; D. F. Klein, 432, Nov. '62.
Therapy : Loeffler's Syndrome Occurring During (C.R.) ; I. C. Wilson, 892, Mar. '63.
- Treatment of Encopresis with (C.R.) ; D. Abrahams, 891, Mar. '63.
- Treatment of Enuresis with (C.N.) ; M. A. Salgado, 990, Apr. '63.
- Treatment : Paroxysmal Auricular Tachycardia Apparently Resulting from Combined Thyroid- (C.R.) ; A. J. Prange, Jr., 994, Apr. '63.
- Treatment of Post-Traumatic Headache with (C.N.) ; G. Paulson, 368, Oct. '62.
- Indoklon : Symposium in New Orleans, Mar. 1962 (C.N.) ; B. E. McLaughlin, 265, Sept. '62.
- I.N.H. : And Cocaine ; Mania Associated with (C.R.) ; F. J. Kane, Jr., 1098, May '63.
- Iodoform : Toxic Psychosis due to (C.R.) ; A. L. Morgenstern, 1180, June '63.
- LSD-25 : Identification and Treatment of Early Deprivation Syndrome in Alcoholics by Means of (C.N.) ; E. Belden, 985, Apr. '63.
- MDS 92 : Comparison of, and Placebo in Chronically Ill Mental Patients (C.N.) ; A. Barron, 68, July '62.
- Mellaril : Ejaculation Disorders (Corr.) ; 87, July '62.

- Meprobamate : High Dosages of, in Chronic Schizophrenia (C.N.) ; L. Snow, 369, Oct. '62.
- Methohexital Sodium : Narcotherapy with (C.N.) ; W. W. Winslow, 886, Mar. '63.
- MP-809 : Effect of, in Depressive States (C.N.) ; H. Azima, 573, Dec. '62.
- Nialamide : Clinical Effects of (C.R.) ; E. J. Halas, 785, Feb. '63.
- Nortriptyline : Evaluation of, in Affective Disorders (and Comparison with Other Drugs) (C.N.) ; J. E. Oltman, 988, Apr. '63.
- Parenteral Magnesium : And Delirium Tremens (Corr.) ; 482, Nov. '62.
- Peperacetazine : New Piperidine Phenothiazine in Chronic Psychotic Patients (C.N.) ; K. H. Tutunjian, 776, Feb. '63.
- Phenelzine in the Treatment of Depression (C.N.) ; H. V. Agin, 1173, June '63.
- Phenelzine Overdose : Severe Brain Syndrome Following (C.R.) ; A. C. Raine, 372, Oct. '62.
- Phenmetrazine HCL : Addiction (Corr.) ; 84, July '62.
- Phenothiazine :
 Comparison of Two, in Treatment of Schizophrenics (C.N.) ; M. Dierks, 775, Feb. '63.
- Compound : Use of, in Rehabilitation of Schizophrenic Patients (C.N.) ; H. O. Gerz, 167, Aug. '62.
- Induced Extrapyrimal System Dysfunction : Effect of Potassium on (C.N.) ; G. Brooks, 1096, May '63.
- Piperidine : New, (Peperacetazine) in Chronic Psychotic Patients (C.N.) ; K. H. Tutunjian, 776, Feb. '63.
- Phenoxypropazine :
 Preliminary Report on (C.N.) ; N. W. Im-lah, 1091, May '63.
- Preliminary Study of, in Depression (C.N.) ; M. R. Leahy, 986, Apr. '63.
- Piperacetazine :
 Evaluation of Carphenazine and, in Previously Placebo-Treated Chronic Schizophrenics (C.N.) ; B. Claffey, 75, July '62.
- Preliminary Investigation of (C.N.) ; J. E. Oltman, 888, Mar. '63.
- Placebo :
 Comparison of MDS 92 and, in Chronically Ill Mental Patients (C.N.) ; A. Barron, 68, July '62.
- Evaluation of Carphenazine and Piperacetazine in Previously, -Treated Chronic Schizophrenics (C.N.) ; B. Claffey, 75, July '62.
- Potassium : Effect of, on Phenothiazine-Induced Extrapyrimal System Dysfunction (C.N.) ; G. Brooks, 1096, May '63.
- Prochlorperazine : Fatal Bone-Marrow Aplasia Complicating, Therapy (C.R.) ; K. Bhas-karan, 373, Oct. '62.
- Procyclidine : And Benztropine Methanesul-fonate Compared in Drug Induced Extra-pyrimal Reactions (C.N.) ; R. T. Childers, Jr., 462, Nov. '62.
- Propiomazine : For Control of Insomnia in Nervous Disorders (C.N.) ; A. J. Krakowski, 461, Nov. '62.
- Thiopropazate : Drug-Induced EEG Ab-normalities as Predictors of Clinical Re-sponse to, and Haloperidol (C.N.) ; L. E. Hollister, 887, Mar. '63.
- Thioridazine :
 Administration : Follow Up of (Corr.) ; 589, Dec. '62.
- Administration : Jaundice Following (C.R.) ; S. L. Block, 77, July '62.
- Galactorrhea, Headache, and Weight-Gain during Treatment with (C.R.) ; P. Castel-nuovo-Tedesco, 1178, June '63.
- Therapeutic Use of, in Premature Ejacula-tion (C.R.) ; H. Singh, 891, Mar. '63.
- Tranquilizers : Influence of 2 Selected, on Driving Skills (C.N.) ; W. J. Huffman, 885, Mar. '63.
- Tranlycypromine :
 Prediction of Response to, plus Trifluopera-zine by MMPI (C.N.) ; E. S. Sulzer, 69, July '62.
- Sulfate : Successful Suicide with (C.R.) ; G. A. Bacon, 585, Dec. '62.
- Therapy : Peripheral Edema and Tachy-cardia during (C.R.) ; J. A. Sours, 584, Dec. '62.
- Trifluoperazine :
 Combined with Amitriptyline in Paranoid Psychosis (C.N.) ; S. F. Cheng, 780, Feb. '63.
- Comparison of Butyrylperazine and, in Chronic Schizophrenic Subjects (C.N.) ; W. Mandel, 70, July '62.
- Massive Doses of, in Treatment of Com-pulsive Rituals (C.N.) ; M. Altschuler, 367, Oct. '62.
- Prediction of Response to Tranlycypromine plus, by MMPI (C.N.) ; E. S. Sulzer, 69, July '62.
- Tri-iodothyronine : Effect of, on Abnormali-ties in the Cerebrospinal Fluid of Chronic Schizophrenic Patients (C.N.) ; G. M. Simpson, 170, Aug. '62.
- UK 738 : Treatment of Parkinsonism with ; D. Sumner, 534, Dec. '62.

- Psychopathology of Sleep and Dreams :
Studies on ; C. Fisher, 1160, June '63.
Psychoprophylaxis : Theories of, in Obstetrics ;
L. Chertok, 1152, June '63.

PSYCHOSIS :

Chlorprothixene in Treatment of Psychotic Patients (C.N.) ; J. A. Barsa, 468, Nov. '62.

Comparison of Temporal Factors in Depressive Psychoses Treated by EST and Anti-depressant Drugs (C.N.) ; J. E. Oltman, 579, Dec. '62.

Drug-Withdrawal Psychoses (Ab.) ; I. P. James, 880, Mar. '63.

Familial Organic : Of Alzheimer Type in Six Kinship of Three Generations ; L. Bucci, 863, Mar. '63.

Five Psychotic Siblings ; S. E. Jensen, 159, Aug. '62.

Model Psychoses and Schizophrenia ; E. D. Luby, 61, July '62.

Model Psychoses and Schizophrenia (Corr.) ; 590, Dec. '62.

New Directions in Inpatient Treatment of Psychotic Children in a Training Center ; J. P. Kempf, 934, Apr. '63.

New Piperidine Phenothiazine (Peperacetazine) in Chronic Psychotic Patients (C.N.) ; K. H. Tutunjian, 776, Feb. '63.

Periodic, of Puberty (C.R.) ; M. D. Altschule, 1176, June '63.

Psychological and Biochemical Syntheses During Recovery from ; S. Bogoch, 128, Aug. '62.

Psychotic Mothers and Their Children : Joint Admission to an Adult Psychiatric Hospital ; H. U. Grunebaum, 927, Apr. '63.

Psychotic Reaction in 11th Century Japan (H.N.) ; J. D. Page, 271, Sept. '62.

Transient Psychotic Reactions during Travel (C.N.) ; D. E. Flinn, 173, Aug. '62.

Toxic, due to Iodoform (C.R.) ; A. L. Morgenstern, 1180, June '63.

Trifluoperazine Combined with Amitriptyline in Paranoid (C.N.) ; S. F. Cheng, 780, Feb. '63.

War (Corr.) ; 1005, Apr. '63.

Psychosomatic Disorders : Phrenotropic Drugs in (Skin) ; E. P. Lester, 136, Aug. '62.

Psychosomatic Illness : Tranquilizers and (C.R.) ; W. Tuteur, 787, Feb. '63.

PSYCHOSURGERY :

Lobotomy in Western Pennsylvania : Looking Backward over 10 Years ; R. L. Vosburg, 503, Dec. '62.

(Review of Progress) ; W. Freeman, 626, Jan. '63.

PSYCHOTHERAPY :

Chlordiazepoxide ; Effective Adjunct to, of Neurotic States (C.N.) ; S. G. Brown, 774, Feb. '63.

Clinical : And Psychiatry (Review of Progress) ; N. D. C. Lewis, 616, Jan. '63.

Differential Success Rates of Psychotherapists with "Process" and "Non-Process" Schizophrenic Patients (C.N.) ; B. J. Betz, 1090, May '63.

Negroes in ; H. Rosen, 456, Nov. '62.

Puberty : Periodic Psychosis of (C.R.) ; M. D. Altschule, 1176, June '63.

Public Institutional Service : Psychiatric Residency Training for ; J. Masserman, 1038, May '63.

Q

Quackery (Ed.) ; 691, Jan. '63.

R

Refractory Psychiatric Disorders : Experience with Chemotherapy in (C.N.) ; F. P. Pignataro, 577, Dec. '62.

REHABILITATION :

And Occupational Therapy (Review of Progress) ; W. A. Mann, 686, Jan. '63.

Therapeutic Process and Behavior—As Observed in Physical ; M. D. Zane, 246, Sept. '62.

Use of Phenothiazine Compound in, of Schizophrenic Patients (C.N.) ; H. O. Gerz, 167, Aug. '62.

Relation between Money and Services (Ed.) ; 1182, June '63.

Relationships, Quantitative : In Systematic Desensitization of Phobias ; J. Wolpe, 1062, May '63.

Release Rates : The Effect of Ataraxic Drugs on Hospital ; L. J. Epstein, 36, July '62.

Reports : Writing Psychiatric ; E. S. Dean, 759, Feb. '63.

RESEARCH :

Nature of Psychiatric, with Reflections on Research of Freud and Hughlings Jackson and on Limitations of Statistics ; M. Levin, 404, Nov. '62.

Project : In Psychiatric Aide Training ; R. M. Vaughn, 555, Dec. '62.

Psychiatric (Corr.) ; 900, Mar. '63.

Training : Effect of, in Study of Psychiatric Drug Treatment ; R. M. Dunham, 748, Feb. '63.

- Ward : New Type Psychiatric ; G. Simpson, 511, Dec. '62.
- Residency Training, Psychiatric : For Public Institutional Service ; J. Masserman, 1038, May '63.
- "Rest Cure" : William Osler, S. Weir Mitchell, and the Origin of the (H.N.) ; J. M. Spneek, 894, Mar. '63.
